Noncrystalline chalcogenides are semiconductors with an activation energy about half of the optical band gap. The glass As_2S_3 taken as a prototype has the following characteristics: $W_e = 1.14\,\text{eV}$, $E_g = 2.32\,\text{eV}$, and $\sigma(300\,\text{K}) \sim 10^{-17}\Omega^{-1}\,\text{cm}^{-1}$.

Irradiation of chalcogenide films with light having an energy comparable to the band gap induces a variety of changes, such as photoluminescence and photoconductivity. Some of these are reversible and some are not, such as the chemical changes involved in lithography applications. Among the most peculiar photoinduced phenomena is the photodarkening corresponding to a reversible shift of the band-gap edge towards lower energy under illumination.

The electron–hole pairs created by illuminating the surface of a Se film is the basis of the xerography process. If the Se film is already positively charged, the photon from the 'image' of the page results in the excitation of an electron. This neutralizes a corresponding positive charge and leads to the formation of a positive electronic image. Carbon black particles are then deposited to give a black image of the documents.

As shown by Tanaka,[25] chalcogenide glasses are prone to photoinduced phenomena such as photorefractivity, photoexpansion, photofluidity, and so on which indicate that the local structure can be easily modified under suitable light irradiation.

4 HALIDE GLASSES

4.1 Introduction

Halide materials usually exist in the crystalline state when cooled from the liquidus. When the halogens are bound to small and highly charged cations, volatile molecular species such as $SiCl_4$ are easily formed. Consequently, a very limited number of halide systems lead to glass formation and the glass to crystal or glass to molecular vapor competition is severe.

Considerable progress has been made during the last two decades in the discovery of new glass-forming compositions, based on group 7 elements (F, Cl, Br, I), characterized by the outer electronic shell $s^2p_x{}^2p_y{}^2p_z{}^1$, showing one bonding electron.

The optical properties, and especially the possibility of extending the IR transparency domain, have been the main motivation for investigating such exotic glasses. Three intrinsic factors limit the technological development of such vitreous materials. Like other halides, they suffer from ready corrosion by moisture or water driven by stronger M–OH_2, M–OH, or M–O bonds. The relative weakness of the M–X bond also results in poor thermal capability, leading to low T_g glasses with high thermal expansion coefficients and sensitivity to thermal shock. Finally, the high electronegativity of the fluorine atom results in the easy formation of ionic bonding and leads to ionic microcrystal formation when crossing the strategic liquidus–solidus line. The optical properties, and especially the scattering losses, therefore suffer from the tendency to devitrify.

In addition to the development of very large IR optics, often difficult to accomplish with crystalline materials, an important property of halide glasses is the potential for the development of very transparent IR optical fibers. With its

unique viscosity–temperature dependence the glassy state represents an ideal situation for transforming a bulk material into a very long waveguide. Several articles reviewing the chemistry and optical properties of these materials have been published.[26–28]

4.2 Glass Formation in Halide Systems

Because of its size, $r(F^-) \sim r(O^{2-}) \sim 1.40$ Å, fluorine is a rather special halogen leading to materials which are generally less sensitive to water corrosion and which are more suitable for practical applications. Consequently, among all the halide compounds which have been claimed to form glasses, only a very limited number are stable enough to be considered as optical materials and this is the case for several fluoride glass compositions. The heavy halide glasses, that is, the chlorides, bromides, and iodides, are all characterized by a high hygroscopicity and, despite their scientific interest, have to be considered as technological curiosities.

4.2.1 Fluoride Glasses

Fluoride glasses can be classified according to structural considerations and although glass-forming ability has been observed in many fluorides they cannot be considered of equal interest because of the high tendency for most of them to devitrify.

In most of these systems, the tendency to ionicity is high, leading to strong glass to crystal competition. This article is restricted to the compositions that are stable enough to make bulk samples, having a significant optical quality either for fundamental investigations or practical applications.

In all the following systems, the polymerization process arises from the twofold coordination of the F atoms which connect the elementary polyhedra in a 3-D manner. The F^- ions situated between two highly charged M^{n+} cations appear to be strongly sp hybridized, with a strong delocalization of the electrons located in the sp_x orbitals towards the empty orbitals of the M^{n+} cation. The formation of long polymerized chains, $\cdots M \leftarrow F^- \rightarrow M \leftarrow F^- \rightarrow M \leftarrow F^- \rightarrow M \cdots$, contributes to the increase in the viscosity in the melt.

MF_2- and MF_3-based Glasses. One of the oldest fluoride materials prepared in the glassy state is beryllium fluoride, BeF_2. This compound, isotypic with SiO_2, shows a strong resistance to crystallization and is based structurally on a giant aperiodic corner-sharing BeF_4 tetrahedral framework. The main difference between the two glasses comes from the comparison between the bond strengths, Be–F and Si–O, which shows up in the difference in the glass transition temperatures, $T_g(SiO_2) = 1100\,°C$, $T_g(BeF_2) = 250\,°C$. Despite the unique optical properties of BeF_2-based glasses owing to their very low refractive index ($n = 1.27$) and low optical dispersion, these materials suffer from high hygroscopicity and toxicity. Several mixed compositions containing AlF_3 have been developed for high-power laser applications. This research has been pursued because of the interesting property that the low nonlinear refractive index reduces the risk of self-focusing and glass breaking.

The MF_3-based glass category is represented by AlF_3 and the transition metal MF_3 group with M = Fe, Co, Ga, and so on. By themselves the MF_3 compounds do not give glasses; they need to be combined with glass modifiers and stabilizers[29,30] such as PbF_2. For instance, an interesting glass composition $PbFeMnF_7$ is found in the ternary system FeF_3–MnF_2–PbF_2 and this material, rich in magnetic ions, exhibits remarkable spin-glass properties at low temperature. It has also been recently demonstrated that a glass composition belonging to the PbF_2–GaF_3–ZnF_2 system can be deposited as a thin layer on a cold substrate by physical vapor deposition.

The structural building units of these glasses are octahedral MF_6 units which, by sharing corners, generate a skeleton related to the ReO_3 structure. Most of these MF_3-based glasses show a great tendency to devitrify owing to the ionic character of the M–F bond.

ZrF_4-based Fluoride Glasses: ZBLAN glasses. The fluorozirconate glasses, based on the glass-forming ability of ZrF_4 when combined with other appropriate fluorides, have attracted considerable interest because of their promising optical properties in the mid-IR. Their discovery[31,32] resulted from a systematic investigation of ternary systems such as ZrF_4–LaF_3–BaF_2 as shown in Figure 12.

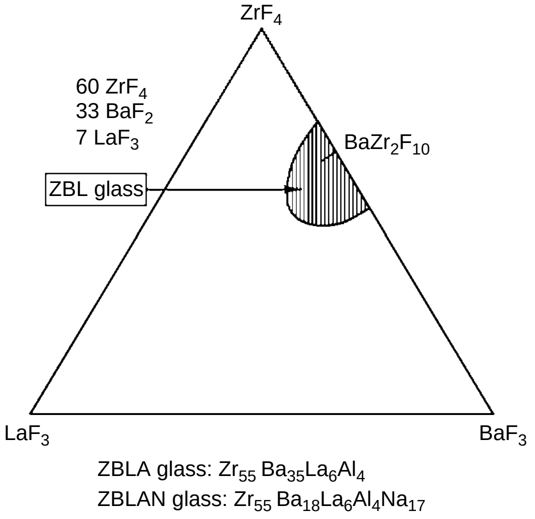

Figure 12 Glass-forming domain in the ternary diagram ZrF_4–BaF_2–LaF_3. The center of the vitreous area is represented by the ZBL glass. The composition $BaZr_2F_{10}$ corresponds to a very unstable glass while ZBLA and ZBLAN (composition in molar % of fluoride) are the acronyms of two very stable glasses

The optimized composition corresponding to the glass having the lowest critical cooling rate R_c, in the range $R_c \sim 1\,°C\ min^{-1}$, is the five-component glass ZBLAN: $55ZrF_4$–$18BaF_2$–$6LaF_3$–$4AlF_3$–17NaF. In this glass, the modifier cation Ba^{2+} has been partially replaced by Na^+ and this introduces an interdiffusion barrier to devitrification because of the competition between Na and Ba fluorozirconate microcrystal formation. From this ZBLAN composition, large pieces of optical glasses of several kilograms, as well as low-loss optical fibers, have been prepared. The good behavior versus devitrification can be also understood by examining the differential scanning calorimetry (DSC) trace of a ZBLAN glass. The glass transition temperature at 280 °C is far from the crystallization temperature ($T_x \sim 400\,°C$), marked by a small exothermic peak. The liquidus temperature is around 550 °C.

The structural modeling of such glasses has been based on X-ray diffraction, molecular dynamics, and X-ray investigations of the parent crystalline materials[33] such as $BaZr_2F_{10}$. The 3-D skeleton as indicated in Figure 13 is built up from ZrF_7 and ZrF_8 polyhedra connected by corners or edges. The large Ba^{2+} cations are ionically bonded to the nonbridging fluorines and play the role of lattice modifiers.

Glass-forming ability has been also observed in several Zr-free fluoride systems, like in In-based glass systems whose IR edge is shifted towards longer wavelengths, as compared to ZBLAN.

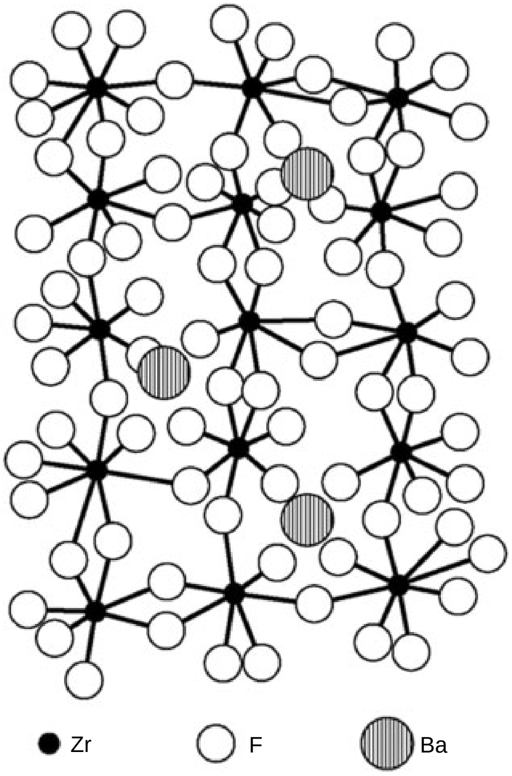

Figure 13 Structural model for the binary glass $BaZr_2F_{10}$. The polyhedra ZrF_7 and ZrF_8 are connected by corners and edges to form the 3-D aperiodic framework where Ba^{2+} ions are statistically distributed

4.2.2 Glasses Based on Heavy Halides

This terminology refers to glasses in which the electronegative part is a heavy halogen X (X = Cl, Br, I). Most of these materials suffer from strong moisture corrosion, low softening temperature, and a tendency to devitrify. The fundamental interest in such glasses is motivated by the fact that from a simple consideration of the masses of the anions, the heavy halide glasses would be expected to be more transparent in the IR than fluoride glasses.

4.3 Optical Properties of Halide Glasses

Considerable progress has been made during the last two decades in the discovery and investigation of halide glasses. The main justification of this research effort is the unusual and critical optical properties of these glasses. Unfortunately, the technical applications for most of them have been severely curtailed by their hygroscopicity and low thermal properties.

4.3.1 Passive Optical Properties

The total intrinsic optical loss in an optical glass is due to three factors, and the corresponding attenuation coefficient α can be expressed as:

$$\alpha = A \exp\left(\frac{-a}{\lambda}\right) + B\lambda^{-4} + C \exp\left(\frac{C}{\lambda}\right) \quad (1)$$

The first term is associated with multiphonon absorption mechanisms and is dependent on the IR edge. The second term represents the Rayleigh scattering and is due to electronic fluctuations on a microscopic scale. At long λ, this term is negligible. The third term, the Urbach tail, is related to the band-gap absorption and describes the limitation of transmission in the UV and visible part of the spectrum. In most of the halide glasses, the value of the band gap is high ($E_g > 3$–4 eV), making these glasses transparent in the visible. This is in contrast to chalcogenide glasses that are always colored or black.

The most important feature of the halide glasses is associated with the possibility of controlling the phonon edge absorption mechanism by shifting the IR edge towards longer wavelengths. By combining all the intrinsic attenuation factors it can be seen in Figure 14 that a limited part of the optical spectrum corresponds to very low optical loss. This ultratransparency region is located close to 1.55 µm for SiO_2 glass with a minimum loss of 0.16 dB km^{-1}, while the same minimum of the V-shaped curve is around 3 µm for fluoride glasses with predicted ultralow-loss performance in the range of 0.01 dB km^{-1}. To take advantage of this ultra

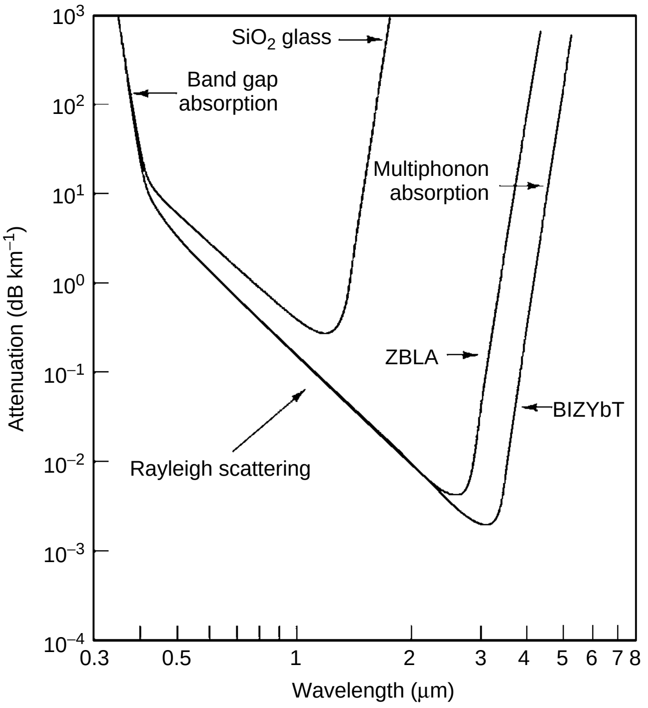

Figure 14 Intrinsic optical loss versus wavelength for SiO_2 and two fluoride glasses (Zr based and In–Ba based). The high transparency region for SiO_2 glass is around 1.5 μm with attenuation of 0.2 dB km^{-1}. The same ultrahigh transparency region is around 3 μm for the fluoride glasses with the theoretical optical loss as low as 0.01 dB km^{-1}

low-loss potential, optical losses of extrinsic nature should to be drastically reduced. The major two factors affecting the intrinsic glass transparency are:

1. colored impurities such as the transition metal ions of Fe, Cu, Co, Ni, and so on, or rare earths, characterized by parasitic absorption bands depending on λ;
2. the scattering defects arising from glass imperfections such as microbubbles, microcrystals, inhomogeneities, metallic particles, microphase separation, and so on, related to the glass making technology.

To date, the best experimental results in terms of fluoride fiber attenuation is 0.45 ± 0.15 dB km^{-1} at 2.35 μm, measured for a 60-m-long ZBLAN fiber.

4.3.2 Fluoride Glass Fiber Lasers

Fluoride glasses have a rather high capacity to accept doping elements such as rare earth ions, owing to their unusual structure. Several spectroscopic investigations conducted with doped glasses show unambiguously that the 4f ions substitute for Zr^{4+} in the glass-forming framework and are consequently subject to a rather well-defined ligand field corresponding to the usual coordination of Zr^{4+} which can vary from ZrF_6 to ZrF_8. Analysis of spectroscopic data indicates that rare earth ions are eightfold coordinate as in the corresponding parent crystalline materials.

As a new optical host for active properties[34] fluoride glasses have the following characteristics.

1. The doping concentrations can be rather high.
2. The broadening of the emission or absorption spectra owing to the glassy state is very limited and the envelope of the peak is in the range of the Stark decomposition.
3. Excitation and emission can be observed in a large spectral domain, 0.3–4 μm.
4. Compared to oxide glass matrices, such as silicates with a phonon energy at $W_p = 1100\,\mathrm{cm}^{-1}$, the value of $W_p \sim 500\,\mathrm{cm}^{-1}$ in fluoride glasses corresponds to much lower nonradiative relaxation and consequently higher quantum efficiency for laser emission.
5. It is also observed that in these glasses up-conversion mechanisms are quite efficient, allowing the population of high energy levels with red or IR pumping.

One of the most spectacular results in the field of active optical properties have been obtained with fluoride glasses shaped into an optical fiber configuration. Indeed, rare earth–doped fluoride glass fibers have been shown to be excellent laser materials.[35,36] Core-doped fibers represent a unique optical geometry that offers high optical power confinement and thus efficient interaction between light and matter over long lengths. In addition, the fiber geometry is adequate for releasing the heat generated by possible nonradiative processes concomitant to lasing. More than 40 lasing wavelengths which range from the mid-IR at 3.5 μm to the near-UV at 0.45 μm have been observed. Blue or green lasers are obtained by up-conversion processes and diode pumping has been achieved, allowing the miniaturization of such a new source of light. Details on the lasing characteristics of rare earth–doped fluoride glass fibers can be found in Ref. 37.

4.3.3 Fluoride Glass Optical Amplifiers

Optical amplifiers are essential components for the development of high capacity telecommunication networks. Silica fibers are characterized by a low-loss optical window that ranges from 1.2 to 1.7 μm, as shown in Figure 4. That window is divided into the ultrashort (XS), short (S), conventional (C) and long (L) bands. The first two bands are centered at 1.3 and 1.47 μm, while the C- and L-bands are equal to 1530–1565 nm and 1565–1625 nm, respectively. Amplification in the C- and L-bands is commonly achieved with Er^{3+}-doped silica fibers. On the other hand, amplification at 1.47 μm and 1.3 μm with Tm^{3+} and Pr^{3+} ions requires the use of materials with lower phonon energy than silica. High gain optical amplification was demonstrated in the XS, S, and C, telecommunication windows with rare earth–doped

fluoride glass fibers. With an estimated lifetime of more than 25 years in normal conditions, state-of-the-art fluoride fiber are compatible with long-term applications such as telecommunications, and *Real-world* amplifiers have been constructed and commercialized. Performances of nonoxide glass amplifiers can be found in Ref. 37.

4.3.4 *Fluoride Glass Channel Waveguides*

Planar and channel waveguides can be obtained by ion-exchange technique with fluoride glasses. The experiment is carried out with Er^{3+}-doped ZBLA fluoride glass samples, treated by HCl gas at a temperature below the glass transition temperature T_g ($T_g = 307\,°C$ for ZBLA). The chemical reaction at the glass surface is:

$$MF_n + xHCl \rightleftharpoons MF_{n-x}Cl_x + xHF \qquad (2)$$

where M represents all the cations in the glass.

Chloride ions, which substitute for part of the fluoride ions, modify locally the composition at the glass surface. The polarizability of Cl^- ions is greater than that of fluorides, and its introduction increases the refractive index. Then, ionic diffusion of Cl^- ions within the glass generates a gradient-index fluorochloride guiding structure.[38] Internal gain of $3.9\,dB\,cm^{-1}$ has been demonstrated at $1.53\,\mu m$ with such amplifying system.

5 METALLIC GLASSES

5.1 Introduction

As defined by Cahn,[39] a solid alloy with a liquid-like atomic arrangement is called a metallic glass, also called a metglass. Most of the metallic materials, which have been cooled to a state of rigidity without crystallization, are alloys and most of them have complex and well-defined compositions. As mentioned by Johnson in a well-documented article,[40] significant progresses have been made in the field, during the last decades and these noncrystalline solids, which were laboratory curiosities in the seventies, are now materials entering the market. This fast and spectacular evolution was due to the mastery of liquid alloy compositions exhibiting excellent resistance towards crystallization during the cooling process. For instance, in the sixties, the first liquid-metal alloys in the Au–Si system were vitrified in the Duwez group[41] by using ultrafast quenching techniques with very high rate of $10^6\,K\,s^{-1}$, while for the last generation of multicomponent Zr–Ti–Cu–Ni–Be alloys, the critical cooling rate is only $1\,K\,s^{-1}$, very similar to silicates or fluoride glasses. Consequently, the size of the glass samples has increased from a thickness of submillimeters to several centimeters.

As mentioned, the first glass-forming systems where fast quenching of the liquid was successfully applied were Au–Si and Pb–Si and it has also been observed that the most favorable region is close to a deep eutectic near 25 atom % Si. This observation is true for all the bulk glass-forming alloys and low-melting liquids are necessary to maintain a low thermal agitation which does not destroy the chemical bonds which take place in the melt and which is materialized by a significant increase of the melt viscosity. The nature of these chemical bonds is not yet well understood. However, clearly it ensures, in cooling, the formation of real out-of-equilibrium metallic glasses, exhibiting glass transition temperatures when reheated.

5.2 Glass-forming Alloy Systems

5.2.1 *Development of Bulk Metallic Glasses (BMG)*

Turnbull[42] had predicted that the ratio of the glass transition temperature T_g to the melting point or liquidus temperature Tl of an alloy, was the essential factor. When the ratio T_g/Tl increases from value near 1/2 to values near 2/3, the homogeneous nucleation of crystallites in the undercooled melt is expected to become more sluggish. This assumption is verified by the work on Au/Si, Pd/Si, and Pd/Cu/Si and is still one of the best rules for predicting the alloys glass-forming ability. A ratio of 2/3 observed in the Pd/Ni/P system was in agreement with the easy glass formation of this alloy leading to bulk ingots of centimeter size for a cooling rate of about $10\,K\,s^{-1}$.

Inoue and his group investigated the aluminum alloys combined with rare earth and transition metals such as the ternary alloys La/Al/Ni or La/Al/Cu. From there, they investigated more complicated alloys and demonstrated that the fabrication of glass samples having a thickness of about 1 cm was possible, for instance, in the alloys La/Al/Cu/Ni.

A similar family of excellent glass-forming materials was found in the alloys Zr/Cu/Ni/Al.

Zirconium-based alloys have received special attention, leading to the discovery, by Johnson group,[40] of several stable glasses and among them the complex composition $(Zr_3Ti)_{0,55}(Cu_5Ni_4)_{0,225}Be_{0,225}$. This material called Vitreloy 1 (V1) is a commercial product used, for instance, for the fabrication of golf clubs.

Attention has been also paid to Fe/Co/Ni rich alloys owing to their magnetic properties. Bulk glass cylinders of 6 mm diameter has been prepared in the system Fe/Co/Ni/Zr/B.[43]

5.2.2 *Glass-forming Conditions*

To make bulk glasses, one must frustrate the process of crystallization in introducing a kind of chemical disorder into the melt in order to avoid the dominant formation of one crystal species. This can be realized in mixing atoms having different

sizes and electronegativities, as well as dissimilar valence electrons configurations. In this situation, solid solutions exhibit critical maximum solubility and become topologically unstable. This destabilization is reflected in the phase diagram by a falling of the liquidus curve which results in a lower melting point which indicate that the liquid phase is stabilized relative to the crystalline phase.

These principles are well illustrated by one of the most stable metallic glasses, which has been discovered in the Zr/Ti/Ni/Cu/Be alloy and which contains four transition metals with very different chemistry and associated to Be, which is considered to be one of the most original elements because of its small size and valence electrons. Both Zr/Be and Ti/Be alloys show deep eutectic valleys in the transition metal-rich region. The same observation is made in the Zr/Ni and Cu/Ti binary alloys where the competing crystalline forms Zr_2Ni and Ti_2Cu limit the glass-forming ability.

It is not surprising that in the Zr/Ti/Ni/Cu/Be system, the five elements acts almost independently, each species preferring different nonequivalent crystallographic sites in the competing crystals. In this case, the alloys appear to be exceedingly frustrated leading in the best glass-forming region to liquidus temperature as low as 700 °C, with glasses having their T_g in the range 360–400 °C. This situation has permitted the fabrication of bulk glassy rods with thicknesses ranging between 5 and 10 cm.

5.2.3 *Crystallization, Phase Separation*

To better characterize the bulk glass-forming ability of metallic alloys, one needs to study crystallization kinetics in detail. An elegant method has been developed to examine nucleation and growth of crystals in the undercooled liquid. Container-less processing using high vacuum and electrostatic levitation provides a means of diminishing the influence of heterogeneous nucleation and facilitates the drawing up of the time-temperature-transformation (TTT) curve which give information on the nucleation and critical cooling rate.[44]

This method, when applied to the V1 alloy, indicates a critical cooling rate in the order of 1 to 2 K/s. For the same alloys the existence of liquid–liquid phase separation into beryllium-rich and poor liquids was also demonstrated. The knowledge of this complex phenomenon is important since it governs the nano-crystallization process and is, consequently, a good guide to select the suitable accurate glass composition. Phase separated domains have been also observed by transmission-electron-microscopy in the Mg/Y/Cu/Li alloys of the Inoue type, showing Cu-poor and Cu-rich regions.

It is also interesting to notice that the crystallization kinetics are also strongly affected by the presence of impurities, especially oxygen at a level below one percent molar. This contamination can alter the critical cooling rate by two order of magnitude. For instance, the glassy alloy V105, which has the composition $Zr_{52,5}Ti_5Cu_{17,9}Ni_{14,6}Al_{10,}$ is characterized by a critical cooling rate of $1\,K\,s^{-1}$ when pure. If contaminated by 1 at % of Oxygen, the glass formation requires rapid solidification, owing to a critical cooling rate which is increased to hundred of $K\,s^{-1}$.

It is also well known that one parameter preventing glass devitrification is associated to the presence of nonmetallic elements, such as Si, P, B, Be, and C, which play an essential role to slow down nucleation during cooling. It is very probable that these elements form clusters containing several metal atoms linked by a directed (partly) covalent bond. This phenomenon introduces a diffusion barrier to long-range organization, which decreases microcrystallite formation during cooling. The metallic radius mismatch between the constituent atoms improves the glass-forming ability by preventing the formation of extensive ordered solid solutions.

5.2.4 *Viscosity of Metallic Glasses*

The exceptional stability of the glass-forming compositions discovered during the last two decades has permitted far more extensive investigation of the temperature dependence of the viscosity for a deeply undercooled metallic system than possible previously. For example, in the 1970s, Chen[45] was limited in measurements to temperatures of only 20–30 K above T_g, by the lack of stability against crystallization of the Pd/Cu/Si alloy that he was studying.

As shown in the article by Johnson,[40] viscosity measurements on the Vitreloy glasses such as the V1, have been obtained, using various methods, in almost all the temperature domain, covering 15 orders of magnitude in viscosity.

The interesting news was in the comparison of these metallic glasses with the other glass-forming systems when introduced in the, now famous Angell[46] diagram, which represents the evolution of the viscosity of many glass-forming liquids versus temperature, more precisely T_g/T. From this universal diagram which allows the classification between strong and fragile glass-forming liquid, it is concluded that a glass such as the industrial alloy V1, exhibits a strong liquid behavior, similar to some silicate or fluoride glasses.

5.3 Properties and Applications of Metallic Glasses

5.3.1 *Chemical Properties*

Metallic glasses exhibit corrosion resistance that can be spectacular, owing to the absence of grain boundaries, with their frequent forms of chemical heterogeneity. The Fe-based glasses have been more extensively investigated and it has been observed that addition of Cr or Mo is particularly effective in increasing corrosion protection against acidic solutions. A glass such as $Fe_{72}Cr_8P_{13}C_7$ passivates immediately in

concentrated HCl solution. Metallic glasses, especially when partially crystallized on a surface, can play the role of catalysts for gas-phase reactions such as the hydrogenation of CO or methanol synthesis. Owing to their excellent corrosion resistance, metallic glasses are good candidates for protective coatings against aggressive environments. Laser amorphization of the container surface as well as glass alloy sputtering have been used to produce corrosion resistant layers. This technology has been successfully applied for developing electrodes having a good electrocatalytic activity for Cl_2 production while being resistant to oxidation by chlorine.

To avoid reaction between the Si substrate and Al metallizations during the manufacture of integrated circuits at high temperatures, diffusion barriers are necessary. It has been demonstrated that high crystallization-temperature glasses such as Ta–Ir glasses make excellent diffusion barriers in many microelectronics applications.

5.3.2 *Magnetic Properties*

For about two decades, amorphous iron based alloys are well known as good soft magnetic materials and alloys belonging in the Fe/Co/Ni/Zr/B system are among the best candidates owing to their interesting ferromagnetic properties. Their tendency to crystallize is such that their technological applications are limited, owing to the ribbon form in which they are commonly produced, in using fast quenching techniques such as the melt spinning or the twin-roller process represented in Figure 15.

As already mentioned, the optimization of the composition has allowed the fabrication of cylinders of a few millimeters diameters. Another alternative method has been recently developed in using successively ball milling of the thin alloy ribbons followed by a hot pressing operation in order to consolidate bulk samples.[47] Examination of the hysteresis loops reveal low coercive fields and fairly large saturation magnetization.

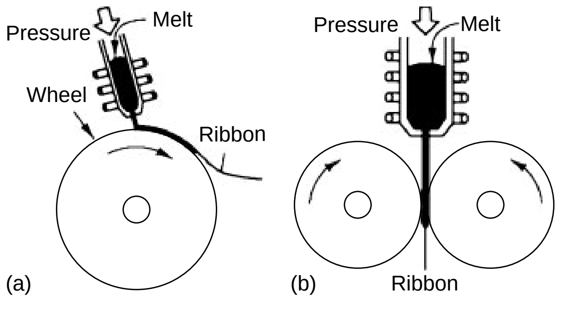

Figure 15 Two selected methods for metallic glass preparation: (a) in the melt-spinning process the molten alloys are projected against a spinning wheel; (b) in the twin-roller quenching technique the melt is cooled between two rotating wheels. In both processes, the aim is to achieve ultrafast cooling

5.3.3 *Mechanical Properties*

The distinctive features of bulk metallic glasses (BMG) are their exceptional mechanical characteristics such as very high yield strengths and high elasticity limits. The elastic strain that a metallic glass can support in tension or bending is at least double that of ordinary commercially crystalline alloys and are therefore premier ‘spring’ materials because they can store high densities of elastic energy.

A variety of composite materials has been obtained by the direct introduction of a reinforcing crystalline solid phase into the glass-forming melt. In many cases, the resistance of the glass to crystallization is good enough to avoid any heterogeneous nucleation at the interface. As an example, the V1 alloy has been used as a glassy matrix to fabricate composite structures with diamond, SiC particles as well as tungsten metal powder or wires. In the case of the W/glass composites, it is proved that the glassy matrix induce localized shear deformation.

The capability to store elastic-energy density in a range of about four time the traditional alloy finds utility in the design of certain types of sporting equipment such as the golf club. This particular application exploits the high strength, favorable density, and ideal elastic behavior of a glass such as the vitreloy V1, which significantly allows to improve the performances of these new generation of iron-free golf clubs.

1 INTRODUCTION

Why would people be interested in metal-nucleic acid interactions? Perhaps because life as we know it is dependent on these interactions. Nucleic acids (DNA and RNA) are actually salts (or complexes) of metal ions from a chemical point of view. Therefore, it is difficult, if not impossible, to separate the behavior of DNA and RNA from their interactions with metal ions. We must also take into account specifically bound water molecules since they frequently mediate interactions between polynucleotides and metal ions.[1,2]

Metal ions are usually required to promote and stabilize functionally active or native conformations of nucleic acids, as well as to mediate nucleic acid–protein interactions. However, metal ions can also cause structural transformation of nucleic acids, or denature their native structures. In addition to structural roles, some metal compounds can induce cleavage (i.e. scission, fragmentation, or depolymerization) and modification (without cleavage) of nucleic acids. Metal–nucleic acid interactions can be either nonspecific or dependent on the chemical nature of nucleotide residues, nucleic acid sequence, or secondary and/or tertiary structure of nucleic acids. The specificity of these interactions is dependent on structural and chemical properties of both the nucleic acids and the metal ions. There are two extreme views of such interactions. The first, among biochemists and molecular biologists, is that properties of metal ions are primitive in comparison with the properties of nucleic acids (presumably because of their smaller size); and the opposite one, common among inorganic chemists, who regard nucleic acids simply as big organic ligands. In reality, both nucleic acids and metal ions exhibit considerable complexity in their interactions, and such interactions could affect the chemical and biochemical properties of both participants.

The involvement of metal-containing species in nucleic acid-dependent processes, including nucleotide biochemistry; genetic information storage and transfer, and control of gene expression (Mg^{2+});[3–7] mutagenesis (e.g. Mn^{2+}, Cu^{2+}, Co^{2+}, and Ni^{2+});[8–10] chromosomal abnormalities (e.g. Be^{2+} and Hg^{2+});[11,12] and carcinogenesis (e.g. Ni^{2+}, Cd^{2+}, Cu^{2+}, Co^{2+}, Fe^{3+}, and Be^{2+})[8,13–16] is well documented (*see* ***Metal Ion Toxicity*** and ***Metal-related Diseases of Genetic Origin***). There are only a few processes for which it is clear that the nucleic acid is the primary target of metal action.[11] In most cases, it is not clear whether the observed effects actually result from direct metal ion–nucleic acid interaction, since other species, such as specific proteins (*see* ***Zinc: DNA-binding Proteins***), may be mediators between the metal ion and the nucleic acid in these processes *in vivo*.[7,11,17,18] To better understand mechanisms of metal–nucleic acid interactions occurring *in vivo*, numerous *in vitro* studies of model reactions and structures of metal–nucleic acid complexes have been carried out (see reviews[19–37]). The interactions of nucleic acids with so-called ‘biological’ metal ions, that is, K^{+}, Na^{+}, Mg^{2+}, Ca^{2+}, Mn^{2+}, $Fe^{2+/3+}$, $Co^{2+/3+}$, $Cu^{+/2+}$, and Zn^{2+}, result in unstable, short-lived complexes with nucleic acids in which ligands bound to metal ions can undergo fast exchange.[37–41] That sometimes creates problems in structure determination of such labile complexes. In contrast, some nonbiological metal ions, for example, $Pt^{2+/4+}$, Pd^{2+}, $Ru^{2+/3+}$, Au^{3+}, Hg^{2+}, and Ag^{+}, form inert complexes with nucleic acids, which are convenient for isolation and investigation; numerous structural studies of such complexes have been described.[26,42,43] Such studies have also led to an interesting body of chemical knowledge, independent of the biological relevance of the species involved.

Eight general research areas can be argued to have contributed the most to what is known today about metal–nucleic acid interactions. The first involves studies of the mechanisms of antitumor activity of certain platinum compounds (*see* ***Platinum-based Anticancer Drugs***), which are believed to have nucleic acids as a critical target.[43–47] The second is concerned with studies of the binding of biological and nonbiological metal ions with nucleobases, nucleosides, and nucleotides.[25,30,35,42,48–50] The third involves studies of metal-binding centers in tRNA molecules,[51–54] catalytic RNAs (ribozymes),[53,55–58] and synthetic oligonucleotides that constitute fragments of natural nucleic acids.[53,59–66]

The fourth area involves studies of the role of metal ions (including Mg^{2+}, Ca^{2+}, Mn^{2+}, Cd^{2+}, Co^{2+}, Zn^{2+}, and Pb^{2+}) in mechanisms of chemical reactions catalyzed by ribozymes, which could play a key role in the origin of life (RNA World hypothesis).[39–41,57,67–69] The fifth involves the same metal ions (as well as Ni^{2+} and Cu^{2+}) as catalysts in reactions that could have resulted in prebiotic synthesis of nucleotides and oligonucleotides.[70–74] The sixth involves the use of certain metal ions and complexes as heavy-atom labels (e.g. for electron microscopy and X-ray crystallography), as well as chemical and spectroscopic probes of nucleic acid structure and function.[75–86] The seventh involves the use of metal compounds as biological diagnostic tools in nucleic acid-based assays and biosensors.[46,87–92] Finally, the eighth area is concerned with the development of applications of metal-nucleic acid complexes in nanotechnology (i.e. microarrays and biochips).[87,91–95]

2 PROPERTIES OF NUCLEIC ACIDS ESSENTIAL FOR BINDING WITH METAL IONS

2.1 Chemical Structures of Nucleic Acids

The chemical structure of nucleic acids[96] provides wide varieties of metal-binding centers that can be involved in the formation of ionic, coordinative (donor–acceptor), hydrogen (H-), and covalent bonds. The term ‘nucleic acid’ is usually used to refer to polynucleotides. The monomeric unit (a nucleotide) consists of a single heterocyclic nucleobase, which can be a purine (adenine or guanine) or pyrimidine (cytosine, uracil, or thymine), attached through an N-glycosyl bond to a pentose sugar (a nucleoside), which in turn is attached to a phosphate by a phosphodiester bond at the 5′- or 3′-terminus (Figure 1). Nucleotides (NMP, where is N = adenosine, A; guanosine, G; inosine, I; cytidine, C; thymidine, T; or uridine, U) can be linked together through 5′ → 3′ phosphodiester bonds to produce linear oligonucleotides (usually <100 nt in length) and polynucleotides (>100 nt), or conjugated to additional phosphate groups to form nucleoside di- and triphosphates (NDPs and NTPs, respectively). Phosphate groups can be attached to a nucleoside through 5′- and 3′-hydroxyl groups of the pentose rings. There are two classes of nucleic acids; those in which the sugar residue bears a hydroxyl group at the 2′-position (ribonucleic acid, RNA) and those in which it does not (deoxyribonucleic acid, DNA). In DNA, the commonly occurring heterocyclic bases are adenine, guanine, cytosine, and thymine, whereas in RNA, thymine is replaced by uracil. The heterocyclic bases are essentially planar, with exocyclic groups lying in the plane of the rings and lone-pair electrons delocalized into the π-systems of the rings. The tautomeric forms of the bases (imino forms for guanine, adenine, and cytosine or enol forms for guanine, cytosine, uracil, and thymine), which are alternatives to the structures

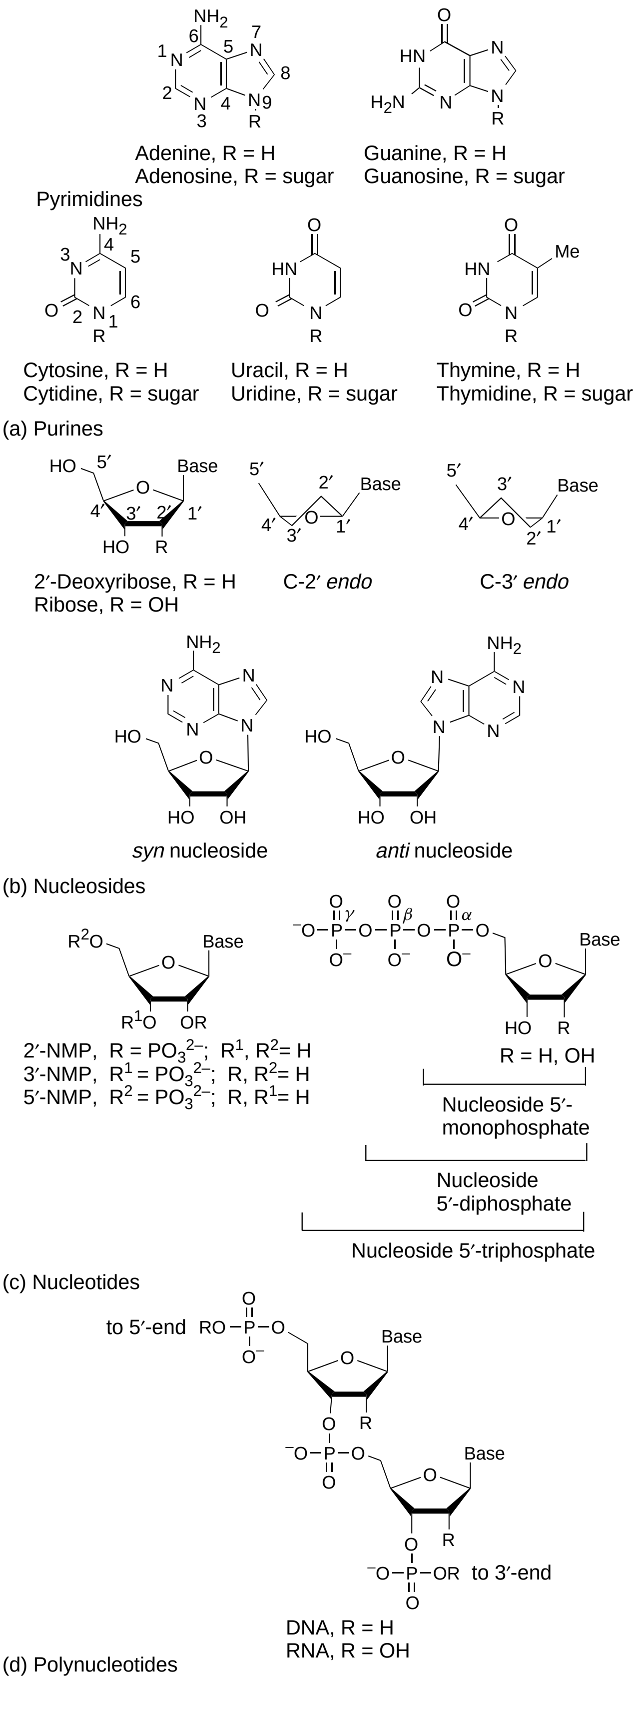

Figure 1 Structures of the nucleic acids and their constituents

presented in Figure 1, do not ordinarily exist in significant concentrations in solution.[97] In comparison to DNA, RNA molecules also have a 2′- OH group that may provide more structural complexity at polynucleotide level and more options for metal binding, as well as higher chemical stability under acid pH conditions. However, the 2′-OH group also makes RNA subject to depolymerization through transesterification catalyzed by many polyvalent metal ions ($M^{\geq 2+}$) at neutral and alkali pH, while such reactions do not normally occur with DNA (see Section 7).

Nucleic acid residues are highly hydrated in water solutions and crystals: two H_2O per phosphate diester and up to six per base pair in DNA and RNA.[2,98,99] There are at least two different types of water molecules bound to nucleic acids. The first involves a highly ordered hydration shell, which is a layer of water molecules interacting via H-bonds primarily with hydrogen bond donor and acceptor groups of nucleic acid residues. These water molecules play important roles in both intra- and intermolecular interactions between nucleic acid residues as well as in metal–nucleic acid interactions that require the interacting surfaces (of both nucleic acids and metal ions) to be partially dehydrated so that either direct (inner-sphere) bonds or bonds through water molecule (outer-sphere) can form.[1,57,99–104] The second water layer is only partially ordered and weakly bound to nucleic acids (through secondary H-bonds or induced dipole–dipole interactions) making it easily exchangeable with bulk water molecules and metal ions. The polarization capability of water molecules can weaken electrostatic interactions between nucleic acids and metal ions.[104]

2.2 Potential Metal-binding Sites in Nucleotides and Nucleosides

Many donor and acceptor atoms in nucleic acids are capable of participating in indirect (outer-sphere) binding through H-bonds with water molecules or other ligands coordinated to metal ions. To understand the direct (inner-sphere) binding between nucleic acid residues and metal ions, both the nucleophilicity and basicity[28] of potential metal-binding sites must be considered. At neutral pH, the principal metal-binding sites in nucleotides (with pK_a's at ionic strength $I = 0.1$ in parentheses) include: terminal phosphate oxygens (1.0 and 6.6), internucleotide phosphate oxygens (1.0), and endocyclic atoms in guanosine (N-7, 2.0), adenosine (N-7 or N-1, 3.8), and cytidine (N-3, 4.2).[28,42] The purine N-3 nitrogen is generally sterically hindered by the sugar and does not bind metal ions, but changing the relative orientation of the nucleic acid base and sugar can make this site available for metal-ion binding. The exocyclic O^2 atom of cytidine is well established as a metal donor atom and constitutes the most important exocyclic metal-ion binding site at neutral pH. The carbonyl groups of other nucleic acid bases, in comparison, are relatively weak donors and usually only bind metal ions if other functional groups participate as well. Upon deprotonation, some endocyclic nitrogen atoms, notably guanosine N-1 (p$K_a = 9.3$), uridine N-3 (9.5), and thymidine N-3 (9.9) become binding sites as well. The exocyclic NH_2 groups in adenosine and cytidine, as well as the ribose 2′-OH group, are poor ligands even when deprotonated (p$K_a > 12$). However, for some metals, binding at specific secondary binding sites can be favorable enough that binding takes place at a pH considerably lower than the nominal pK_a.

There are also metal interactions that do not involve coordination chemistry. For example, cytidine and uridine can form covalent bonds with Hg via C-5.[105,106] Another metal-binding site is the 5,6-alkenic bond in thymidine, which can be oxidized by hexavalent Os or by heptavalent Mn.[105]

All transfer RNAs (tRNAs) contain a number of modified nucleobases and typically 2′-*O*-methylated nucleosides.[107,108] DNA also contains a more limited number of such species. Some of these modifications, for example, N-7 methylation of guanosine, diminish the metal-binding ability of the bases. A few functional groups, such as the exocyclic S in 4-thiouridine and 2-thiocytidine and the exocyclic substituent in 5-carboxymethylaminomethyluridine, enhance the ambivalent nature of the bases.[35] Some of these modifications change the basicity of primary metal-binding sites.

To create new metal-binding centers or affect the stability and specificity of existing metal–nucleic acid bonds, certain nonnatural derivatives of nucleic acid bases, sugars, and phosphates have been artificially designed. One example is the thiophosphate moiety, in which one nonbridging or bridging oxygen of the normal phosphate diester is substituted by a sulfur atom (see Figure 1).[109,110] To remove or shield specific metal-binding sites, selected nucleic acid residues can also be modified (e.g. by ethylation of phosphate ester oxygens or methylation of ring nitrogen atoms in purine nucleotides).[111,112]

3 POSSIBLE EFFECTS OF POLYNUCLEOTIDE STRUCTURES ON METAL-ION BINDING

3.1 Polyelectrolyte Effect

The initial interaction between positively charged metal ions and the negatively charged phosphate groups of nucleotides and polynucleotides involves a fast electrostatic interaction that is weak and nonspecific.[37,103,104,113] For example, the increasing phosphate content (and hence negative charge) in the series A < AMP < ADP < ATP governs the increase in affinity toward alkaline earth metal ions, which bind predominantly to the phosphate groups of nucleotides.[114,115] The cation concentration in proximity to the polynucleotide polyanions is far higher than in the bulk solvent.[116] For low ionic strength solutions of DNA, the ratios of these concentrations ('the polyelectrolyte effect') for Na^+ and

Mg^{2+} were estimated to be roughly 3×10^3 and 9×10^6, respectively,[22] reflecting the greater attraction of divalent cations.[116] However, at a high ratio of monovalent to divalent cations, a competition for the available phosphate anion binding sites occurs, in addition to the dielectric effects of single charged cations; in some cases, this can effectively shield the negatively charged sites from polyvalent cations.[10] The electric field produced by a polyanion in association with that of the compensating counterions increases the pK_a values of the nucleic acid bases slightly and promotes polarization of water molecules bound both to the nucleic acid and metal ions.[98]

The negative charge density, and hence the polyelectrolyte effect, is smaller for single-stranded polynucleotides than for multistrand species (see below).[22] Nonspecific binding of metal ions with nucleic acid phosphates exhibits negative cooperativity, because bound cations reduce the net charge of the polyanion.

Nucleic acids usually bind alkali monovalent metal ions only in an 'atmospheric manner' (in which the M^+–phosphate distance is larger than 7 Å).[37,117] For polyvalent metal ions, two additional types of binding have been characterized: outer-sphere binding, in which a water molecule coordinated to the metal ion produces a hydrogen bond with the phosphate oxygen, and inner-sphere binding, in which the metal ion is bound directly to the phosphate oxygen (the M^+–phosphate distances associated with these two mechanisms are about 6 and 3 Å, respectively).[117] Because the ionic radii of divalent metal ions (Table 1) are about 10-fold smaller than the distance between adjacent phosphates in stacked polynucleotide chains, divalent metal ions generally do not bind with two phosphates simultaneously by an inner-sphere mechanism.[118] As was demonstrated for the interaction between Mg^{2+} and oligoriboadenylates, short flexible oligonucleotides may more easily bend to afford a loop structure in which two phosphate residues can provide full charge compensation by binding directly to a single metal ion.[118]

For many metal ions, the initial electrostatic interaction can be followed by stronger and more specific binding with nucleic acids via the formation of outer- and inner-sphere complexes. The formation of such complexes may be strongly accelerated (in comparison to binding to nucleosides and nucleotides) because of the polyelectrolyte effect.

3.2 Internucleotide Interactions

In addition to the polyelectrolyte effect, nucleotide sequence (or primary structure), and secondary and tertiary

Table 1 Basic features of hydrated metal ions involved in metal–nucleic acid interactions

Ion	Ionic radius[119,120]	Coordination number[120]	Typical geometry of inner-sphere complex[120]	First pK_a of $[M(H_2O)_n]^{M+a}$,[121,122]
Ag^+	1.26	2 > 4	Linear	9.8–11.7
Al^{3+}	0.51	6 > 4	Octahedral	4.3–5.0
Ba^{2+}	1.34	8	Square antiprism	13.4–14.0
Be^{2+}	0.35	4	Tetrahedral	5.7–6.7
Bi^{3+}	0.96	6	Octahedral	Unstable
Ca^{2+}	0.99	8	Square antiprism	12.6–13.4
Cd^{2+}	0.97	6 > 4	Octahedral	7.6–10.2
Co^{2+}	0.72	6	Octahedral	7.6–9.9
Co^{3+}	0.63	6	Octahedral	0.9–2.0
Cr^{2+}	0.89	6	Octahedral	8.7–11
Cr^{3+}	0.63	6	Octahedral	3.8–4.4
Cu^+	0.96	4	Tetrahedral	Unstable
Cu^{2+}	0.72	4 > 6	Square planar	6.8–8.5
Eu^{3+}	0.95	9	Variable	4.8–8.5
Fe^{2+}	0.74	6	Octahedral	5.9–6.7
Fe^{3+}	0.64	6	Octahedral	≈2.5
Hg^{2+}	1.10	2 > 4.6	Linear	2.4–3.7
In^{3+}	0.81	6	Octahedral	≈3.7
Mg^{2+}	0.66	6	Octahedral	11.4–12.8
Mn^{2+}	0.80	6	Octahedral	10.6–10.9
Ni^{2+}	0.69	6	Octahedral	6.5–10.2
Pb^{2+}	1.20	6 > 9	Octahedral	6.5–8.4
Sn^{2+}	0.93	3 > 6	Pyramidal	3.7–6.8
Sr^{2+}	1.12	6	Octahedral	13.2–13.8
UO_2^{2+}	0.80 (U^{6+})	6 > 8	Octahedral	≈5.7
VO^{2+}	0.63(V^{4+})	6	Octahedral	≈5.4
Zn^{2+}	0.74	4 > 6	Tetrahedral	8.2–9.8

[a]Dependent on ionic strength.

structures of single-stranded polynucleotides may dramatically affect the kinetics, mode, and affinity of metals ion binding through internucleotide interactions (base stacking, H-bonds) and the spatial arrangement of potential metal-binding centers (steric effects). These characteristics also vary among different types of polynucleotides. For example, the affinity of Mg^{2+} for individual types of polynucleotides is in the order tRNA $>$ poly(I) $\gg$ poly(A) $\sim$ poly(A)·poly(U) $\sim$ poly(I)·poly(C) $\sim$ DNA $\geq$ denatured DNA $>$ poly(C) $>$ poly(U).[123]

3.2.1 Base Stacking

In solutions of ordered polynucleotides, the heterocyclic bases are stacked, that is, packed vertically one upon the next. The greatest stability is for purine–purine base-stacking interactions. The next are purine–pyrimidine interactions, which in turn impart greater stability than pyrimidine–pyrimidine stacking interactions.[124,125]

Base-stacking interactions may strain or disrupt metal binding. This can occur in the plane of the nucleobase heterocycles, owing to the absence of proper geometry for chelation of neighboring nucleobases (e.g. binding of *cis*-$(NH_3)_2PtCl_2$ with neighbor purine bases),[47] and also for binding from above or below the plane (e.g. for the 5,6-double bond of T), because of steric hindrance.[96,125] Alternatively, base stacking can actually favor metal π-complex formation where the metal ion is inserted between two stacked bases.[125]

3.2.2 Hydrogen Bonds

The main factor determining the specificity of intra- and intermolecular interactions of polynucleotide chains is interbase H-bonding interactions, which occur between the amidate or exocyclic amine nitrogen donors of one nucleobase and the keto oxygen or heterocyclic nitrogen acceptors of another base.[97,125] The common H–bonding schemes involve Watson–Crick base pairs: A·T (A·U) and G·C or I·C in DNA (RNA) duplexes; T·A·T (or U·A·U) and C^+·G·C in triplexes; and G_4 in quadruplexes (Figure 2). There is also evidence for a few other types of interbase arrangements, for example, Hoogsteen and reverse Hoogsteen base pairs.[126] In some cases, nonWatson–Crick interactions may occur as frequently as Watson–Crick base pairs and play an important role in stabilizing the structure of RNA, for example, for G·U base pairs and tertiary (nonduplex) A·G pairs in tRNAs (Figure 2b)[124] and the active center of the hairpin ribozyme.[127]

As a consequence of base pairing, only a limited number of possible metal-binding sites in the bases are available in duplexes;[37,130] even fewer sites are accessible in triplex and quadruplex structures (Figure 2). The electron density of donor atoms that remain available for metal binding also differs from the electron density in isolated base residues.[32] For example, the affinity of purine N-7 and N-3 atoms for

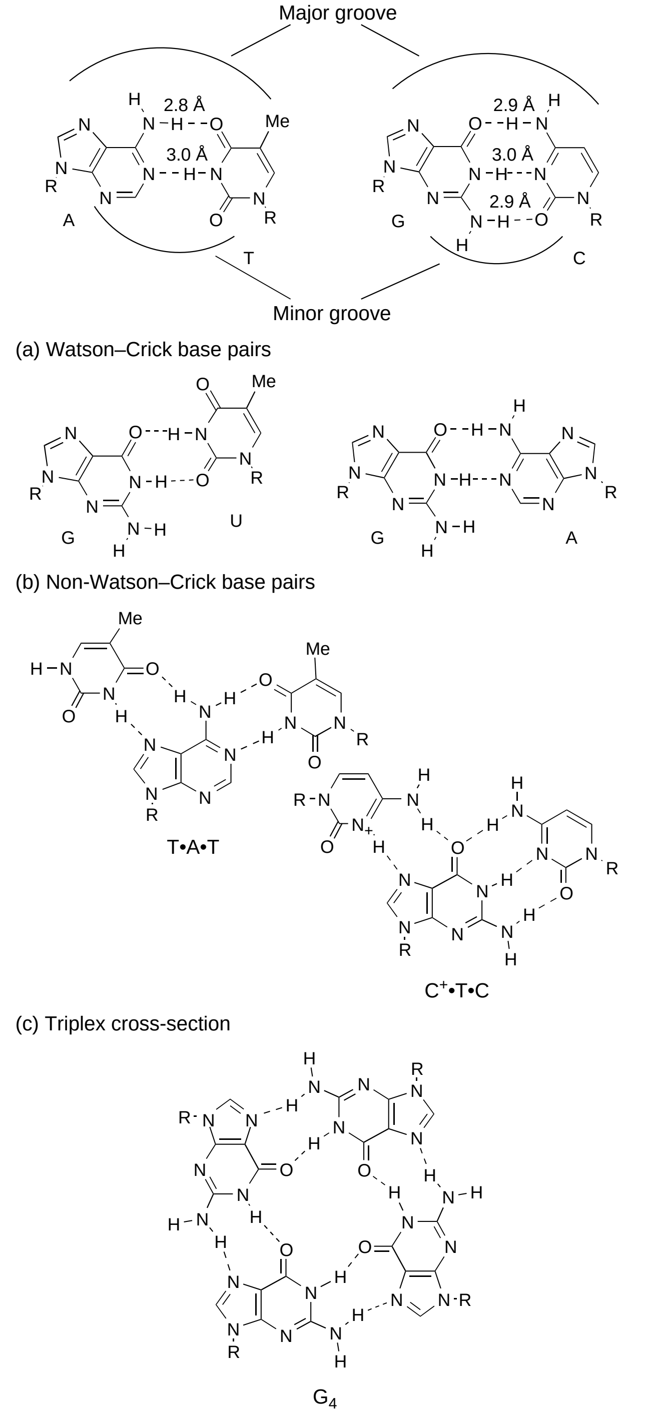

Figure 2 Structures illustrating cross-sections of nucleic acid duplexes, triplexes, and quadruplexes[76,128,129]

metal ions is greater in DNA duplexes than for the free nucleotides.[125]

There are a few additional types of H-bonds in nucleic acids. For example, the sugar 2′-OH group in RNA can act as a H-bond donor to the neighboring 3′-phosphate oxygen

anion.[97,125] The hydrogen atoms of water molecules interact with phosphate oxygen anions and sugar OH groups; water oxygen atoms form bonds with donor (N–H and C–NH_2) atoms in the nucleobases, while water hydrogen atoms interact with acceptor (N and C=O) atoms/groups. The hydrogen atoms of pentose 2′-OH groups in RNA also can interact with water oxygens. Such complex arrangement of internucleotide interactions between bases, sugar, and phosphate residues occurring in a GAAA tetranucleotide loop of a hairpin RNA is illustrated in Figure 3.

Interactions of the same water molecules with RNA nucleotides (via H-bonding) and metal ions (via inner-sphere coordination) could stabilize specific metal ion–nucleic acid complexes (e.g. in Mg^{2+}–tRNA chelates)[52] and also create the possibility for direct proton transfer through a 'water chain' that could play a role in ribozyme–metal ion catalysis[133] and in the mechanism of metal-dependent nucleases and polymerases.[134] Similar types of H-bonds between different nucleotide residues have been found in tRNA tertiary structures, where they provide additional stabilization of tertiary interactions.

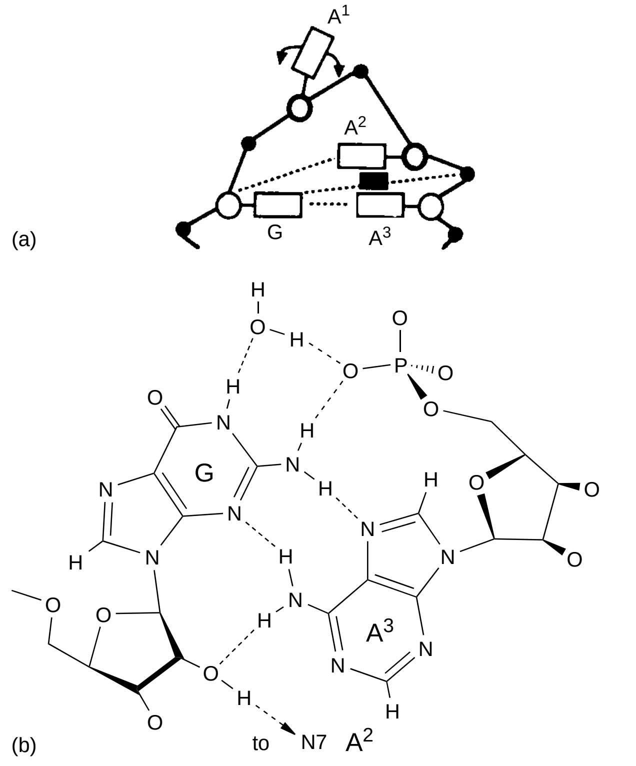

Figure 3 Structural features for the GAAA tetranucleotide loop in the hairpins. (a) General scheme of specific contacts between bases (boxes), sugars (large circles) and phosphates (boldface small circles). Hydrogen bonds and stacking interaction are shown by dotted lines and by a black box, respectively. (b), Putative hydrogen bonding network with the guanosine residue in the GAAA tetraloop structure. The N7 atom of the A^2 residue can make a hydrogen bond with 2′-hydroxyl group of G[131,132]

3.3 Intra- and Intermolecular Structures Formed by Polynucleotides

3.3.1 Secondary Structures

Single-stranded regions exist in most of the naturally occurring single-stranded RNAs, and in a few viral DNAs, as well as in denatured (see below) double-stranded DNAs. The single polynucleotide chains in solution may assume flexible right-handed helical structures as a result of base stacking and intramolecular H-bonds.[124] However, there are mostly short single–stranded regions present in single-stranded polynucleotides. As a result of folding back of the single polynucleotide strands, complementary H-bonds may form between bases, producing intramolecular duplexes and triplexes (see below) as well as internal loops, hairpin loops, and bulges (Figure 4a). Such structures, whether formed intra- or intermolecularly, are secondary structure elements.

The most prominent motif, which binds together all other secondary structure elements, is duplex (double helix). Most natural DNAs and a few viral RNAs are double-stranded and normally present in solution as duplexes, which are antiparallel (in terms of strand orientation), right-handed double helixes (Figure 5, A-B), stabilized through base–base interactions by both stacking and Watson–Crick H-bonding (see Figure 2). Double-stranded structures are less flexible than single-stranded ones, which limits the number of nucleic acid ligands that may participate in chelation of metal ions. In addition to the specific interbase (stacking and complementary) interactions, the restricted conformational freedom of pentose rings (involving C-2′ and C-3′-*endo* conformational isomers) and rotation about single bonds (see Figure 1), as well as steric (i.e. nonbonding) interactions between the bases and sugars, and electrostatic repulsion between phosphate groups, result in a limited variation in double helical structures. The conformational flexibility of double-stranded RNA is even more limited because of the added bulkiness of the 2′-OH group in ribose residues, which stiffens the sugar–phosphate backbone. In normal B-form DNA (Figure 5, B) the base pairs, intersecting at the helix axis and stacking perpendicular to it, form a central hydrophobic pillar surrounded by the hydrophilic sugar–phosphate backbone. In the usual A-form RNA double helix, the base pairs are located away from the center and tilted about 15° from the helical axis (Figure 5, A). There are other significant differences between these forms, such as the diameter of the backbone cylinder (which is slightly narrower in B-form than in A-form duplexes), the number of base pairs per helix turn (approximately 10 vs. 11), and the axial rise per base pair (3.4 vs. 2.8 Å for DNA and RNA duplexes, respectively). These structural features produce a major groove that is deep and narrow in A-form duplexes and a shallow, wider minor groove. In contrast, B-form duplexes have a wide major groove and narrow minor groove; both are of comparable depth (Figure 5). In the major groove of B-form DNA, potential metal-binding centers – atoms N-7 and

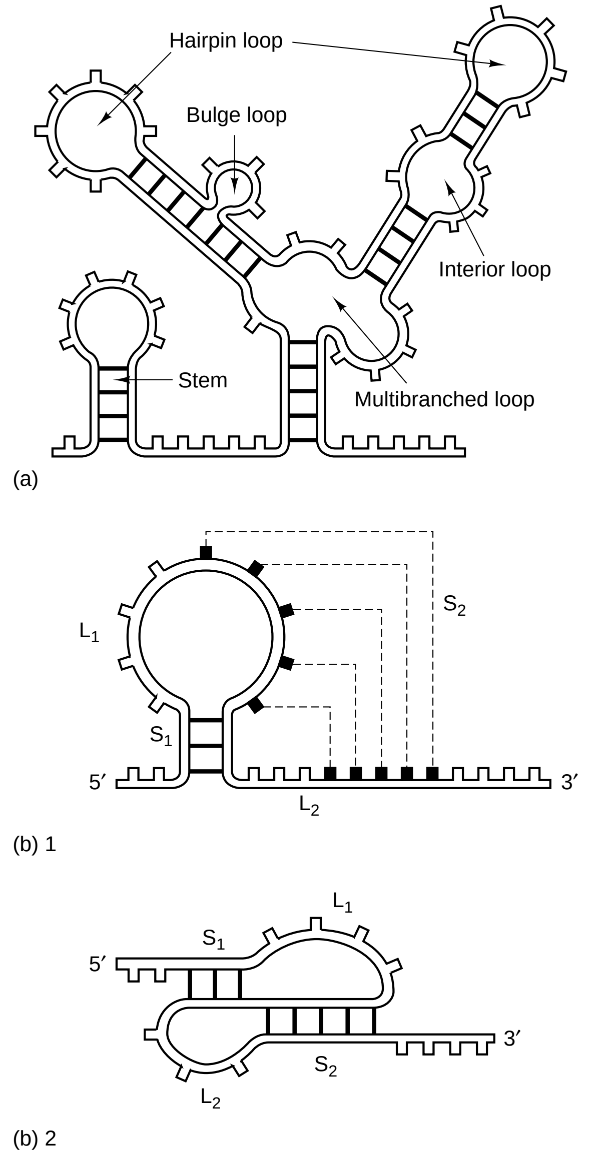

Figure 4 Tertiary structures of RNA's including (a) various stems, loops, and bulges, (b) an RNA pseudoknot. (Reprinted from Ref. 135, © 1990, with permission from Elsevier)

$O^6(N^6)$ of the purines and $O^4(N^4)$ of the pyrimidines are quite accessible; this is also true for N-3 of purines in the minor groove of DNA.[136,137]

Under conditions of reduced hydration, for example, in the presence of either high salt (of certain monovalent cations) or ethanol concentrations, or in crystals, DNA may adopt the A-form.[99] DNA–RNA hybrids (an intermediate in both forward and reverse transcription) exist as A-form duplexes.[126] Alteration of a duplex conformation can dramatically affect the accessibility of potential metal-binding sites.[37,139]

The most striking structure that has been observed for a DNA duplex is the left-handed Z-form DNA having Watson–Crick base pairing and a 'zigzag' sugar phosphate backbone (Figure 5, Z); this structure forms in alternating pyrimidine–purine sequences (e.g. CGCGCG) in the presence of appropriate polyvalent metal ions. The transition from B- to Z-form DNA is facilitated enormously by certain divalent metal ions, reflecting the importance of this metal ion to the stabilization of Z-DNA structure.[140,141] Z-form DNA is believed to exist in specific regions of DNA *in vivo*, and may play an important role in functions such as regulation of gene expression.[124]

Covalently closed circular DNAs exist in nature in a variety of organisms. Such topologically constrained DNAs can form both negatively supercoiled structures, which create a torsional stress on the double helix and favor its unwinding, and positively supercoiled molecules, which enforce tighter winding of the double helix. When the sugar–phosphate backbone of even one strand is broken, the supercoils are relaxed, forming an open circle of duplex DNA. Such backbone cleavage reactions can result from the action of metal compounds on DNA.[12]

DNA is prone to structural polymorphism: its structure can differ markedly from the classical double helix. For example, under superhelical stress, circular closed DNA can adopt an unusual structure, denoted H-DNA, in which homopurine–homopyrimidine tracts unwind and utilize the pyrimidine-rich strand to form an intramolecular triplex with another homopurine–homopyrimidine tract; the remaining purine single strand is left unpaired. The formation of H-DNA requires the presence of metal ions such as Mg^{2+} or Ca^{2+}.[142,143]

The great interest in triple-helix formation relates less to its possible physiological significance (which is currently unclear) than to potential applications (e.g. in gene-targeted therapy and genetic engineering) that can exploit the ability of single-stranded oligonucleotides to bind selected double-stranded DNA sites.[144] In triplexes composed of one polypurine and two polypyrimidine strands, the polypyrimidine 'third' strand lies in the major groove parallel to the purine strand of an A-form double helix. This additional strand interacts with the Watson–Crick duplex via Hoogsteen base pairing to form T·A·T and C^+·G·C triplets (see Figure 2c). The formation of the latter triplet is optimal at acid pH and markedly decreased at $pH > 6$ because of the need for cytidine protonation. However, the use of certain base analogs and phosphodiester backbone modifications allows triplex formation at physiological pH.[144] There are a few others type of triplexes that have been observed including G-rich pyrimidine–purine–purine structures.[144] Not surprisingly, triplex formation affects accessibility of potential metal-binding sites and requires certain divalent metal ions to stabilize the repulsion resulting from the negatively charged backbones of polynucleotide strands brought into close proximity. However, metal ions may both stabilize and destabilize the formation of triplex structures (see Section 6).

Both natural and synthetic polynucleotides containing repeats of G-rich sequences can also form quadruplexes (see

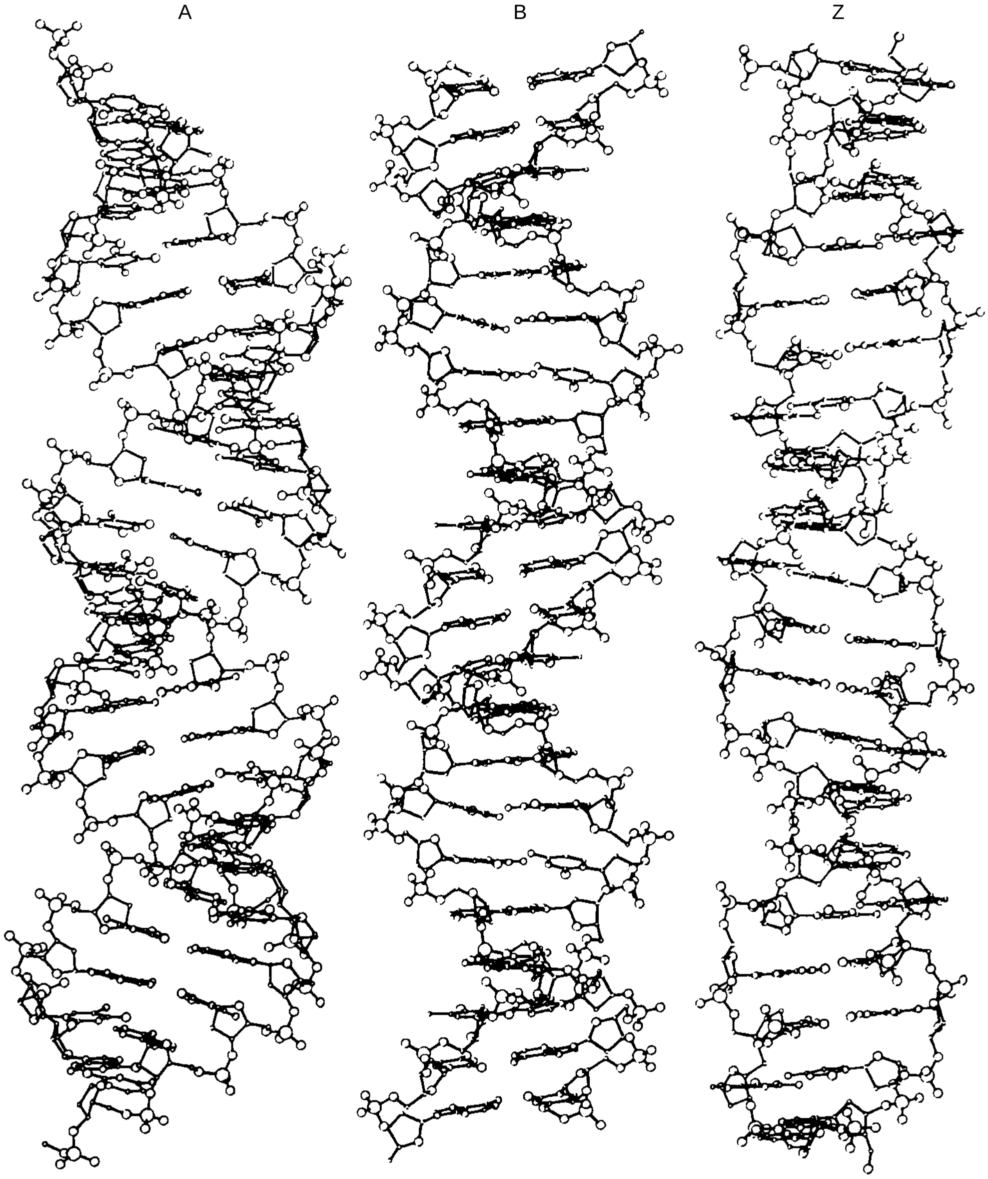

Figure 5 Structures of A, B, and Z-form DNAs[138]

Figure 2d), including parallel interstrand (most stable) and antiparallel intrastrand (fold-back) structures in DNA and RNA. These types of multistranded DNA structures have been proposed to be important in chromosomal telomer formation, immunoglobulin gene switching, and genetic recombination.[129] The large hydrophilic channel within the quadruplex structure is stabilized by monovalent metal ions such as $K^+ > Rb^+ \sim Na^+ > Li^+$ (in order of their effectiveness)[129,145–147] (also see Section 6).

3.3.2 *Tertiary Structures*

The structures described above, whether formed intra- or intermolecularly, are secondary structure elements. Additional interactions between these secondary structure elements, for example, base pairing between two loops or between a loop and a single-strand region, constitute tertiary structure (Figures 4b and 6). Most known tertiary interactions (including base triples, intercalation (insertion) of a base from one secondary structure element between two neighboring bases in another, and pseudoknots) have been found in RNA molecules, including tRNA.[124,148] DNA supercoiling (see above) is a feature of tertiary structure as well.

Single-stranded regions of nucleic acids provide metal ions with access to all possible binding sites in the nucleotide residues. In contrast, nucleic acid tertiary structure, while creating some restrictions on metal binding in certain regions, may also provide other sites at which donor atoms located

in appropriate orientations chelate selected metal ions very specifically. The best-known examples of such complexes are also found in tRNAs (Figure 6). Metal binding, in turn, may stabilize such structural elements of nucleic acids (see below), which would otherwise assume a number of different conformations in solution.

One more interesting structure, also representing an unusual metal-binding center, is the DNA cruciform (or four-way junction) structure.[11,151] This type of structure results from rearrangement of palindromes (inverted repeat sequences) and may be formed reversibly under certain conditions (e.g. to relax strain in supercoiled DNA). The relative efficiency of different divalent metal ions in promoting the formation of DNA cruciform structures is $Mg^{2+} > Mn^{2+} > Co^{2+} > Ni^{2+} \sim Cu^{2+}$.[152,153]

Another class of tertiary structures involving nucleic acids comprises complexes between nucleic acids and proteins. Some of these complexes, whose structure and function are under the control of metal ions, are described in ***Zinc: DNA-binding Proteins***. Specific interactions between certain amino acid residues in proteins with nucleotide residues (e.g. via H-bonds, stacking, and electrostatic interaction with phosphate anions) in nucleic acid–protein complexes may also restrict metal-binding sites on the nucleic acid. Structural rearrangement of nucleic acids upon interaction with proteins, in turn, can also lead to the formation of new metal-binding sites (e.g. as a result of local denaturation of a duplex).[11] There is also evidence for the formation of metal-binding sites in nucleoprotein complexes that involve both the nucleic acid and protein residues (such as imidazole, –SH, $–SCH_3$, NH_2, and CO_2^-)[17] (*see* ***Peptide–Metal Interactions***).

3.3.3 Denaturation and Renaturation of Polynucleotide Structures

Complete disruption (unfolding) of specific, functionally important ('native') conformations of single-stranded and multistranded polynucleotides (as well their complexes with proteins) is called denaturation. Denaturation (or 'melting') of DNA is the simplest example of the unwinding of the double helix resulting in partial or complete separation of polynucleotide strands. Triplex melting proceeds in two steps: the first involves dissociation of the 'third' strand from the intact Watson–Crick duplex; the second involves duplex denaturation, which occurs under more stringent conditions.[154] Reassembly of the separated strands is called renaturation, or else hybridization (annealing) if the DNA strands were originally from different sources or if a DNA strand is matched with a complementary RNA strand.

The stability of multistrand nucleic acid secondary structures depends both on internal and external factors. Since the G·C base pair contains three H-bonds compared with two for the A·T (or A·U) base pair (Figure 2a), and because stacking interactions decrease in the order G > A > C > U, a duplex with greater GC content is expected to be more stable.

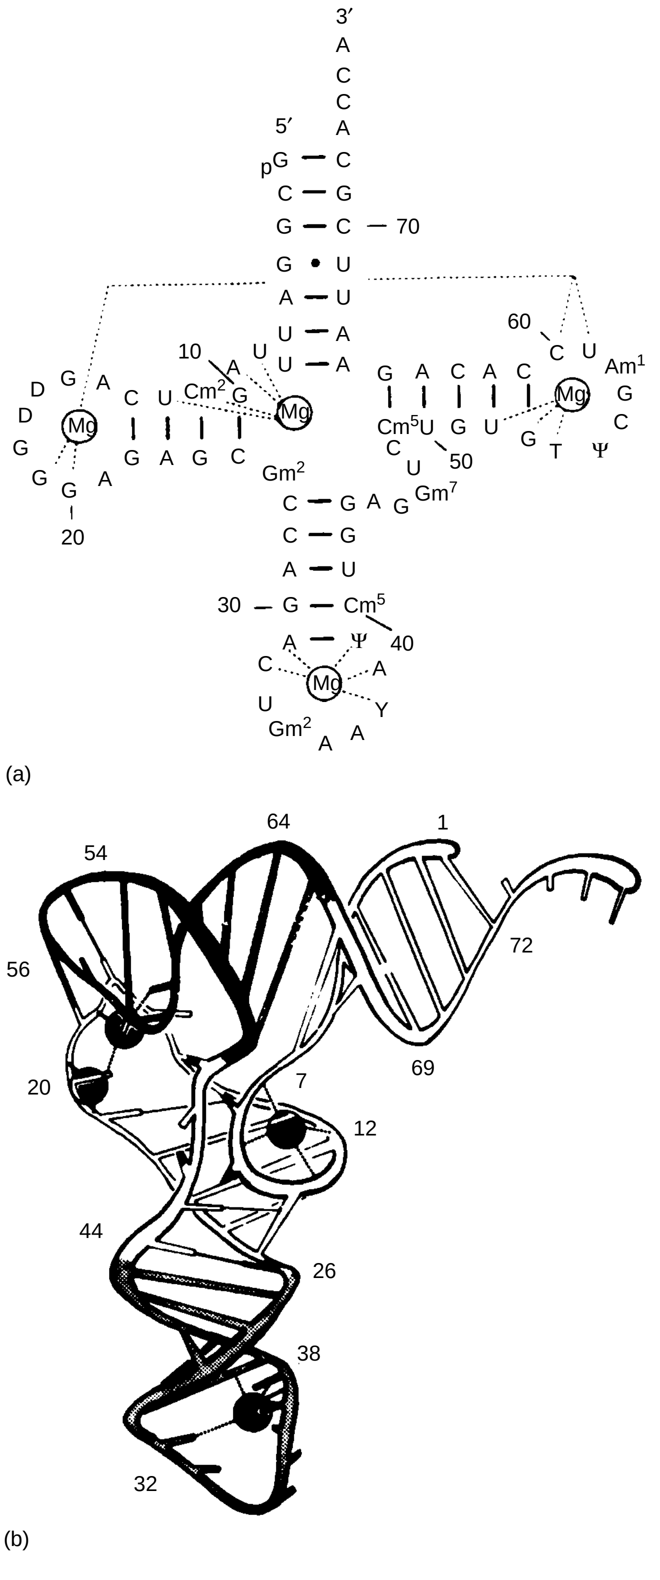

Figure 6 Sites of specific binding of Mg^{2+} ions in yeast $tRNA^{Phe}$. (a) secondary structure. (Ref. 149. Reproduced by permission of American Society for Biochemistry & Molecular Biology) (b) tertiary structure. (Ref. 150. Reproduced by permission of Oxford University Press)

Likewise, duplex stability tends to increase as the number of base pairs increases. Because there is electrostatic repulsion between negatively charged oxygens in the sugar–phosphate backbone, the structures of multistrand polynucleotides are unstable in pure water at temperatures above 0 °C; their stabilities increase with increasing concentrations of monovalent metal cations that act as counterions for the phosphate oxygens.[154] The influence of di- and trivalent metal ions on the stability of nucleic acids is more complicated and may be both stabilizing and destabilizing (see below).[7] Usually, the relative stability of nucleic acid hybrids increases in the order DNA–DNA < DNA–RNA < RNA–RNA.[155] In addition to elevated temperature, extremes of pH also may be used to disrupt multihelical polynucleotide structures, since protonation or deprotonation of bases involved in H-bonding destabilizes base pairing. Alkaline conditions (pH > 11.5) are suitable for denaturation of DNAs, but not for RNAs, which are cleaved at high pH. In comparison, acidic conditions (pH < 2.5) are suitable for denaturation of RNA, but cause depurination of DNA.[154] Some proteins can also induce local denaturation of DNA.[156] When the temperature or pH is restored smoothly to the 'biological' range (25–45 °C and pH 7–8, respectively), the denatured strands can renature to restore the intact duplex, but fast cooling (e.g. in ice) or shifting to neutral pH typically results in intrastrand collapse without proper interstrand base pairing. Denaturation of multistrand polynucleotide structures usually increases accessibility of potential metal-binding sites but may decrease or change the specificity of metal binding (see below).

The difference between native and denatured forms of RNA tertiary structures[124,157] are not quite as simple (or clear) as in the case of multistrand DNA structures. Stabilization of the RNA tertiary structures by metal ions and changes in metal-binding modes upon denaturation are based on a similar principle as for DNA but apparently are more complex processes.[57,104,157–163] For example, specific tertiary structures of tRNA molecules can exist at high concentration of Na^+, but are very unstable in the absence of divalent metal ions.[159] The tRNA tertiary structure provides the specific binding sites for divalent metal ions (naturally – Mg^{2+}) (Figure 6), which disappear with the liberation of the bound metal ions as a result of the tertiary structure unfolding under denaturing conditions.[158] However, if all endogenous Mg^{2+} ions were removed from a tRNA molecule (e.g. by heating the solution in the presence of excess of strong chelating agents such as EDTA) and then added back to solution in exactly the original amount, the native tertiary structure can be restored, but not for each tRNA molecule,[160] presumably because Mg^{2+} ions can stabilize both native RNA structures and also can trap RNA in relatively stable 'alternative' structures.[164] Interestingly, some RNA complexes containing certain metal ions (e.g. Mg^{2+} and Mn^{2+}) can survive under ambient temperatures even in the presence of EDTA (despite the strong metal affinity of EDTA: log K stability for [Mg^{2+}-EDTA] and [Mn^{2+}-EDTA] are 9.1 and 14.0, respectively[121]) presumably because of the electrostatic repulsion and steric inaccessibility of EDTA to some metal ions bound in internal pockets of RNA tertiary structure.[158,161,165] For this reason, to most effectively remove divalent (or trivalent) ions bound to RNA, the RNA should be heat-denatured in the presence of chelating agents and high concentrations of monovalent cations to accelerate ligand-exchange reactions if possible.[161]

3.4 Structure-Specific Binding of Metal Compounds to Polynucleotides

The specificity of metal ion/compound binding to a polynucleotide depends on its nucleotide sequence and structure as well as presence of modified nucleotides and reaction conditions (e.g. metal concentration, pH, and temperature). The specific binding always involves the formation of comparatively thermodynamically stable or kinetically inert (see below) metal–nucleic acid bonds. The term 'comparatively' means that the relative (not absolute) stability or inertness of the different bonds constitute the principal determinant of the specificity of interaction. There are different kinds of metal-binding selectivity, including (1) 'atom-specific' interactions, involving individual donor atoms in the nucleic acid residues; (2) 'group-specific' interactions, involving combinations of nucleotide residues such as phosphate, sugar, and nucleic acid bases; (3) 'base-specific' interactions in polynucleotides; (4) 'sequence-specific' interactions; (5) interactions specific to secondary structure, that is, involving binding to single-stranded or double-stranded polynucleotides; and (6) 'tertiary structure-specific' interactions, which are usual for RNA molecules and nucleoprotein macromolecular complexes. As the complexity of the structure of a nucleic acid increases, so does the probability of highly specific metal binding because of the greater opportunity for formation of unique ligand environments. In general, different metal ions bind to different sites in the same polynucleotide and vice versa – the same or closely located (see below) metal-binding centers of polynucleotides would bind different metal ions. For example, many specific metal-binding sites for different metal ions (for Mg^{2+} - see Figure 6) have been found within the $tRNA^{Phe}$ molecule.[51,53,54] (also see Section 5.5).

4 PROPERTIES OF METAL IONS ESSENTIAL FOR INTERACTION WITH NUCLEIC ACIDS

4.1 Metal-nucleic Acid Bond Formation Occurs Through Ligand-exchange Reactions

As mentioned above, metal ions and nucleic acids are equal partners in metal–nucleic acid interactions. Surprisingly, the number of potential bonds (both inner- and outer-sphere) that

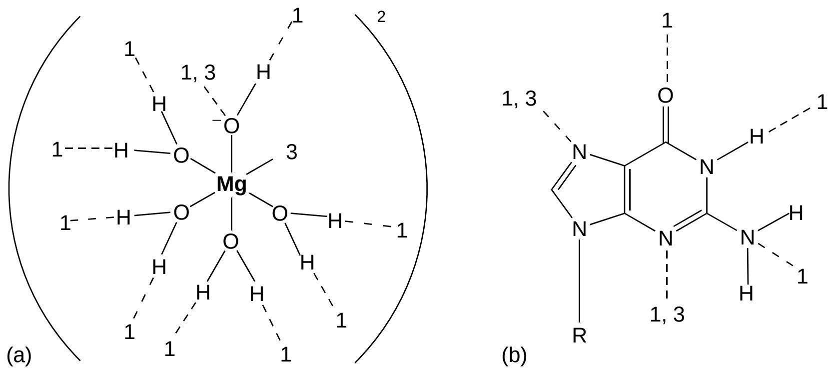

Figure 7 Types of specific bonds that can be formed by hydrated metal ion (a) as compared to guanine (b). The bond types are designated as follows: 1 – hydrogen, 2 – ions, and 3 – coordinative (donor–acceptor)[166]

can be formed by metal ions may even exceed this number for nucleic acid bases – as schematically shown in Figure 7 comparing $[Mg(H_2O)_6]^{2+}$ and the guanine residue.

In aqueous solutions, most metal ions (M^+, M^{2+} and M^{3+}) exist as aqua complexes $[M(OH_2)_x]^{n+}$, which tend to act as acids to form aqua-hydroxo complexes $[M(OH_2)_{x-1}(OH)]^{(n-1)+}$ (see Table 1 for pK_a values) owing to the influence of the positive charge and electron acceptor property of the metal ion that facilitates deprotonation. In buffered solutions the behavior of metal ions is affected by many factors. The acidity constants for the same metal-aqua complexes may vary with ionic strength and temperature.[121] While pH < pK_a (Table 1) favors aqua-complex (M-OH_2) formation, pH > pK_a favors formation of M–OH, which is resistant to ligand substitution[28] and also decreases or even neutralizes the positive charge of the metal complex, resulting in precipitation of metal hydroxides.[167] For instance, both $Pb(OH)_2$ and $Fe(OH)_2$ begin to precipitate at pH 7.5 and are almost completely insoluble ($\sim 10^{-5}$ M) at pH 9.0 and 9.7, respectively.[168] In contrast, $Mg(OH)_2$ doesn't begin to precipitate until pH 10.4.[168] Therefore, it is important to optimize the solution pH depending on the metal ions to be used. The formation of hydroxy forms also can result in oxidation (see Section 4.5) of metal ions as, for example, Mn^{2+} and Co^{2+} at pH $\geq$ 8.5.[169]

In addition to H_2O and hydroxide anion (^-OH), other neutral (e.g. NH_3, imidazole, and nucleobases) or negatively charged ligands (e.g. RS^-, Cl^-, $CH_3CO_2^-$ or PO_4^{3-}) can be bound simultaneously to the same metal cations. Some ligands, such as ClO_4^- and NO_3^-, have no tendency to coordinate to metal ions even in rather concentrated aqueous solutions but most others (e.g. Cl^-, $MeCO_2^-$, and PO_4^{3-}) can substitute coordinated H_2O molecule(s).[170] Some commonly used biological buffers (e.g. polyamines, Tris, and phosphates) also can form metal-ion complexes of varying degrees of stability.[122] Moreover, cationic buffer components may also compete with metal ions for electrostatic and outer-sphere metal-binding sites in nucleic acids. In aqueous, buffered solutions, coordination compounds undergo exchange reactions, wherein inert ligands are retained while labile ones are substituted by water (aquation) or by ionic buffer constituents (*see* ***Coordination & Organometallic Chemistry: Principles***). Beyond its dependence on the nature and concentrations of metal ions and buffer solutions, the composition of the internal coordination spheres of dissolved metal ion complexes depends on pH (see above) and temperature. High temperature accelerates exchange processes, whereas low temperature (without freezing) usually slows it down.

Inner-sphere (direct) metal-nucleic acids bonds can be both formed and dissociated as result of preexisting ligand substitution (exchange) reactions, wherein inert ligands keep their places while labile ones are substituted. Mechanistically, there are generally considered to be three main classes of ligand-substitution (replacement) reactions: dissociative (1), associative (i.e. going through a transition state involving an inner-sphere complex) (2), and interchange (exchange of ligand X and Y between inner and outer coordination spheres of the metal) (3), as illustrated by the following equations:[120,170]

$$\text{M–X} + \text{Y} \longrightarrow [\text{M} + \text{X}] + \text{Y} \longrightarrow \text{M–Y} + \text{X} \quad (1)$$

$$\text{X–M} + \text{Y} \longrightarrow [\text{X–M–Y}] \longrightarrow \text{M–Y} + \text{X} \quad (2)$$

$$\text{X–M} + \text{Y} \longrightarrow [\text{X–M–Y}] \longrightarrow [\text{X–M–Y}] \longrightarrow \text{M–Y} + \text{X} \quad (3)$$

Since coordination positions are available on square-planar complexes from above or below the plane, and the fifth ligand can be added to form an inner-sphere intermediate (activated complex), an associative mechanism is generally observed for ligand substitution of such complexes. In contrast, six-coordinate complexes can form inner-sphere, seven-coordinated intermediates only with difficulty, owing to interligand steric constraints. Therefore these complexes are generally observed to react by dissociative or interchange mechanisms. Because dissociation of M–X is generally rate limiting in the dissociative mechanism, a first-order rate law obtains for such reactions; accordingly, such reactions do not depend on the concentration of nucleic acid. In contrast,

reactions that proceed by an associative mechanism are bimolecular and do depend on nucleic acid concentration.

Ligand-substitution reactions in aqueous solutions rarely proceed directly. Instead, the leaving ligand is first replaced by H_2O, which is present in aqueous solution at a concentration of ~55 M, the entering ligand then substitutes the metal-bound H_2O (M–OH_2) in the so-called anation reaction.[120] Therefore, the rate constant of forward reactions, which could be considered as the *reactivity* of aquo-metal species, will parallel the order of water substitution in the inner coordination sphere of the corresponding metal ions: $Cs^+ > Ba^{2+} > Hg^{2+} > K^+ > Cr^{2+} \sim Cu^{2+} > Na^+ > Sr^{2+}$ $Li^+ > Ca^{2+} > Cd^{2+} > Mn^{2+} \sim Zn^{2+} > Fe^{2+} > Co^{2+} > Mg^{2+} > Ni^{2+} > Pd^{2+} > Pt^{2+} > Cr^{3+}$.[120,170,171] In most cases, the interactions between hydrated metal ions and nucleic acids are fast with $t_{1/2}$ in the range 10^{-9}–10^{-3} sec.[171–174] However, if the limiting step of a substitution reaction is dissociation of a relatively stable bond(s), for example, AMP in the reaction with Pt–Cl[175] or Pt–OH,[176] the rate of this reaction could be quite slow ($t_{1/2}$ up to several hours or even days).

The general factors affecting the ability of coordination compounds to participate in substitution reactions include the nature of the central metal ion, the leaving and entering ligands (e.g. size, charge, nucleophilicity, and basicity), as well as the effects of other coordinated ligands, especially those in *trans* and *cis* positions to the leaving group.[66] The *trans* effect of donor atoms (i.e. the tendency to facilitate substitution in the position *trans* to themselves) has proven very useful for directed synthesis of model metal–nucleic acid complexes, especially in the cases of Pt^{2+}, Pt^{4+}, and Pd^{2+} complexes.

Because of the polyelectrolyte effect (Section 3.1), the rate of metal–polynucleotide reaction to form 'coordinative-covalent' bonds will depend on the positive charge of the metal species; accordingly, the rate can be increased significantly by introduction of additional positive charge to the reagent, for example, $[(NH_3)_2PtCl(H_2O)]^+ \rightarrow [(NH_3)_2Pt(H_2O)_2]^{2+}$. The rates of selected metal–nucleic acid reactions are given in Table 2.

Table 2 Kinetic parameters of selected metal–nucleic acid interactions[a]

System	k_f (M^{-1} s^{-1})	$t_{1/2}$	k_r (s^{-1})
Ni^{2+} + 5′-CMP[b] [171]	1.9×10^5	–	2×10^3
Ni^{2+} + 5′-CDP[b] [171]	6.2×10^5	–	1.8×10^2
Ni^{2+} + 5′-CTP[b] [171]	1.4×10^6	–	5×10^1
Ni^{2+} + 5′-ATP[c] [171]	4.1×10^6	–	$>4 \times 10^4$
Mg^{2+} + 5′-ATP[c] [171]	1.2×10^7	–	1.2×10^3
Co^{2+} + 5′-ATP[c] [171]	9.2×10^7	–	2×10^3
Mn^{2+} + 5′-ATP[c] [171]	$>10^9$	–	$>10^4$
Ca^{2+} + 5′-ATP[c] [171]	$>10^9$	–	$>10^5$
Hg^{2+} + poly(U)[d] [173]	1.4×10^6	–	–
Hg^{2+} + poly(A)[d] [173]	1.2×10^5	–	–
Hg^{2+} + poly(A)·poly(U)[d] [173]	2.7×10^4	–	–
Hg^{2+} + UTP[e] [172]	–	20 min[h]	–
$[Pt(NH_3)_2Cl_2]$ + AMP[f] [175]	9.3×10^{-3}	–	–
$[Pt(NH_3)_2Cl_2]$ + ADP[f] [175]	7.8×10^{-3}	–	–
$[Pt(NH_3)_2Cl_2]$ + ATP[f] [175]	6.3×10^{-3}	–	–
$[Pt(NH_3)_2(H_2O)Cl]^+$ + DNA[g] [176]	2×10^{-3} s^{-1}[g]	6 min[h]	–
$[Pt(NH_3)_2Cl_2]$ + DNA[g] [176]	10×10^{-5} s^{-1}[g]	120 min[h]	–

[a] k_f is the rate constant for the forward reaction and k_r for the reverse one; $t_{1/2}$ is the half-time of the forward reaction. [b] The metal ion concentrations were equimolar and ranged from 10^{-4} to 2×10^{-2} M nucleic acid in 0.1 M KNO_3, pH 6–7, at 15 °C. [c] The nucleotide and metal-ion concentrations were equimolar and ranged from 10^{-5} to 10^{-4} M in 0.1 M KNO_3, pH 5.5–7.5, at 25 °C. [d] The rates of coordination complex formation were determined at 15 °C at polynucleotide concentrations of about 10^{-4} M, $[Hg^{2+}]$/[nucleotide] = 0.25, in 10 mM Na phosphate buffer, pH 5.6–7.0, containing 0.25 M $NaClO_4$. [e] The rate of covalent mercuration of UTP was determined at 50 °C at a nucleotide concentration of 6×10^{-4} M ($[Hg^{2+}]$/[nucleotide] = 6.5) in 0.1 M Na phosphate buffer, pH 6.0, containing 0.25 M $NaClO_4$. [f] The nucleotide concentration ranged from 1.2 to 2.4 mM ([Pt]/[nucleotide] $\leq$ 0.1) in 0.5 M $NaClO_4$, pH 7.0, and 40 °C. [g] The pseudo first-order rate constant for monofunctional binding to N-7 of G in chicken erythocyte DNA was determined at a nucleotide concentration of 0.46 M ([Pt]/[nucleotide] = 0.07) in 1 mM Na phosphate, pH 6.5, containing 3 mM NaCl at 37 °C. [h] Since the half-life for a second-order reaction is dependent on the concentration of the reactants, the significance of these entries is not entirely clear.

4.2 Thermodynamic Stability of Metal–Nucleic Acid Bonds

Consistent with the definition of 'hard and soft' metal ions (*see* ***Hard & Soft Acids and Bases***) based on the nature of the stable complexes that they form with different ligand donor atoms,[170,177] these metal ions behave similarly toward donor atoms of nucleic acids and their derivatives (Figure 8).[178]

'Hard' monovalent cations (M^+) usually interact with nucleic acid polyanions only in a diffuse 'ion atmosphere' manner, whereas 'hard' and 'borderline' polyvalent ($M^{\geq 2+}$) cations can form both outer- and inner-sphere complexes. 'Soft' metal ions tend to form inner-sphere complexes, however. 'Hard' metal ions (class A) prefer O-donor ligands (usually phosphate oxygens), while 'soft' ones (class B) prefer N-donor atoms of the nucleic acid bases as well as S atoms in thio derivatives of nucleic acids (*see* ***Ammonia & N-donor Ligands***; and ***S-donor Ligands***).

The first-row transition metal ions have borderline 'hard–soft' properties. Therefore, there is no simple rule to predict comparative complex stabilities for a given metal ion with the different donor atoms. In contrast, the stability of complexes of these metal ions with a given ligand does follow a general trend. Thus the stability constants for complexes with NTP increase with the metal ion in the order $Co^{2+} < Mn^{2+} < Zn^{2+} < Ni^{2+} < Cu^{2+}$,[49,178] which is the usual Irving–Williams order,[170] except for the reversal of cobalt and manganese. The usual decrease in stability with increasing atomic number is observed for the complexes with metal ions of the alkaline earth series.[21,49] The stability of the

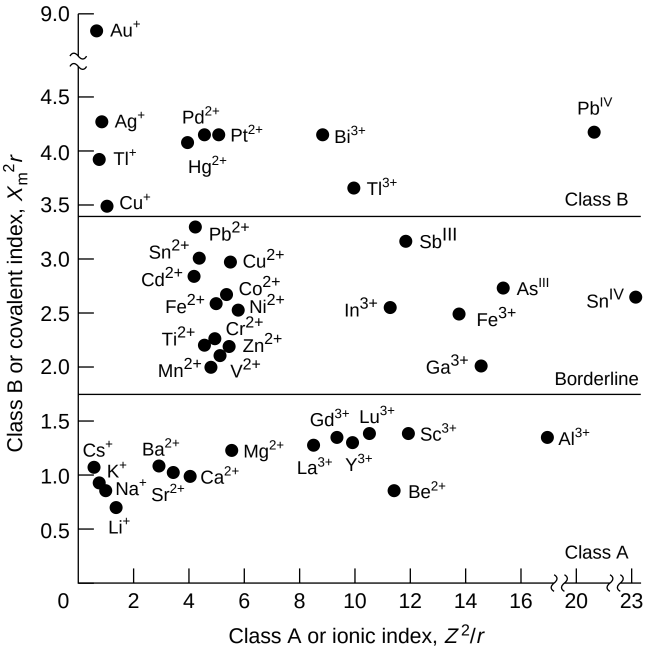

Figure 8 Classification of metal ions according to binding preferences[177]

complexes of these metal ions (other than Cu^{2+}) is largely independent of the nature of the nucleic acid base in NTPs, NDPs, and NMPs because the phosphate groups constitute the most favorable ligands.[115] The small differences in the stability of these complexes has been interpreted as resulting from predominant outer-sphere coordination of the phosphate oxygens to the metal ions.

The tendency to favor N- over O-donors for selected 'hard' and 'borderline' metal ions is in the order $Mg^{2+} \ll Mn^{2+} < Fe^{2+} < Zn^{2+} < Co^{2+} < Cd^{2+} < Ni^{2+} < Cu^{2+}$.[170] Some metal ions in this group preferentially form mixed ternary complexes (involving phosphate oxygens and nucleic acid base nitrogens or oxygens as ligands), which are significantly more stable than those containing only one kind of donor atom.[28]

The relative stabilities of the metal complexes of nucleosides are generally considered to be in the order $G > A$, $C \gg U$, T;[49] however, this order does not obtain universally.[21,42] Thus the relative base affinities of Hg^{2+} and of Pb^{2+} appear to be $T > C > A > G$ and $C > G > A$, respectively.[21,49,179] This difference results from the variety of sites to which metal ions can bind on the nucleic acid bases. Stability constants of the complexes between selected metal ions and nucleic acids (from nucleosides to nucleoside triphosphates) are shown in Table 3.

Metal binding to polynucleotides that exist as duplexes is weaker than to single-stranded or denatured, double-stranded nucleic acids, reflecting the added binding capabilities of unpaired nucleic acid bases. Metal–nucleic acid binding could result in formation of a single bond as well as by chelation, involving multiple bonds between a metal ion and several available, appropriately located nucleic acid ligands. In some cases, one or more of the participating ligands alone may not have a particularly high affinity for the metal ion, but they get bound anyway because of the incremental gain in free energy that can be realized following initial metal-ion binding with more favorable ligands.

Thus Mg^{2+}, which binds only to phosphate oxygen anions in DNA, has a higher affinity for duplex DNA ($K_a = 2 \times 10^5\,M^{-1}$) than species such as Mn^{2+} and Cu^{2+}

Table 3 Logarithms of the stability constants of metal–nucleic acid complexes in aqueous solutions at 25 °C

	Metal Ion

($K_a = 10^4\,M^{-1}$), but a lower affinity than these metal ions (which also bind to nucleic acid bases while Mg^{2+} does not) for single-stranded DNA. In addition, two classes of divalent cation binding sites in tRNA have been reported.[53,185] The first form complexes with stability constants between 2×10^4 and $5 \times 10^6\,M^{-1}$; the second involve weaker complexes with constants ranging from 5×10^2 to $10^4\,M^{-1}$, depending upon experimental conditions. For example, there are four strong and 'intermediate' magnesium-binding sites in yeast $tRNA^{Phe}$ (see Figure 6) as well as about 20 weak ones that still have structure-specific binding sites.[53,54,163,185,186]

4.3 Kinetic Lability of Metal–Nucleic Acid Bonds

In addition to the thermodynamic stability of metal–nucleic acid complexes, the rates at which nucleic acid ligands dissociate from a metal-ion coordination sphere are as important as the thermodynamic stability of the metal–nucleic acid bond.

The relative rates of reaction of the nucleic acid bases with heavy transition metal ions at neutral pH are in the same order as the relative nucleophilicites of the bases, that is G > A > C ≫ U or T.[79] This order parallels the relative rates of reactions for *cis*-$[(NH_3)_2Pt(OH_2)_2]^{2+}$ (see Figure 9), while the equilibrium constants for the same reactions are very close in magnitude.[79] In contrast, H_3CHgOH, which is more labile to substitution, undergoes more favorable binding with deprotonation at N-3 of thymine residues in nucleic acids.[79] Thus the relative facilities of individual reactions can lead to differences in initial product formation (kinetic control). Subsequent changes in the metal–nucleic acid complexes can be under kinetic or thermodynamic control.

The fact that a specific ligand is considered to be kinetically inert does not necessarily mean that the metal complex will persist in solution under ordinary conditions for an indefinite length of time. Clearly, complexes that are both thermodynamically stable and kinetically inert will tend to persist for the greatest length of time. A good example is Pt^{2+}, which forms complexes with nucleic acids containing single Pt–N bonds that are very stable thermodynamically and kinetically inert. Investigations of Pd^{2+} complexes with nucleic acids have been very useful in establishing a thermodynamic baseline for certain Pt^{2+} complexes, which undergo ligand substitution 10^5 times more slowly than the corresponding Pd^{2+} complexes.[170] Owing to the kinetic and thermodynamic properties of platinum complexes (*see* ***Platinum: Inorganic & Coordination Chemistry***), the unforced cleavage (dissociation) of a Pt–N bond with a nucleic acid base is not expected within a reasonable time (e.g. 100 h at 37 °C).[33] In comparison, the lifetime for Mg^{2+} bound to DNA is ≈ 4 ms at room temperature.[187] Indeed, the rate of ligand exchange is about 10^3 times slower for Mg^{2+} than for Ca^{2+}, and increases in the order $Ni^{2+} < Mg^{2+} < Co^{2+} < Fe^{2+} < Mn^{2+} < Zn^{2+} < Ca^{2+}$.[171] Mn^{2+} forms thermodynamically stronger complexes than Mg^{2+}, especially when nitrogen is a ligand or with multidentate ligands, but undergoes ligand exchange about 100 times faster than Mg^{2+}.[171]

Complexes of platinum group metals, which are more substitution labile than platinum, can undergo isomerization, which involves cleavage of the N–metal bond formed initially under kinetic control, and formation of a more thermodynamically stable complex. For example, $[(dien)Pd]^{2+}$ migrates from N-7 to N-1 in A and from N-3 to N^4 in C; likewise $[(NH_3)_5Ru]^{2+/3+}$ moieties migrate from N-1 to N^6 in A and from N-3 to N^4 in C.[33] Adenosine is of special interest, because both highly reactive donor atoms N-1 and N-7 are unprotonated at neutral pH and available for metal binding, in contrast to the situation in guanosine. In spite of the fact that N-1 of A is intrinsically 320 times more basic than N-7, the ratios of stability constants, $[M,\text{ N-1}]/[M,\text{ N-7}]$, for protons and selected metal ions have been determined as follows: $H^+(320) \gg [(dien)Pd]^{2+}(4) > Ni^{2+}(3) \geq Cu^{2+}(2.5) > Zn^{2+}\,(1)$.[32]

In the presence of millimolar concentrations of stronger nucleophiles such as CN^- and thiourea for Pt^{2+} complexes, or molar concentrations of Cl^- for Hg^+ complexes, nucleic acid base substitution takes place. However, steric constraints can lead to surprising inertness, as demonstrated for N-3-platinated T and U.[33] In contrast to coordination bonds of Hg^{2+} to heterocyclic N-atoms of nucleic acid bases, the covalent bond of mercury ion to C-5 of pyrimidines (*see* ***Mercury: Organometallic Chemistry***) is stable even in the presence of 1 M NaCl.[172]

4.4 Coordination Numbers and Geometry of Metal–Nucleic Acid Complexes

Most compounds containing metal–nucleic acid bonds are *Coordination Complexes* (*see* ***Coordination Numbers & Geometries***),[170] in which a central metal cation is bound (or coordinated) to a number of donor atoms that contain electron pairs (e.g. N, O, or S). In addition to the nucleic acids, many simple or sophisticated, negatively charged or neutral ligands can be bound to the same central metal ions. Water and hydroxyl anion also act as ligands (*see* ***Water & O-donor Ligands***). The total charge carried by

the coordination complex, being the sum of the charges possessed by a metal cation and its ligands, depends on the mode of binding (e.g. with or without proton dissociation or substitution in a nucleotide ligand) and pH, because of the ability of coordinated ligands to undergo deprotonation. The known coordination complexes of transition metals with nucleic acid constituents far outnumber those of the A group metals such as Na^+, Mg^{2+}, or Ca^{2+}.

Metal binding to the nucleic acid bases may formally be considered in terms of number of bases N bound per metal M ($n = N/M$, e.g. $n = 4$, 3, 2, 1, or less for Pt^{2+}) (Table 4). While the maximum number of nucleic acid bases that can be bound by single bonds to the metal ion is given by its nominal coordination number (values 2, 4, and 6 are the most common), low n values in multinuclear complexes can result from the binding of more than one metal at separate donor atoms in a single nucleic acid base.

Despite the fact that metal cation binding to a neutral nucleic acid base usually reduces its overall basicity (proton affinity),[33] this effect is not sufficient to prevent attachment of more than one metal species per nucleic acid base in the presence of an excess of the metal species. An example is the diplatination of G (via atoms N-7 and N-1) (Table 4). The N-1 atom in purine nucleosides and nucleotides is frequently identified as a binding site in solution, in spite of the fact that it has been documented less frequently in X-ray structural studies.[29] In N-7-platinated guanosine, the acidity of the N-1 proton is increased from pK_a 9.3 to pK_a 7.8,[188] thus making the N-1 site more susceptible to additional metal binding at neutral pH. Pt^{2+} behaves similarly to many other transition metals in this respect.[34] It is also possible that a coordinated metal may increase the basicity of a nucleic acid base through charge back-donation from the metal into the heterocyclic ring.[33] For example, substitution of the protons at N-1 and N-7 of G as well as N-3 of U or T by Pt^{2+}, having a smaller polarizing effect relative to H^+, actually increases the basicity of atoms N-3 in diplatinated G and O^4 in monoplatinated U or T. As a consequence, an additional metal ion can be bound to these sites, leading to a large class of multinuclear complexes, for example, triplatinated G.[33] Formation of multinuclear complexes with the participation of exocyclic amino groups has been observed for complexes of 1-methylcytosine and H_3CHg^+ or $Pt^{2+/4+}$; the metal–N bonds are formed in a condensation reaction between a M–OH moiety and an amino proton. The increased metal affinity of singly metalated base anions was also found for some heteronuclear metal complexes, for example, for Pt^{2+} and Ag^+ bound to 1-methyluracil.[33]

The coordination number and geometry of complexes (Table 1) is thought to be dictated by the valency (i.e. oxidation state of the central metal ion – also see Section 4.5), the number of electrons possessed by the metal to be shared with ligands, the relative sizes of metal ions and ligands, as well as symmetry considerations.[120] Small metal ions and large ligands favor low-coordination numbers and vice versa.

Consistent with the assumption that ligands repel one another, they tend to separate from each other spatially in a fashion that minimizes ligand–ligand repulsion, while remaining bound to the central metal ion.[170] Accordingly, two unidentate (i.e. having one donor atom) ligands should give rise to a linear arrangement, four to a tetrahedral arrangement, and six to an octahedral arrangement. Most metal complexes conform to these geometries, but there are also many exceptions (Table 1), which are believed to result from interligand nonrepulsive interactions and chelation geometry. In particular, the metal ions of Groups 8–11 of the periodic table often form square planar, rather than tetrahedral, complexes (Table 1). Some four-coordinate Ni^{2+} and Cu^{2+} complexes are tetrahedral, others are planar. In six-coordinate Cu^{2+} complexes, four ligands are strongly bound in square-planar geometry, while two weakly coordinated ligands (with longer internuclear distances) occupy axial positions that result in overall pseudooctahedral geometry of such complexes.[170]

There are some correlations between coordination number of metal ions (as well as geometry of the derived complexes) and metal-binding site in nucleic acid bases. Unhindered donor atoms (e.g. N-7 of purines) can be involved in octahedral complexes, while atoms that are in sterically hindered environments (e.g. N-3 of C, which is adjacent to the bulky N^4H_2 and O^2 groups, or N-1 of A, which is influenced sterically by the adjacent N^6H_2 substituent) prefer to form complexes in which the metal ion has coordination numbers of four or two.[27]

Strong binding between metal ions and ligands precludes their exchange and permits the resolution of geometric isomers: *cis*, in which the relevant ligands are adjacent to each other, and *trans*, in which the ligands are opposed. The dependence of metal–nucleic acid reactions on the geometrical arrangement of ligands about the metal ion is important when the reaction results from substitution of labile

ligands with retention of inert ones.[189] These requirements are met in the case of the reactions of the isomers of $[(NH_3)_2PtCl_2]$, in which only Cl^- ions are substituted, and the bond positions available for nucleic acid base binding are 90° apart in the *cis* isomer and 180° apart in the *trans* isomer (see Figure 9). Geometrical isomers would also be formed as a result of the interaction of $[PtCl_4]^{2-}$ (see Figure 9) with nucleic acid bases because the reactivity of a Pt–Cl bond is strongly dependent on the nature of the ligands in the *trans* position.[189]

4.5 Oxidation State of Metal Ions in Complexes with Nucleic Acids

A metal oxidation state of a metal ion usually does not change as a result of binding to nucleic acids; however, there are some exceptions for the metals in high oxidation state (see below). Some metal ions in nonstable oxidation states can be stabilized in complexes with nucleic acids; examples include $[Cr^{3+}–ATP]$,[190] $[Co^{3+}–tRNA]$,[191] and $[Cu^{+}–DNA]$.[192] Metal ions at higher oxidation states are usually stabilized by 'hard' ligands, those at lower oxidation states by 'soft' ligands (see above and ***Hard & Soft Acids and Bases***).[38] Following coordination to a nucleic acid, certain metal ions having more than one oxidation state could be oxidized (e.g. tRNA-bound Co^{2+} was oxidized to Co^{3+})[191] or reduced (e.g. DNA-bound Cu^{2+} was reduced to Cu^{+}, and bound Fe^{3+} was reduced to Fe^{2+})[192] under mild conditions without obvious alteration of the binding sites or integrity of the nucleic acid. However, the oxidation of $[(NH_3)_5Ru]^{2+}$ bound to DNA via N-7 of G[193] as well as of Cu^{2+} and Fe^{2+} bound to DNA or RNA resulted in site-specific modification and cleavage (also see Section 7) of the bound nucleic acids, presumably by generation of reactive oxygen species.[166,194–197]

The oxidation state of some metal ions can be reduced as a result of binding to nucleic acids. For example, certain complexes of Pt^{4+} species attached to purine residues of DNA underwent reduction to Pt^{2+} without direct damage to the platinated DNA.[43] However, complexes of Pt^{4+}, which are stable in high oxidation states, can act as alkylation agents. These complexes kinetically prefer binding at the N7 atom of guanine residues. A transfer of positive charge from the metal cation to the platinated guanine residue results in the formation of abasic sites that could be determined by the site-specific cleavage of DNA via a β-elimination reaction.[166,198] Interestingly, the guanine platination and formation of the abasic sites is highly specific for single-stranded DNA and does not occur in duplexes. In contrast, the complexes of Pt^{2+}, which have substantially less electron acceptor capacity than Pt^{4+}, cannot promote the oxidative removal of guanine residues.[199]

Amino complexes of Ru^{3+}/Ru^{4+} act similarly to their platinum relatives, Pt^{2+}/Pt^{4+} (*see* ***Ruthenium: Inorganic & Coordination Chemistry***). Although coordination of $[(NH_3)_5Ru]^{3+}$ to N7 of guanine residues in DNA does not promote efficient depurination, after disproportionation of Ru^{3+} the corresponding complex of Ru^{4+} is able to carry out this reaction.[200] Base-specific N7-guanine modification by tetramine-Ni^{2+} complexes in the presence of $KHSO_5$ also results in Ni^{3+}-mediated oxidative guanine alkylation and removal of the modified guanine residue.[196] A possible 'template' role for nickel ions is to bridge guanine and oxidant species. This reaction is also highly specific for single-stranded or mismatched regions in polynucleotides, and has been successfully used as a structural probe for both DNA and RNA molecules.[196]

Reaction between DNA/RNA and MnO_4^- or OsO_4^{2-}, where the formal metal oxidation states are Mn^{7+} and Os^{6+}, results in base-specific modification of thymidine/uridine residues. These anionic metal species can oxidize the pyrimidine C5-C6 double bond, which results in formation of *cis*-5,6-dihydroxy-5,6-dihydro-pyrimidine.[96] This reaction is followed by opening of the pyrimidine ring and its subsequent removal from the polynucleotide chain. Permanganate can also oxidize and remove guanine residues (but not adenine) while osmium tetroxide acts much more specifically on pyrimidine residues with the following kinetic preferences (relative rates shown in parenthesis): $T\ (45) \gg U(4.5) > dU(2.8) > C(1.8) > dC\ (1)$.[96] The relatively bulky permanganate and osmium tetroxide anions are very sensitive to secondary structure and react preferentially with pyrimidines in single-stranded regions, single-base mismatches, bulges, loops, unstacked nucleobases in four-way junctions, curved $(A\text{-}T)_n$ tracts, B–Z and Z–Z junctions, H-DNA, and premelting of AT-rich sequences in supercoiled DNA.[201,202] This feature makes them very useful probes for detection of local distortions in DNA molecules under different conditions and upon binding of other molecules including small drugs and proteins.

5 METAL-BINDING MODES AND STRUCTURE OF METAL–NUCLEIC ACID COMPLEXES

5.1 Problems in Relating Crystal Structures and Solution Composition

Most available (and most detailed) information on the mode of metal binding to nucleic acid molecules is provided by X-ray structural studies. Until recently, diffraction-quality crystals of nucleic acids with bound metal ions were generally obtained most readily for molecules of limited size (from nucleosides to oligonucleotides).[30,37,60,64,137,203] Interestingly, crystallization of metal complexes with nucleotides and oligonucleotides was generally found to be more facile relative to the nucleoside complexes, which may be attributed to several factors including (1) the lower stability generally observed for nucleoside complexes, (2) the presence of the phosphate group(s) in (oligo)nucleotides, which can compensate for the charge of the metal ion and thereby facilitate crystallization of the complexes as neutral species, and (3) the greater

opportunity for hydrogen bonding between water molecules coordinated to metal ions and the phosphate oxygen anions, thereby supporting specific intra- and intermolecular contacts in the crystals.[30] Newly developed techniques can now provide crystallization of large RNA from ribozymes[55,204,205] to subunits of ribosomal RNA,[206] allowing the study of structures of biological metal binding inside these RNA structures.

X-ray crystallographic analyses usually provide structural information that correctly represents the actual structures of metal ion–nucleic acid complexes in the crystal; this usually represents an environment that is drastically different from normal solution conditions. Obviously, such analyses are limited to complexes that are both stable and amenable to crystallization.[37] In comparison, solution NMR spectroscopy data are much more generally applicable to the analysis of metal ion–nucleic acid structure,[53,84,148,207] but can be more easily misinterpreted owing to factors such as the distribution of metal ions among several binding sites and the intrinsically weaker nature of some of the interactions that are studied. Also, nucleic acid crystallization requires the formation of ordered and uniform intermolecular interactions between nucleic acids.[208,209] These intermolecular interactions may either compete or interfere with the formation of certain metal–nucleic complexes and promote the formation of unnatural metal binding centers.[210]

Often, more than one structure of a metal–nucleic acid complex of a given nucleic acid will exist in solution at the same time, and these complexes may well be in dynamic equilibrium.[36,37] When multiple complexes are present, crystals are less likely to form; there are, for example, a dearth of examples of crystalline ambidentate isomers that have been characterized structurally. In principle, some of these isomers could be isolated as discrete species and crystallized separately, but this is possible only for thermodynamically stable and kinetically inert complexes. Therefore, the definition of the mode of binding of metal species to nucleic acids is usually very difficult, since many complexes of (biological) interest lack sufficient stability to permit their study as single species. Conditions favorable to crystal growth include high concentrations of the species of interest and also of organic solvents (and, therefore, low hydration) that can facilitate crystallization. Because both the specific intermolecular contacts in the crystals and the special environment from which the crystals are produced do not ordinarily exist in solution, some atom–atom interactions determined by X-ray crystallography may not occur in dilute aqueous solution where binding to (or through) water molecules would predominate.[210] For example, in solid-state structures, the formation of polymeric species in which each metal ion is bound to two or more nucleotide ligands is a common phenomenon. The relevance of such structures to solution geometry is also unclear. Likewise, in the highly concentrated solutions needed for crystal formation the pH, which can dramatically affect the mode of metal-ion binding, is generally not well controlled and could also change as a result of metal ion–nucleic acid interactions. Also, the low water activity inside the crystals of nucleic acids may promote formation of unusual direct (inner-sphere) bonds between dehydrated metal ions and nucleic acids. For example, in crystals, even monovalent ions (such as Li^+, Na^+ and Tl^+) can exhibit direct coordination with nucleobases and ribose residues.[24,211] Such interactions do not normally occur in dilute solutions.[37,103,212]

Interestingly, specific M^{2+}–nucleic acid interactions determined in solution for the hairpin ribozyme by spectroscopic and chemical interference methods were not later found in their X-ray crystal structures.[127,213] Even more confusing were results of X-ray crystallography[214,215] and initial solution experiments,[216–218] which both determined up to two, presumably functionally important Mg^{2+} ions in the catalytic center of the hammerhead ribozyme. However, as demonstrated recently in biochemical experiments in solution, neither of these ribozymes require either inner- or outer-sphere interactions with particular metal ions for catalysis.[56,57,219,220]

All of these factors dictate that great care must be exercised in relating well-defined crystal structures to the predominant structures that exist in solution.[30] Moreover, it is important to remember that there is a wide range of microenvironments present *in vivo*, each of which would also be expected to affect the metal–nucleic acid interactions in a fashion (superficially) analogous to a specific solvent or the absorption of the metal ions to a particular surface.[221]

5.2 Suggested Classification of Metal–Nucleic Acid Binding

According to the number of labile ligands bound to a metal ion that can be substituted by donor atoms of the nucleic acid ligand, metal species (ions and compounds) may be classified as *mono-, bi-, tri-, or multifunctional* reagents, up to the maximum limited by the metal coordination number.[40] Monofunctional attachment of a metal reagent to a nucleic acid is often followed by multifunctional binding, *chelating*, or *cross-linking*, which may occur both *intramolecularly* and *intermolecularly*. Since, in the initial monofunctional adduct, the effective local concentrations of the resulting metal species and the next potential ligand(s) can be very high (up to a few moles per liter), the rate of subsequent reactions can be much higher than the initial reaction where an associative mechanism is involved. The acceleration does not occur if a dissociative mechanism of ligand substitution obtains or if potential donor atoms are either not sterically accessible or not situated favorably.

5.3 Metal Binding to Nucleic Acid Bases

5.3.1 *Monofunctional Binding*

Monofunctional metal–nucleobase bonds constitute the usual mode of metal binding to nucleotides and

polynucleotides. Most known metal-binding modes involve derivatives of nucleic acid bases in which chemically unreactive groups are attached to pyrimidine N-1 and purine N-9 atoms to mimic the N-glycosyl bond. This results in nucleic acid base models that behave in a fashion reasonably similar to that of the actual naturally occurring nucleosides, at least at the level of metal coordination to the heterocyclic bases. In contrast, metal-ion binding to free nucleic acid bases often gives products that are more complex and may bear less relevance biochemically. Despite obvious limitations, work with nucleic acid base models is meaningful in that fundamental questions such as binding patterns and ligand rotation processes may be studied conveniently.[25,42,48]

'Pure' monofunctional, inner-sphere binding to metal species usually obtains only when some chemical or structural restriction applies. Binding of this type generally results from (1) the use of monofunctional metal reagents having only one labile ligand, for example, $[(dien)PtCl]^{2+}$, $[(NH_3)_5RuCl]^{2+}$, and H_3CHgOH;[26] (2) transformations carried out at low pH, where additional metal-binding sites are 'blocked' via protonation;[32] or (3) modification of highly reactive S atoms in thio-substituted nucleic acid bases, for example, 6-thio-G and 4-thio-U.[79]

The mercury complexes of neutral uracil and dihydrouracil, the latter being a minor base found in tRNAs, reveal an unusual mode of coordination, wherein Hg^{2+} is bound not to the endocyclic N-3, which is blocked by a proton, but rather to the exocyclic atom O^4, which is a stronger donor atom than O^2.[222,223] The 'usual' binding to N-3 of deprotonated U and T residues proceeds slowly in buffered solution at neutral or slightly alkaline pH with heavy metals (e.g. in reactions with H_3CHgOH, Hg^{2+}, or Pt^{2+} species).[223] Although both purine and pyrimidine bases can form coordination bonds with mercury ion, U and C alone can form covalent bonds between C-5 and Hg.[172]

The rare nucleic acid base tautomers, ordinarily present to the extent of ~0.01% relative to the preferred tautomers, can be stabilized by metals via coordination of lone-pair electrons. For example, the 4-imino-2-oxo tautomer of cytosine has Pt^{4+} bound to its N^4 group, while the 4-hydroxy-2-oxo tautomer of U and T bases is platinated at N-3.[33]

5.3.2 *Bifunctional Binding*

The study of intrabase chelation can be effected most readily using model compounds that lack additional binding sites. Such intrabase chelates are usually obscured by the formation of 'macrochelates' in nucleotides and polynucleotides involving phosphates or neighboring nucleic acid bases. Such intrabase chelates may, nonetheless, sometimes be of importance biochemically.

Direct (inner-sphere) chelates involving donor atoms of the nucleic acid base heterocycles have only been observed for complexes of $[bis(cyclopentadienyl)Ti^{3+}]$ with derivatives of guanine (involving atoms N-7 and O^6), xanthine (N-1, O^2), and theophylline (N-7 and O^6), as well as for a complex of Pt^{4+} and 1-methylcytosine (N-3 and N^4).[33] In these chelates the angles about the metals can deviate strongly from the normal 90°, which implies considerable variation of the geometry of metal-centered chelate rings. For both Cu^{2+} and Hg^{2+} there is also evidence of binding to cytosine via a strong bond to N-3 and a weaker one to the O^2 carbonyl oxygen.[25]

As demonstrated for the 1-methylcytosine chelate, nucleic acid base deprotonation can be achieved intramolecularly under mild conditions by a Pt–OH group already coordinated via N-3. Similar reactions might be anticipated for a large series of metal–nucleic acid base complexes, including chelates of adenine (N-1 and N^6) and guanine (N-1 and N^2 or N-1 and O^6).[33] However, the existence of a (N-7 and O^6) chelate of guanine and *cis*-$[(NH_3)_2Pt]^{2+}$, whose possible role as a key DNA adduct in the mechanism of antitumor action of *cis*-diclorodiammineplatinum has been controversial for some time and has not yet been proven unequivocally (*see* ***Platinum-based Anticancer Drugs***).[33,47] In contrast, there are reliable data that 6-mercaptopurines bind soft metal ions such as Pd^{2+} and Cu^{2+} via both N-7 and S^6 atoms.[25]

5.4 Metal Binding to Nucleosides, Nucleotides, and Polynucleotides

5.4.1 *Metal–Ribose Binding*

There are only a few complexes known in which the ribose hydroxyl groups are involved in coordination to metal ions.[27,42] One of these is the bis(pyridine)osmate ester of adenosine, in which Os^{6+} chelates adenosine through deprotonated 2′- and 3′-OH groups; another is polymeric $[Cd_2(5'\text{-IMP})_3(H_2O)]_n$, in which one Cd^{2+} ion binds simultaneously to N-7 of one IMP molecule and to the protonated 2′- and 3′-OH groups of another IMP. These compounds may be considered somewhat atypical since they are prepared using extreme conditions. However, the complexes of VO_2^{2+} and 5′-ATP, the solution structure of which is pH dependent (Figure 10), includes bonds to the protonated 3′-OH group (at pH 3) or to the deprotonated 2′- and 3′-hydroxyl groups (at pH 7–12).[224] For Cu^{2+} the chelation of ribose *cis* hydroxyl groups in nucleosides has been detected only in solution owing to difficulties encountered in crystallization of the complexes.[29] One can speculate that RNA tertiary structure could favor inner-sphere coordination of a metal ion to the 2′-OH group, in spite of its intrinsically low affinity for metal ions, by the appropriate arrangement of potential ligands in specific metal-binding pockets.[218]

5.4.2 *Intranucleotide Chelation*

In reflection of the fact that the purine N-7 is the most favorable metal-binding site in nucleic acids, a number of different metal chelate structures involving this atom can be formed with purine nucleoside 5′-phosphates.[34,42] This

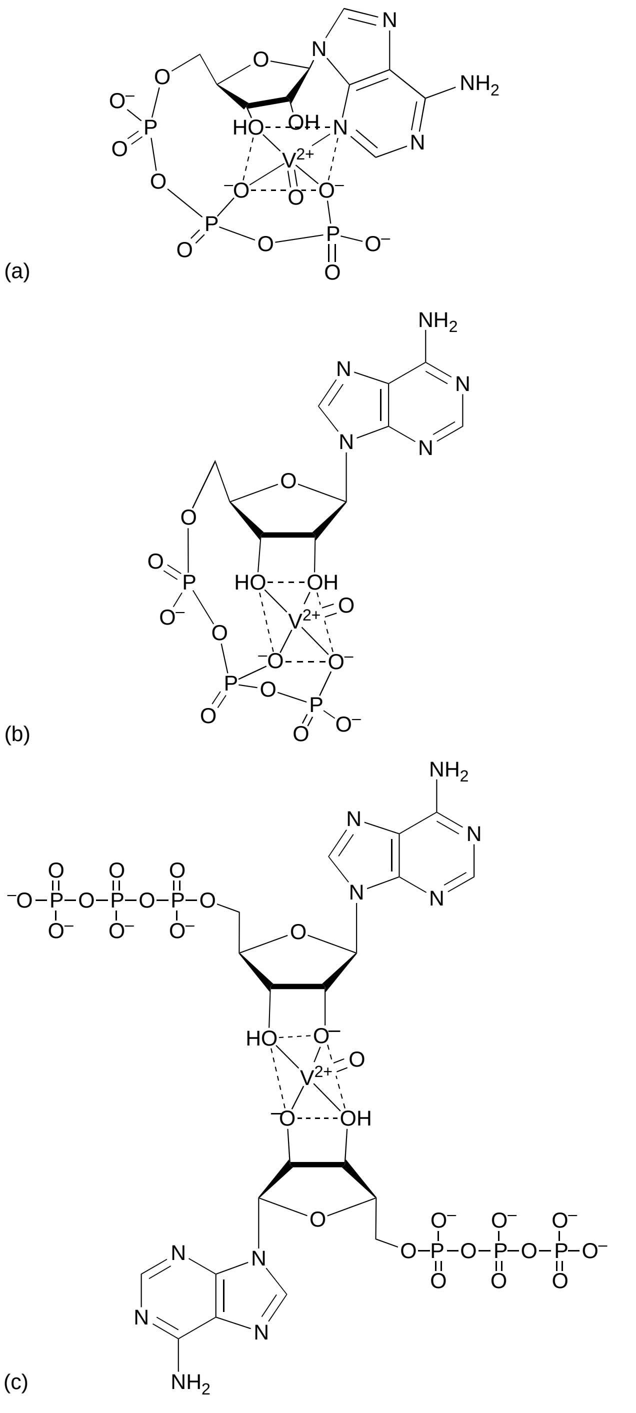

Figure 10 Possible structures of three types of ATP–vanadyl complex: (a) 1:1 complex at low pH, (b) 1:1 complex at neutral pH, (c) 2:1 complex at high pH[224]

includes chelates in which the metal ion participates in (1) inner-sphere binding to both the N-7 atom and phosphate group (Figure 11a); (2) inner-sphere binding to the N-7 atom and outer-sphere binding, that is, via water, to the phosphate group (Figure 11b); (3) outer-sphere binding to the N-7 group, but inner-sphere binding to the phosphate

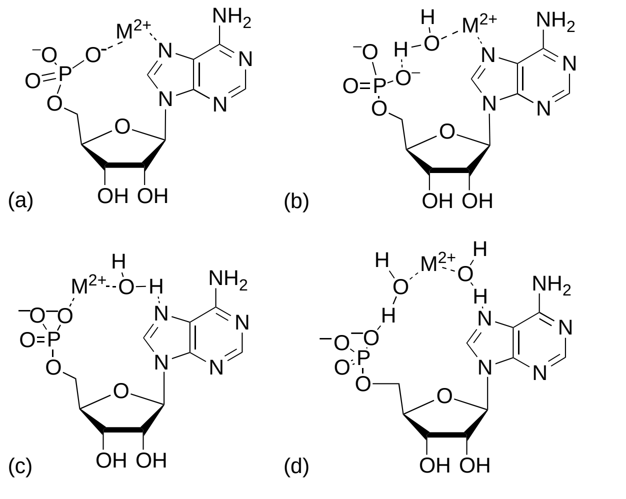

Figure 11 Four types of metal complexes involving N-7 of purine nucleosides[34]

group (Figure 11c); and (4) outer-sphere binding to both sites (Figure 11d). The proportion of complexes having these structures will differ for individual purine residues and metal ions. For example, inner-sphere binding has been confirmed for [*cis*-$(NH_3)_2$Pt(GMP)] and [$(\eta^5$-$C_5H_5)_2$Mo(dAMP)] and predominates for [Cu(GMP)$(H_2O)_4$] and [Ni(AMP)$(H_2O)_4$], where molybdenum is tetravalent and the other metal ions are divalent.[34,35] [Ni(IMP)$(H_2O)_5$] is representative of the largest class of structures that bind to N-7 via an inner-sphere mechanism and to the phosphate group via an outer-sphere mechanism.[34,35] For complexes of GMP and Mg^{2+}, Ca^{2+}, Sr^{2+}, or Ba^{2+}, the most probable structures involve inner-sphere binding to the phosphate group and outer-sphere binding to N-7.[34,35] Chelates involving outer-sphere binding to the N-7 and phosphate groups are probably best exemplified for the alkaline earth elements.[34,35,103]

In contrast to the relatively simple structures incorporating one of the first three binding motifs, the polymeric complex [Cu_3(5′-GMP)$_3(H_2O)_8]_n$ has three distinct coordination environments about different Cu^{2+} ions.[225] While this complex is unusually sophisticated, the polymeric nature of the material is common for many metal complexes with GMP or IMP, in which inner-sphere binding occurs to both the N-7 atom and phosphate oxygens of a single nucleotide residue, but does not involve the same metal ion.[29] As described in Section 5.5, there are also unusual structures (‘open complexes’) of Cu^{2+} species and GMP, which involve only inner-sphere metal binding to the phosphate group.

The anti conformation preferred by the adenine residue in 5′-AMP (Figure 1b) disposes this nucleotide to simultaneous inner-sphere binding of metal ions both to the phosphate oxygen and N-7 atoms. As would be expected, neither 2′- nor 3′-AMP (Figure 1c) is able to participate in forming the same type of complex for steric reasons. As was shown in experiments involving Mg^{2+}, Mn^{2+}, Cd^{2+}, Co^{2+}, and Cu^{2+},

intramolecular interactions of a phosphate-coordinated metal ions are possible for all three positional isomers of AMP, but the stability of these bonds decreases in the order 5′-AMP > 2′-AMP ≫ 3′-AMP (see Table 3).[34,35] Perusal of the structures shown in Figure 1 illustrates the fact that the most likely candidate for an additional binding site is the N-3 atom in both the anti conformational isomer of 2′-AMP and the *syn* isomer of 3′-AMP, although chelates involving the adjacent 3′-OH (or 2′-OH) groups might also exist.[34,35]

The results of model building suggest the probable formation of different chelates for purine nucleoside 5′-di- and triphosphates (Figure 1c). Inner-sphere coordination of the N-7 nitrogen and both the β- and γ-phosphate oxygens makes direct coordination of the α-phosphate oxygen improbable, but this group is coordinated via outer-sphere binding.[34,35] Potentially, there are many different combinations of inner- and outer-sphere bonds that are possible for metal–NTP complexes, involving both participation of heterocyclic donor atoms and for phosphate groups alone.[19,34,35,226] Metal binding to the α- and β-phosphate oxygens also creates new chiral centers and can lead to the formation of diastereomeric complexes.[227] One particularly interesting complex, derived from VO^{2+} and ATP, contains inner-sphere bonds to the metal ion V^{4+} and also involves all three structural components of the nucleotide, that is, the N-3 atom of the nucleic acid base, the β- and γ-phosphate oxygens, and the 3′-OH group of ribose (Figure 10a).[224]

Metal complexes of pyrimidine nucleotides have been studied much less intensively than those involving purines, undoubtedly reflecting the weaker coordination ability of the pyrimidine N-3 atom, relative to atoms N-7 and N-1 of purines. Nonetheless, the principal structures of such complexes have been determined.[27,29,42,50] Some of these are described below.

Although inner-sphere coordination of both N-3 and phosphate has been documented for at least four metal–5′-CMP complexes (involving Pt^{2+}, Co^{2+}, Zn^{2+}, and Cd^{2+}), dimeric $[(en)Pt(5'\text{-CMP})]_2 \cdot 2H_2O$ is the only example of a nonpolymeric complex in which the metal ion (Pt^{2+}) is bonded to N-3 of one CMP and to the phosphate oxygen of another.[27]

In the structure of the polymeric complex of Mn^{2+} and 5′-CMP, an unusual cytosine inner-sphere coordination complex has been demonstrated involving O^2, rather than N-3, as well as four phosphate oxygen atoms of three different nucleotides and one water oxygen atom.[50] Thus, in the case of CMP binding, it seems clear that O^2 can act as a significant metal-binding site alone, or together with N-3 in chelate structures.

Exclusive binding via phosphate oxygens at neutral pH, including both inner- and outer-sphere modes, has been documented for dimeric complexes of Cu^{2+}, as well as polymeric complexes involving Co^{2+} and 5′-UMP.[27]

Many enzymes use [Mg–NTP] complexes as substrates and effectors, where the Mg^{2+} is coordinated exclusively to the oxygens of the triphosphate group forming mono-, bi-, and tridentate complexes.[114] In solution, Mg^{2+} can be replaced by several other metal ions in these complexes with NTPs and their thiophosphate analogs. The alternatives include both soft (e.g. Cd^{2+}) and intermediate (e.g. Mn^{2+}, Co^{2+} and Zn^{2+}) metal ions that, in contrast to the hard Mg^{2+} ion, can chelate both through O and S atoms.[227] The preference for O relative to S coordination in the complexes is estimated to be about 3×10^4 for Mg^{2+}, 3×10^3 for Ca^{2+}, and 2×10^2 for Mn^{2+}. In a similar complex, Cd^{2+} is bound to S atom 60-times more strongly than to O atom.[228] These differences are reflected in the structural nature of the metal-ion complexes formed with ligands such as ATPβS (Figure 12a).

The S_p and R_p stereoisomers of the nonbridging phosphorothioate group also provide the wherewithal for different modes of metal binding (Figure 12a,b). The positions of the phosphorothioate groups (α, β, or γ) (Figure 12c) affect both the stability of the formed M–S bonds (e.g. there is a

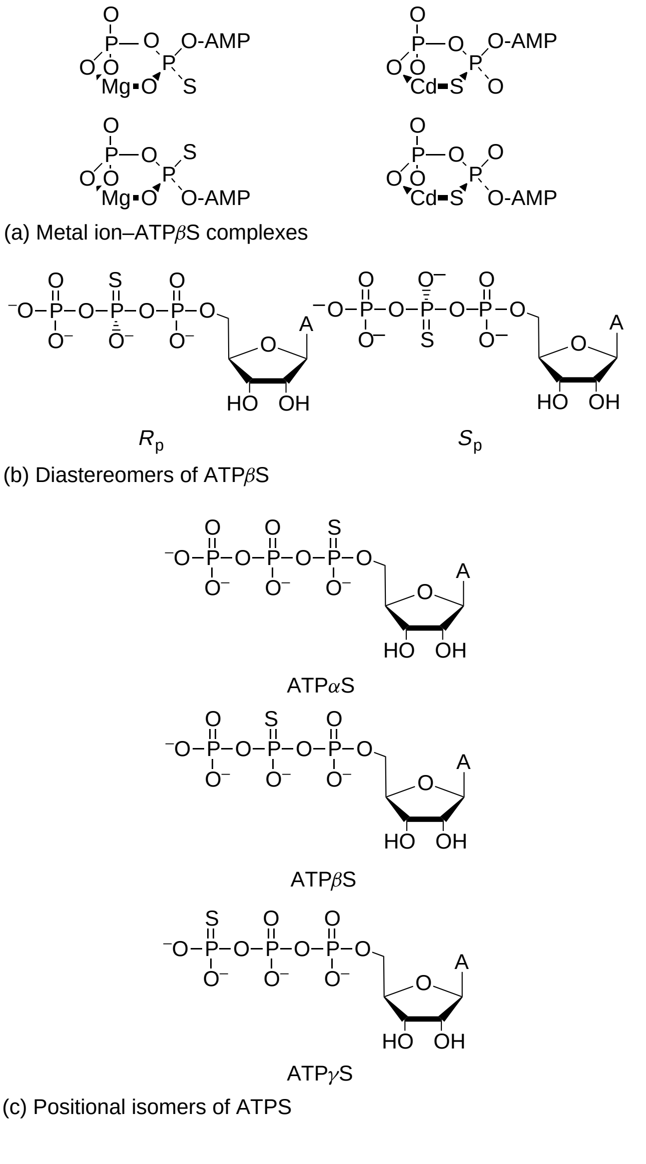

Figure 12 Structures of S analogs of ATP and representative metal complexes[227]

10-fold lower preference for Cd–S interaction in ATPαS as compared to ATPβS[227]) and the type of coordination. Thus complexes of Cd^{2+} with ATPαS, in contrast to those with ATPβS, do not include inner-sphere coordination of atom N-7, because of favorable α, β, γ-phosphate tridentate chelation.[228] In fact, the release of inner-sphere N-7 in complexes involving Zn^{2+} or Cd^{2+} and ATP upon addition of a second ligand, L (e.g. imidazole, NH_3, or OH^-), to form $[M(ATP)(L)]^{2-}$, suggests that N-7 coordination is the 'weak' point in such macrochelates.[34,35]

In contrast to phosphate oxygen atoms, the negative charge in the phosphorothioate is largely localized on the more polarizable sulfur.[229] Hard divalent metal ions (e.g. Mg^{2+}) prefer to bind only the phosphorothioate oxygen, whereas softer metal ions, for example, Co^{2+}, Mn^{2+}, and Zn^{2+}, can bind (chelate) both oxygen and sulfur, while Cd^{2+} ions have stronger affinity toward sulfur (*see* ***Hard & Soft Acids and Bases***).[228,230] The difference in affinity of these metal ions toward phosphorothioate O and S atoms (both bridging and nonbridging S_p or R_p stereoisomers) have been used in 'rescue' experiments to determine whether direct interaction of a particular phosphate oxygen(s) with the metal ion(s) is essential for promotion of the specific RNA cleavage, and the stereochemical course of the cleavage reaction.[231–236]

5.4.3 *Internucleotide Binding: Intra- and Interstrand Cross-linking*

Different types of bifunctional binding of metal species that form bridges between two base residues in single- and double-stranded nucleic acids have been identified. There are two main types of interbase binding. In the first, the metal ion is bridging two bases in the same (intrastrand cross-linking) in ether single- or double-stranded polynucleotides. In other words, the metal ion is bound bi-functionally to nucleic acid bases, which are not in the same plane as the metal ion. The *cis* orientation of labile ligands in the coordination sphere of a bifunctional metal reagent is more favorable to intrastrand cross-linking of DNA than the corresponding *trans* isomer.

It has been suggested that Cu^{2+}, bound to duplex DNA in a nondenaturing fashion, may afford a charge-transfer, π-complex between adjacent purines on the same strand, with the purine aromatic ring playing the role of donor and the metal ion acting as the acceptor.[22] A recent model of interstrand binding of one Cu^{2+} ion between adjacent GC pairs has also been described.[237] This type of binding between metal ions and nucleic acid bases has also been proposed for Ag^+ and Fe^{2+}.[125]

In the second type of internucleotide binding, the metal ion acts as a bridge between two bases that belong to opposite strands paired in a double helix. The 'bridging' process is favorable for ions able to form stable, linear chelates (e.g. Ag^+, Cu^+, Hg^{2+}, and Au^{3+}).[238,239]

To form interstrand or intrastrand bonds in a duplex, a mononuclear metal species has to open (form internal loop) or bend the duplex structure. In contrast, dinuclear metal reagents with sufficiently long bridging groups connecting the reactive metal centers may be able to cross-link complementary polynucleotide strands without denaturation.[240–243] Owing to the presumed biochemical significance of metal-mediated cross-links in nucleic acids, numerous model complexes with nucleic acid bases,[25,48] synthetic oligonucleotides, and polynucleotides[43,238,239,244] have been characterized in detail.

Most of the data concerning bifunctional binding to nucleic acids involve platinum reagents, because of its possible relationship to the molecular mechanism of their anticancer activity. The major DNA products formed by *cis*-$[(NH_3)_2PtCl_2]$ (see Figure 9) *in vitro* are 1,2-intrastrand cross-links between the N-7 atoms in GG (about 70% of the total products) and AG (about 25%) sequences.[43,47,245] The ability of the *cis* isomer to chelate AG but not GA sequences in DNA is a result of different distances between the platinum and purine N-7 atoms in the two isomers.[43,246] Most intrastrand cross-links formed in linear duplex DNA by *cis*-$[(NH_3)_2PtCl_2]$ occur at G·C sites.[43,47,247] Intrastrand cross-links are generally more abundant than interstrand ones. The formation of the Pt-mediated interstrand cross-links requires partial disruption of the Watson–Crick base pairing,[43,248] and one could, therefore, expect such cross-linking to be rather slow. Surprisingly, kinetic measurements indicate that interstrand cross-linking is as fast as intrastrand cross-linking, or even faster.[249] These results suggest that the low occurrence of interstrand cross-links in *cis*-platinated DNA is due to slow initial platination of guanines involved in d(GCGC) sequences.[249]

Trans-$[(NH_3)_2PtCl_2]$ (see Figure 9) forms predominantly interstrand cross-links that are 1,3- and, to a lesser extent, 1,4-adducts. Adducts form at XNG and XNNG sequences (where X = A or C and N is any intervening nucleotide) via purine N-7 and cytosine N-3 atoms.[43] DNA interstrand cross-linking by the platinum reagents occurs predominantly between two N-7 atoms of G residues on opposite strands. The 5′GC3′ sequence within a miniduplex is better able than the 5′GC3′ sequence to form a bridge with *cis*-$[(NH_3)_2Pt^{2+}]$, because the former has the more appropriate spatial orientation of donor atoms.[43]

T–Hg^{2+}–T interstrand cross-linking can occur in the alternating copolymer poly(dA-T)·poly(dA-T), but not within or between homopolymeric strands in poly(dA)·poly(T).[250] The related complex $[Hg(1\text{-methyl-}T)_2]$ in which Hg^{2+} ion coordinates the deprotonated N-3 atoms of two pyrimidine residues, has been described as well.[251]

Metal ion-binding modes, that compete with H-bonds for the donor and acceptor atoms of nucleic acids, normally destabilize the base pairs or prevent their formation, and thus promote melting (dissociation) of DNA at elevated temperatures.[125,252,253] However, some of these metal ions, for example, Cu^{2+}, Mn^{2+} and Al^{3+}, can also promote renaturation of the dissociated DNA strands upon cooling presumably via cross-linking between complementary polynucleotide strands.[239,252,254]

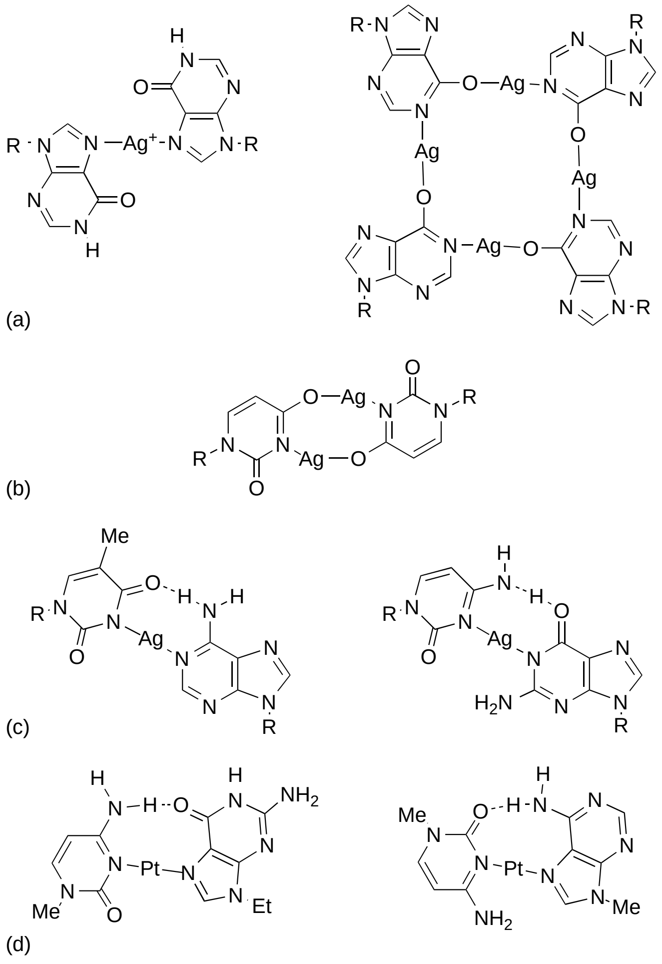

Figure 13 Examples of interstrand metal ion cross-links in polynucleotides[238,257,258]

A few helical polynucleotide structures containing interstrand metal cross-links in place of hydrogen bonds between natural bases have been described.[255,256] The structures of the complexes depends both on the nature of the cross-linked nucleic acid base and pH. Thus Ag^+ ions form a linear (N-7)–Ag–(N-7) 'bridge' between two poly(I) strands at low pH without base deprotonation, while at high pH a 'square' complex forms via (N-1)–Ag–(O^6) coordination that involves four Ag^+ ions and four polynucleotide strands and requires deprotonation of the N-1 proton on each strand (Figure 13a).[238] With poly(U) at high pH, a (N-3)–Ag–(N-3) complex forms with loss of the N-3 protons, but at neutral or low pH, two silver ions produce a centro-symmetric dimer via (N-3)–Ag–(O^4) coordination (Figure 13b).[238] A similar structure, wherein two 1-methylcytosines are bound by two (N-3)–Ag–(O^2) 'bridges', has been described.[257] The structures of related complexes in DNA, which involve one silver ion per A·T or G·C base pair and replacement of one proton by Ag^+, have been proposed (Figure 13c).[258]

It has been demonstrated that the *trans*-$[(NH_3)_2PtCl]^+$ adduct of 1-methylcytosine, bound via N-3, can form cross-links with either 9-ethylguanine or 9-methyladenine as a result of Cl^- substitution by purine N-7 atoms.[33] Additional H-bonds between exocyclic groups of cross-linked nucleic acid bases provide additional stabilization of the individual complexes (Figure 13d). Binding of the related complex $[(NH_3)_2Pt(N\text{-}3\text{-}cytosine)Cl]^+$ with d(GG) leads to the formation of a major product in which the platinum is bound only to N-7 of the 5′-nucleotide.[44]

Recent reports indicate that divalent transition metal ions, such as Cu^{2+}, forming links between two artificial hydroxypyridone nucleobases can efficiently replace the hydrogen bonding between natural nucleobases, A-T and G-C, in oligonucleotides.[259–262] Such artificial metal-mediated base pairs results in a moderate increase in the thermal stability of the duplex. They could lead to nucleic acid materials with novel chemical and physical properties. Such oligonucleotide derivatives are of interest for the design of biosensors, nanomolecular wires, and switches.

Despite the fact that complexes containing more than two (e.g. 3–6) coordinated nucleic acid bases have been synthesized,[33,263] as yet no examples of this type of binding have been found in natural polynucleotides, presumably due to structural constraints.

5.5 Outer-sphere Complexes and Ligand–Ligand Interactions

Some ligands (X and Y) in ternary inner-sphere ([X–M–Y]) and outer-sphere ($[M - W\cdots Y]$) or ($[M - X\cdots Y]$) complexes, where M is the metal ion and W is a water molecule, may interact directly with each other, forming noncovalent bonds (e.g. H-bonds and ion pairs) or undergo steric or electrostatic repulsion, depending on the ligands and the geometry of the complex.

Outer-sphere complexes at the nucleoside and nucleotide[50,103,264] are more favorable than intermolecular chelating because the indirect binding ligands to metal ion provide fewer geometrical and steric constraints for a larger number of ligands.

Typical examples of the mixed outer-sphere interactions are present in the crystal structure of yeast $tRNA^{Phe}$.[51,52,54] In contrast to a number of outer-sphere H-bonds between the metal-coordinated ligands and tRNA residues, these site-specific complexes contain only a few direct, inner-sphere bonds either to phosphate alone (Mg^{2+}),[52,54,57] to phosphate and bases (Mn^{2+}),[51] or to guanine alone (Pt^{2+})[51] (Figure 14).

Recently, high-resolution crystal structure of many RNAs other than tRNAs have been published, providing detailed information about different binding modes of the hydrated metal ions.[53,57,103,205] Strikingly, for each divalent metal ion, different binding patterns within the same RNAs have been found. Moreover, even if two similar (e.g. Mg^{2+} and Mn^{2+})

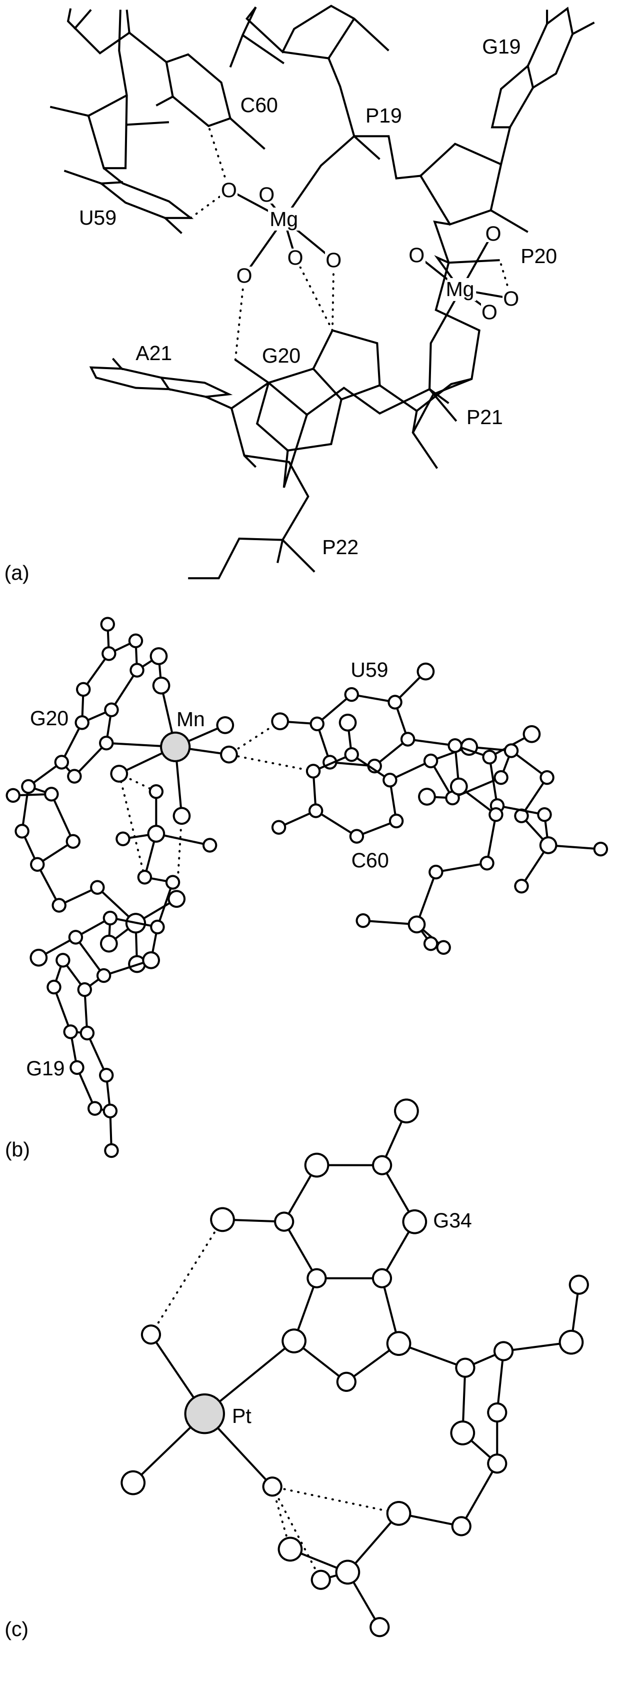

Figure 14 Binding of (a) Mg^{2+}, (b) Mn^{2+}, and (c) *trans*-[$(NH_3)_2PtCl_2$] to $tRNA^{Phe}$[51,52]

metals both occupied the same 'binding pocket', their RNA coordination partners were different. For example, although Mn^{2+} has been thought to mimic Mg^{2+} in biochemical experiments,[265] in $tRNA^{Phe}$ crystals only one of three strongly bound Mg^{2+} ions could be substituted by Mn^{2+}.[51,52,54] Structural elements providing a wide diversity of potential ligands, such as bulges, loops, and pockets in tertiary structures of RNA molecules (Figures 4a and 6a), have been found as primary centers for specific and strong binding of metal ions.[53,57,62] Surprisingly, specific metal-binding sites have been also identified in RNA and DNA duplexes.[60,174,175,197,266–269]

In contrast to *cis*-[$(NH_3)_2PtCl_2$], *trans*-[$(NH_3)_2PtCl_2$] (see Figure 9) binds very strongly and specifically to a single site in $tRNA^{Phe}$. The reason for this difference is presumably that only the *trans* isomer allows the formation of hydrogen bonds between one NH_3 ligand and atom O^6 of G-34, and between another NH_3 and the 5′-phosphate group of the same nucleotide residue (Figure 14c).[51]

Interaction of *cis*-[$(NH_3)_2PtCl_2$] or [(en)$PtCl_2$] with DNA gives intrastrand cross-linking via atoms N-7 of adjacent guanine residues in about 65% yield.[270] The high percentage of intrastrand GG cross-links cannot be explained by an initial random, monofunctional reaction of these platinum reagents with any G in DNA, followed by a bifunctional reaction with a second G adjacent to the first one. One hypothesis, which posits the recognition of the GG sequence by Pt prior to covalent binding via specific interligand interactions between *cis* coordinated amino ligands and H-acceptor atoms of G (N-7 and O^6) and phosphate O, has been proposed to explain this observed phenomenon.[33]

Ligand–ligand H-bond interactions can be employed to design base-specific metal reagents.[271] The chelating ligands in metal reagents, which play a key role in the specificity of interaction with nucleic acids, can be divided into three major categories: (1) ligands having only H-bond donor sites, such as en and trien; (2) ligands having only H-bond acceptor sites, such as acac; and (3) ligands having both types of sites, such as glycylglycinate. In model reactions of Co^{3+} complexes of *cis*-β-[Co(trien)Cl_2]$^+$ and [Co(acac)$_2$(NO_2)$_2$]$^-$ with nucleosides,[271] the relative affinities for these metal reagents was dT > dG > dC, and A ≫ C, respectively. No binding was observed to the remaining nucleosides. Representations of the possible interactions between coordinated trien and the bases are shown in Figure 15. The interligand interactions between the bases and coordinated acac oxygens, which are substantially different from those in the trien system, result in the reverse order of reactivity.

There are also a few examples of interligand stacking interactions to give complexes of the form [M(L)(nucleotide)], where L is a π-aromatic base such as bipy, phen, or tryptophanate (Trp^-) (Figure 16).[34,35,272] Metal–phosphate bonding, rather than bonding direct to the heterocyclic bases, becomes the dominant interaction in these complexes.

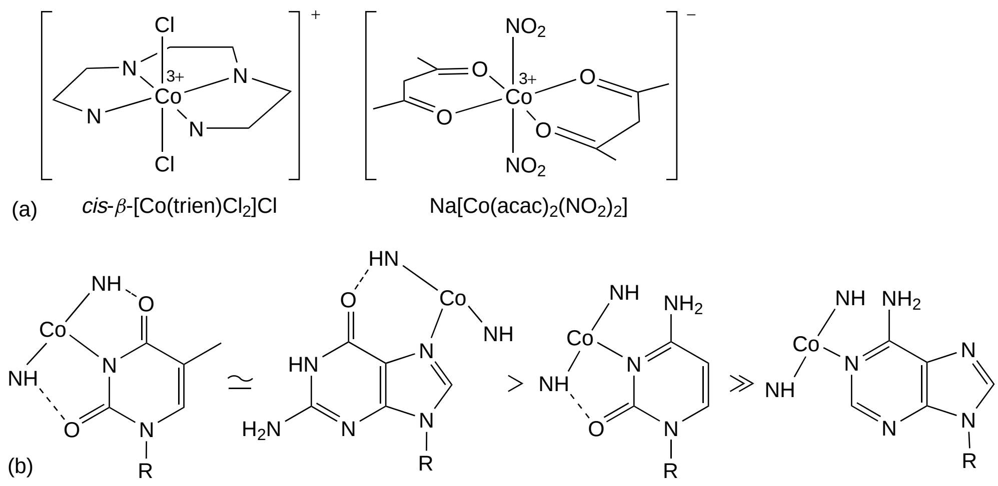

Figure 15 Structure of (a) *cis*-β-[Co(trien)Cl_2]Cl and Na[Co(acac)$_2$(NO_2)$_2$], and (b) putative complexes between *cis*-β-[Co(trien)Cl_2]Cl and nucleosides[271]

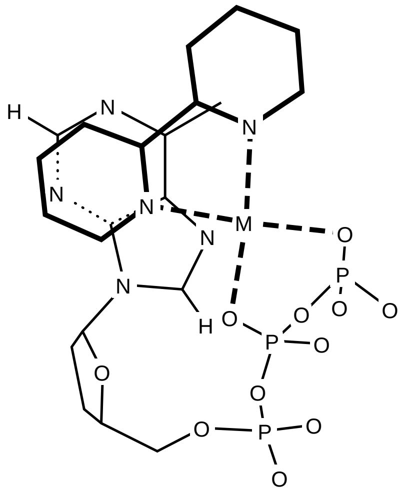

Figure 16 Simplified structural representation of the ternary complex formed between Cu(2,2′-bipyridyl)$^{2+}$ and ATP^{4-} or ITP^{4-}[273]

The extent of intramolecular stacking interactions depends strongly on both the nature of the bases involved (i.e. purines stack better than pyrimidines) and the steric features of the nucleotides. For example, the stability of Cu^{2+} complexes of the type [Cu(phen)(AMP)] decreases in the order 2′-AMP > 5′-AMP > 3′-AMP. [Cu(5′-AMPH)(bipy)(H_2O)]$_2^{2+}$ and [Cu(3′-GMP)(phen)(H_2O)]$_2$ are the only known Cu–purine complexes in which N-7 is not involved in coordination to Cu^{2+}.[27]

There is evidence for interligand interactions, without inner-sphere metal–nucleic acid binding, in three different types of complexes. In the first, the potential metal-binding sites are blocked by a proton, for example, in ‘saltlike’ structures of the complexes of protonated bases 9-ethylguanine, hypoxanthine, and cytosine with $[PtCl_4]^{2-}$, $[AuCl_4]^{-}$, and $[PdCl_4]^{2-}$, respectively.[25] In the second type of complex, metal ions occur as constituents of inert complexes in which the small ligands cannot participate in exchange reactions. For example, in $[(NH_3)_6Co]^{3+}$ the ability of the amino groups to freely rotate, and thereby easily accommodate to the unique arrangement(s) of phosphates in structured polynucleotides, makes it useful as a probe for metal-binding sites in RNA molecules and mechanisms of RNA catalysis.[148,274] In the third type of the inert complexes, such as $[Cu(phen)_2]^{2+}$,[275–278] $[Pt(terpyridine)(SCH_2CH_2OH)]^{+}$,[77,279,280] metalloporphyrins[82,281–283] and metal complexes with different class of macrocyclic ligands[284] have been shown to bind primarily via stacking of the aromatic ligand with nucleic acid bases. Steric nonbinding restrictions in addition to wide types of engineered interligand interactions[285] make the latter complexes powerful probes for structural and physical properties of RNA and DNA molecules.

6 METAL BINDING CAN INDUCE CONFORMATIONAL CHANGES OF POLYNUCLEOTIDE STRUCTURES

An interaction of metal ions with phosphates usually leads to stabilization of polynucleotide secondary and tertiary structures, depending on the metal ions and their concentrations, whereas base binding or chelating base and phosphate by the same metal ion may result in destabilization, conformational change, or denaturation of the polynucleotide structures[238,286] (see also Sections 3.3.1 and 3.3.2). However, phosphate–specific binding can also induce significant conformational changes in DNA structure. The mechanisms of the latter structural interconversions are

presumably based on the stabilization (by metal ions) of DNA conformations in which the phosphate groups can come closer together than in usual B-form of DNA duplex.[37,287]

For example, the interaction of some divalent (e.g. Zn^{2+} and Ni^{2+}) and trivalent (e.g. Cr^{3+} and Tb^{3+}) metal ions as well as polycationic inert metal species (e.g. $[Co(NH_3)_6]^{3+}$ and $[Ru(NH_3)_6]^{3+}$) could lead to dramatic changes in conformation of the double helical structure, namely transition from the right-handed B- to A- or C-forms and even to the left-handed Z-form.[140,141,286–297]

Metal ions are also known to play important roles in the formation of unusual DNA structures, the exact configuration of which is sometime difficult to elucidate. Such a delicate structural change of DNA, for example, that adopted by a single 5′-AGC-3′/5′-GCT 3′ trinucleotide under physiological conditions in the presence Zn^{2+} or Co^{2+} ions, may contribute to some genetic diseases[298] (*see* ***Metal-related Diseases of Genetic Origin***).

Certain divalent metal ions, such as Zn^{2+}, Co^{2+}, Ba^{2+}, and Mn^{2+}[299,300] as well as *cis*-$[(NH_3)_2PtCl_2]$[43] can promote sequence-directed bending of normally straight DNA duplexes. The efficacy of divalent metal ions required for the correct folding of four-way DNA cruciform junctions (yet another form of conformational polymorphism in DNA duplex) could be placed in the order as follows: $Mg^{2+} > Mn^{2+} > Co^{2+} > Ni^{2+} \sim Cu^{2+}$.[152]

Most trivalent metal cations would be anticipated to cause DNA collapse (aggregation) into condensed toroidal structures that are considered to be a model for DNA packaging in viruses and chromosomes.[238,301] $[Co(NH_3)_6]^{3+}$ induces this effect at five times lower concentration than spermidine, $[^+H_3N\text{-}(CH_2)_4\text{-}NH_3{}^+\text{-}(CH_2)_3\text{-}NH_3{}^+]$, whereas divalent metal ions and putrescine, $[^+H_3N\text{-}(CH_2)_4\text{-}NH_3{}^+]$, are incapable of causing DNA condensation in aqueous solution.[301,302] Some polyvalent metal compounds, including Al^{3+} ions,[303] also can relax supercoiled DNA, probably through single-strand DNA cleavage (see Section 7).

Triplexes are usually less stable than related double-strand structures because of the stronger electrostatic repulsion of the third chain. However, certain metal cations at appropriate concentrations can favor the formation of such structures by neutralization of the repulsive phosphate negative charges by the metal cations.[304] For example, at Na^+ concentrations about or less than 0.2 M, duplex poly(A)·poly(U) is predominant, but at higher concentrations of monovalent cations or in the presence of certain divalent metal cations (e.g. Mg^{2+} and Mn^{2+} at concentrations $\geq$ 10 mM), the duplex disproportionates to form poly(A)·2poly(U) triplex and a free poly(A) strand.[21,154]

Similar intramolecular processes are known for homopurine–homopyrimidine tracts in circular covalently closed DNA. Under the superhelical stress in such circular DNA, half the pyrimidine strand is unpaired and forms Hoogsteen base pairs with the remaining polypurine-polypyrimidine duplex, whereas the other half of the purine strand is left single-stranded (H-DNA) or vice versa toward purine and pyrimidine strands (*H-DNA). Such unusual structural transitions depend on the level of supercoiling, pH, and the presence of divalent metal ions. For example, Mg^{2+} is strictly required at neutral pH to support the H-type, $(dA)_n\cdot 2(dT)_n$, structure in plasmid DNA.[305] In supercoiled DNA, $(dG)_n\cdot(dC)_n$ sequences fold into halves from the center of this tract forming *H-type, (dG)·(dG)·(dC) triplex in the presence of Mg^{2+}, Ca^{2+}, or Mn^{2+}, whereas Zn^{2+} ions cannot support this particular triplex structure.[304,306] Moreover, Zn^{2+} can inhibit this structural conversion, if Zn^{2+} and Mg^{2+} are both present, via interfering with the magnesium binding to the $(dG)_n\cdot(dC)_n$ tract.

For heterogeneous polypurine–polypyrimidine tracts, the effect of various divalent metal ions on the transition to and stability of the *H-DNA triplexes can be very different depending on the sequence of such tracts.[142,143,175,307–309] For example, Cd^{2+}, Co^{2+}, Mn^{2+}, Ca^{2+}, and Zn^{2+} ions can stabilize the intramolecular triplex $(dTC)_n\cdot(dGA)_n\cdot(dAG)_n$, whereas Mg^{2+}, Ca^{2+}, Ba^{2+}, and Hg^{2+} cause destabilization.[309] For the sequence $(dCT)_{22}\cdot(dAG)_{22}$, the efficiency of promoting the corresponding duplex-triplex transition was found to be: $Zn^{2+} > Cd^{2+} \gg Mn^{2+}$, whereas Mg^{2+} was without effect in this system.[142] In another set of experiments, the formation of intermolecular Pu-Pu-Py triplex between a synthetic oligonucleotide and a fragment of the human papilloma virus DNA, occurred in the presence of Mn^{2+}, but not Mg^{2+} or Zn^{2+} ions.[309] Generally, the types of unusual structures adopted by long Pu-Py repeats in DNA are complex and heterogeneous with multiple different conformers.[307] Some monovalent cations were found to inhibit intermolecular Pu-Pu-Py triple-helical DNA conformation (with K^+ and Rb^+ being most effective, followed by Na^+), presumably via promotion of other multistrand structures.[310]

Triple-helix formation by G-rich oligonucleotides is supported by Mg^{2+} but strongly inhibited by physiological concentrations of certain monovalent cations, especially K^+, most likely due to oligonucleotide self-association in competitive structures such as guanine-quadruplexes.[311–313] Variation of the cation environment can differentially promote the assembly of multistranded nucleic acid structural alternatives. For example, by specifically counteracting the induction/stabilization of quadruplex structures by potassium ions, certain divalent ions (i.e. Mn^{2+}, Co^{2+}, and Ni^{2+} but not Mg^{2+}) at low millimolar concentrations allow triplex formation in the presence of 150 mM K^+.[313] In contrast, certain mono- and divalent metal ions can promote the transition from Watson–Crick duplexes to G_4 quadruplex structures relatively efficiently: $K^+ > Ca^{2+} > Na^+ > Mg^{2+} > Li^+$.[146,147,314]

The tertiary structure of single-stranded RNA molecules is affected by metal ions even more dramatically because of the complexity and flexibility of such species.[157] By stabilizing one RNA structure and destabilizing others, metal ions can promote structural transformations. Such conformational

changes, induced by different (primarily biological) metal ions, have been studied extensively for several classes of RNA molecules, including tRNAs,[104,158–161,315] ribosomal RNAs,[157,316–318] and ribozymes.[57,319–322]

Certain complexes of platinum metals (such as Pt^{2+} and Ru^{2+}), containing planar aromatic ligands, bind DNA through intercalation between base pairs without distorting them. However, such metallo-intercalation agents can induce changes in the superhelical shape of DNA, producing extension, unwinding, and stiffening of the DNA helix.[279,280,284]

In addition to the formation of inner- and outer-sphere complexes, high concentrations of metal ions can affect RNA and DNA hydration through binding water molecules and affecting their activity and properties (polarization, orientation, and mobility) of adjacent water molecules.[323–325] Through effects on the local ordering of water molecules near and in the polynucleotide first hydration shell,[2,253] structure-promoting (kosmotropic)[325] ions and structure-breaking (chaotropic)[325] ions may indirectly alter the structure and stability of nucleic acids.

7 METAL BINDING CAN INDUCE HYDROLYSIS AND CLEAVAGE OF NUCLEIC ACIDS

Metal ions can catalyze the cleavage of nucleic acids through different mechanisms, which are discussed in detail elsewhere.[40,166,326] Briefly, these metal-dependent mechanisms may involve direct interaction of metal ion catalysts with either the atoms flanking the cleavable bonds or the nucleic acid functional groups participating in the cleavage chemistry. The hydrated metal ions can act either as general acids ($M–OH_2$) or general bases (M–OH). Alternatively, metal ions can stabilize the transition states of cleavable bonds. In addition, metal ions can promote cleavage through modification of nucleobase or sugar residues, resulting in destabilization of the N-glycosidic bond between these moieties (see Section 4.5). Oxygen radicals generated by some metal ions can also cleave both RNA and DNA (see Section 4.5).

However, not all cleavage reactions of nucleic acids promoted by metal ions occur through direct involvement of metal ions in cleavage chemistry. For example, metal ion cofactors stabilize the catalytically active conformations of several ribozymes, but do not participate directly in catalysis.[56]

Cleavage of nucleic acids refers to a reaction that results in the breakage of bonds in the phosphodiester backbone of a polynucleotide chain. There are two types of reactions resulting in the cleavage of either P–O or C–O bonds in the nucleic acid backbone (see Figure 1d).[96] Cleavage of the P–O bond occurs as a result of nucleophilic attack on the phosphorus atom via either an *inter*molecular reaction with a H_2O molecule (*hydrolysis*) or an *intra*molecular reaction involving the ribose 2′-OH (*transesterification*). Of these two reactions, transesterification is specific to RNA (since DNA lacks a 2′-OH moiety) and can be catalyzed by many $M^{\geq 2+}$ ions albeit with different efficiencies (see below), generating 5′-OH and intermediate 2′,3′-cyclic phosphate ends. The same metal ions can then promote subsequent hydrolysis of the 2′,3′-cyclic phosphate[96] resulting in an equimolar mixture of 2′- and 3′-phosphates (see Figure 1c). It is a common mistake to use the term ‘hydrolysis’ when referring to RNA cleavage by the transesterification mechanism. Only the postcleavage opening of the 2′,3′-cyclic phosphate proceeds via a hydrolytic mechanism.

A large variety of metal ions catalyze the cleavage of RNA through the transesterification mechanism, and some of them can also catalyze hydrolysis of cyclic phosphates (e.g. Pb^{2+}, Zn^{2+}, and Cd^{2+}) and nucleoside phosphomonoesters (e.g. Pb^{2+}, La^{3+}, and Th^{3+}).[96] The most efficient cleavage of RNA in aqueous solutions by free metal ions is achieved by the action of rare metal ions (e.g. Eu^{3+}, La^{3+}, and Tb^{3+}), Pb^{2+}, and Zn^{2+}.[39,96] Zn^{2+} is only about 4% as efficient as Pb^{2+},[327] but other catalytically active metal ions (e.g. Al^{3+}, Cd^{2+}, Mn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, or Mg^{2+}) are 1–2 orders of magnitude less efficient than Zn^{2+}.[328] As a rule, RNA cleavage has a maximum rate at pH values around the pK_as of the first metal-bound H_2O (see Table 1), that is, when the hydroxo-metal species still bear positive charge.[329]

Just as metal ions can bind nucleic acids both specifically and nonspecifically, they can promote both specific and nonspecific cleavage of nucleic acids. The rate and specificity of the cleavage reactions varies markedly with the identity of both metal ions and nucleic acid structures, as well as with the conditions of experiments. Higher pH, temperature, and concentrations of metal ions could enhance the rate of the polynucleotide cleavage but would decrease the specificity.

Numerous studies of metal-induced cleavage of RNA provide considerable insight into the relationship between nucleic acid structure and the specificity of polynucleotide cleavage. A higher rate of phosphodiester bond cleavage promoted by metal ions is observed for polynucleotides than for short oligonucleotides.[330] In RNA oligomers, the nature of the adjacent phosphate group can affect the rate and primary position of metal-dependent cleavage of internal phosphodiester bonds.[330] The nucleotide composition and the nature of the nearest-neighbor base of RNA molecules also affects the rate of metal-promoted cleavage.[252] This sequence specificity is presumably determined by specific interactions (e.g. stacking and H-bonds) between adjacent bases that determine the local conformation of the ribose–phosphate backbone at the site of cleavage.[331]

Secondary structure also affects the cleavage specificity. RNA duplexes are more resistant to cleavage by metal ions than single-stranded RNAs.[327,332,333] One of the principal reasons for this could be that base pairing interactions stabilize the conformation of the dinucleoside phosphate moiety such that the phosphorus atom is moved away from the sugar 2′-OH group and rotation about the C3′-O bond is restricted, which can interfere with the conversion of the polynucleotide to a conformation suitable for the transesterification reaction.[334]

Metal ions bound site-specifically within the RNA tertiary structure could induce cleavage of the phosphodiester backbone near the binding sites. One group of metal ions, including Eu^{3+},[335–338] Pb^{2+},[62,321,329,339–348] Zn^{2+},[335,349,350] Fe^{2+},[351,352] and Mn^{2+}[350,353,354] can induce specific nonenzymatic cleavage of different RNAs at neutral pH. Another group, which includes Mg^{2+}, Ca^{2+}, Ba^{2+}, Sr^{2+}, and Cu^{2+}, requires higher pH (8.5–9.5) to promote the specific cleavage of RNA molecules efficiently.[62,329,335–338,344,348,349,355,356]

Because of their high efficiency of RNA cleavage, Pb^{2+} ions have been used routinely as a probe of RNA structure.[332,357] Pb^{2+}-induced cleavage occurs preferentially in single-stranded regions of RNA, which include loops, bulges, and single-base mismatches, while stable double-stranded stems and highly structured tetraloops are partially resistant.[358] However, cleavage may also occur in destabilized base-paired regions. Similar to Pb^{2+}, lanthanide metal ions (e.g. Eu^{3+} and Tb^{3+}) have been used as probes of RNA folding as well as to map metal-binding sites in RNA molecules.[332,347,359–362]

There are three general approaches based on metal-induced cleavage of RNA to identify (map) metal-binding sites. In the first approach, the location of strongly bound $Mg^{2+}$and Ca^{2+} ions can be revealed by inducing cleavage at pH 9–9.5.[336,344,347,349,356] The second approach, is based on the assumption that certain metal ions (e.g. $Fe^{2+}$and Pb^{2+}) can replace Mg^{2+} at the same binding sites and induce RNA cleavage upon binding.[329,332,344,352] The third technique takes advantage of the fact that metal-induced cleavage of RNA (e.g. by Pb^{2+} or Zn^{2+}) can be inhibited when the reaction mixture is treated with increasing concentrations of Mg^{2+}, owing to substitution of the cleaving metal at the particular sites with Mg^{2+}.[186,332,344] However, the metal-dependent cleavage of RNA at a particular site does not automatically implicate the involvement of these nucleotides in the binding of this metal ion. Also, some specifically bound metal ions may not be able to induce cleavage at their binding sites because of the restricted flexibility or steric accessibility of the surrounding polynucleotide backbone, or unfavorable spatial orientation between metal ion and the relevant internucleotide bond. Moreover, different metals most probably will have different binding patterns even if they bound within the same metal-binding pocket.

8 CONCLUSION

This article does not attempt to be comprehensive, but rather presents selected examples to illustrate key facets of metal ion–nucleic acid interaction. The focus is on the chemical and structural properties of nucleic acids and metal ions relevant to their interactions, and in illustrating that both contribute as equal partners to the complexity of their interactions.

1 INTRODUCTION

All organisms including humans require essential minerals for survival, reproduction, and other physiological functions. As Underwood and Mertz stated,[1] the number of elements recognized as essential reflects the knowledge at a certain time point. Essentiality is established when a further reduction of a certain mineral intake (exposure) below the range of tolerable levels results in a consistent and reproducible impairment of a physiological function.[1] The essential inorganic nutrients consist of the major elements and the trace elements. The major elements include sodium, potassium, calcium, magnesium, chlorine, phosphorus, and sulfur. The trace elements include iron, copper, zinc, manganese, cobalt, chromium, molybdenum, vanadium, nickel, arsenic, selenium, iodine, fluorine, silicon, and boron. Tin, cadmium, lead, rubidium, and lithium can be added to the list of essential trace elements. Evidence of essentiality is limited for arsenic, boron, cadmium, fluorine, lead, lithium, nickel, rubidium, silicon, tin, and vanadium. Recently, noncorrin function of cobalt as a cofactor of methionine aminopeptidase in humans was found in addition to the well-known function as a metal center of vitamin B_{12} (*see* ***Cobalt: B_{12} Enzymes & Coenzymes***).[2] Ultratrace elements can be defined as trace elements whose requirements are approximately less than 1 mg day^{-1} for humans or 1 mg kg^{-1} diet for animals. In this context, most trace elements except for iron, zinc, copper, and manganese are classified as ultratrace elements.

For simplicity and brevity, this review will focus on human nutrition, but will also discuss other systems, where appropriate. The nature and amount of each element required by a given organism has been painstakingly determined by trial-and-error using purified (historically, synthetic or semisynthetic) diets to measure both essentiality and required amounts. For microorganisms and plants in hydroponic culture, such studies are a relatively easy matter once the difficulties of trace element contamination have been conquered. Investigations of endemic diseases revealed the essentiality of inorganic nutrients for humans such as zinc (dwarfism with hepatosplenomegaly in Egypt and Iran)[3] and selenium (Keshan disease in China).[4] Because the essentiality of minerals is the basic principle, occurrence of deficiencies of inorganic nutrients including zinc and selenium has been found to be worldwide rather than restricted in local areas. The technical ability to provide complete nutrient supplements intravenously, through total parenteral nutrition, has permitted the precise determination of how much of each element is required. The inadvertent omission of one or more trace elements led to serious pathological consequences that could be reversed by administration of the missing element(s).

Optimal dietary intake is difficult to determine. Dietary Reference Intakes (DRIs) in the US are reference values that are quantitative estimates of nutrient intakes to be used for planning and assessing diets for apparently healthy people.[5] DRIs are composed of reference values including Estimated Average Requirements (EARs), Recommended Dietary Allowances (RDAs), Adequate Intakes (AIs) and Tolerable Upper Intake Levels (ULs). Most nations have established the equivalent of the US DRIs. These are consensus and statistical values obtained from retrospective public health dietary studies, controlled experiments on metabolic wards, epidemiological surveys, isotopic tracer investigations, and extrapolation from animal models.

The values are a function of age, sex, and pregnancy. RDA is defined as the average daily dietary intake level that is sufficient to meet the nutrient requirement of nearly all (97 to 98%) healthy individuals in a particular life stage and gender group. AI is defined as a recommended intake value based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of healthy people that are assumed to be adequate. AIs are used when an RDA cannot be determined. UL is defined as the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects for almost all individuals in the general population. As intake increases above the UL, the risk of adverse effects may increase. EAR is defined as a daily nutrient intake value that is estimated to meet the requirement of half of the healthy individuals in a life stage and gender group. One may notice that EAR is defined as ‘median’ although it literally means ‘average’.

The prevalence (***D***) of the deficiency of the particular nutrient is the proportion of the individuals with the deficiency of the particular nutrient in the population.

$\boldsymbol{D} = \boldsymbol{\Sigma}$(Individuals whose dietary intake < requirement) / (total number of individuals).

For the continuous distribution, the following equation with double integrals is obtained, where x is the dietary intake, y is the requirement, *Ro* is EAR, and p is the distribution function of the dietary intake and the requirement:

$$D = \int_{-\infty}^{+\infty} \int_{x}^{+\infty} p(x, y; R_o)\mathrm{d}y\mathrm{d}x \qquad (1)$$

When the distribution function of the dietary intake and the requirement follows the specific form, the above equation is used to estimate the prevalence of deficiency or inadequacy under the given condition and to evaluate the average requirement from the population data of the nutritional status.[6]

Values of RDAs and AIs for several minerals and trace elements from the current US DRIs are shown in Table 1.

All living systems require the major cations and anions: Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, PO_4^{3-} and SO_4^{2-}. These ions are involved in the (1) regulation of intra- and extracellular electrolyte balance, (2) maintenance of bioelectric potentials and function of bioexcitable membranes, (3) control of pH, (4) stabilization of membrane structure and integrity, (5) mineralization of endo- and exoskeletons, (6) metabolic regulation and control as 'second messengers', (7) biomechanical contractility, (8) modulation of various ion channels and receptors, (9) activity of metallo-cofactors for various enzymes, (10) generation and utilization of energy as phosphate esters, and (11) structure and function of sulfo- and phospho-organic molecules. These major ions must be continually supplied in adequate amounts to maintain homeostasis.[7]

The trace elements comprise about 0.01% of the total wet weight of an organism. They serve six principal functions: (1) catalytic centers for enzymatic reactions, (2) oxidation–reduction centers, (3) oxygen binding and transport, (4) structural integrity of macromolecules, and (5) metabolic regulation and control, (6) modulation of various ion channels and receptors.[7] Modulation of various ion channels and receptors is added to the original lists in the second edition of this chapter for the major and trace elements based on the recent advancement in this field such as zinc finger proteins (*see* ***Zinc: DNA-binding Proteins***)[8] and cyclic nucleotide-gated (CNG) cation channels with nickel.[9]

Frequently, a given metal may be operative in two or more modes. Thus, iron can serve as a metallo-cofactor of an enzyme (uteroferrin; *see* ***Iron Proteins with Dinuclear Active Sites***), as a redox electron carrier (cytochrome; *see* ***Iron: Heme Proteins & Electron Transport***), in oxygen transport (hemoglobin; *see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), for structural integrity of a protein (transferrin; *see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***), and as a regulator of a metabolic reaction (aconitase; *see* ***Iron–Sulfur Proteins***; ***Metalloregulation***).

2 REGULATION

The regulation and control of all required inorganic nutrients are a function of eight coherent parameters:[7]

- availability of the total amount of the nutrient in the diet, soil or medium;
- solubility of the element;
- permeability of the element across membranes;
- ligand exchange rates of the metal ions among potential binding sites;
- transport of the element in cell and organs;
- assimilation of the element into its cellular or tissue target molecule;
- storage of the element for depot reserve or detoxification;
- excretion of excess nutrient to maintain homeostasis and prevent toxicity.

Examples of how each of the above operates in mineral nutrition may serve to illustrate the principles involved.

2.1 Availability

The proverbial 'well-balanced diet' should be able to provide adequate amounts of all of the necessary inorganic elements the body requires. The balancing act is not as simple as it may seem. Dietary restriction both in quantity and diversity is frequently encountered for economic, social, ethnic, esthetic, and religious reasons, as well as ignorance.

In both the developing and developed nations, inadequate intake of iron, calcium, zinc, and iodine gives rise to the most widespread and serious nutritional deficiencies. Iron and zinc are present in greatest abundance in red meats and organ meats. Oyster is a special source of zinc and copper. Milk and dairy products are the best source of calcium. Legumes and unrefined grains are good sources of copper, nickel, and chromium. The practice of fortifying flour and breakfast cereals with iron is widely used. Fortification of table salt with iodine has been widely employed (iodinated salt). Dietary supplements, either individual nutrients or multivitamin/multimineral preparations, are effective. A perspective of the amounts of iron, copper, and zinc in a few foods is shown in Table 2.

Diets low in meats and high in grains and legumes do not provide adequate available iron. The preparation of food in cast-iron utensils can significantly increase iron availability. Iron deficiency anemia is manifest as low hemoglobin concentrations, reduced myoglobin, and loss of activity of respiratory enzymes (*see* ***Cytochrome Oxidase***). Impaired growth, lethargy, and reduced exercise performance and attention span have been observed.[10]

Prospective studies in postmenopausal women have demonstrated that manganese, copper, zinc, magnesium, and boron are involved in the maintenance of bone density.[11] These trace elements appear to be essential for the synthesis of the organic matrix of bone.

Table 1 Dietary reference intakes: recommended intakes for individuals, Food, and Nutrition Board, The Institute of Medicine, National Academies

Note: This table presents RDAs in bold type and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98%) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to determine RDA. Sources: Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride (1997), Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids (2000), and Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc (2001). These reports may be accessed via www.nap.edu.

Table 2 Iron, copper, and zinc in selected foods

	Serving (g)	Iron (mg)	Copper (mg)	Zinc (mg)
Calves' liver, pan-fried	67	4.01	10.0	7.97
Ground beef, 75% lean meat, pan-browned	85	2.24	0.068	5.24
Chicken breast, roasted	98	1.05	0.049	1.00
Pacific cod, raw	116	0.30	0.030	0.46
Oyster, eastern, farmed, raw	84	4.86	0.620	31.9
Broccoli, raw	88	0.64	0.043	0.36
Bread, white, commercially prepared	25	0.94	0.063	0.18

Table 3 Calcium in selected foods

	Serving (g)	Calcium (mg)
Milk, whole, 3.25% milk fat	244	276
Cheese, cheddar	28	202
Yogurt, plain, whole milk	245	296
Broccoli, raw	88	41
Bread, white, commercially prepared	25	38

Goiter is the human pathology of hyperplasia of the thyroid gland induced by the deficiency of dietary iodine. The disease is localized in those regions where soils are low in iodine or where seafood is not consumed. Fortification of table salt with sodium iodide, where applied, has practically eradicated this disease. Unfortunately, many regions of the world do not practice this public health policy.

Inadequate amounts of dietary calcium contribute to loss of bone mineral density and increased rates of fracture observed in osteoporosis, a disease which afflicts over 40% of postmenopausal women in the developed nations.[12] The primary source of dietary calcium is dairy products (Table 3). The preparation of corn meal using calcium hydroxide 'fortifies' this grain. Because the intake of dairy products by adult females is low, their average calcium consumption (550 mg) is well below the recommended 1000–1200 mg. Supplementation with various forms of calcium is prudent. Fortification of fruit juices and soft drinks with calcium complexed with citric and malic acids has been achieved.

Amounts of dietary sodium in excess of the kidney's ability to dilute and to excrete it in the urine leads directly to hypertension and indirectly to coronary heart disease and stroke.[13] Although sodium chloride is required at about 1 g day^{-1}, a typical Western diet, in fact, may contain from 8 to 12 g day^{-1}. If renal transport is impaired, sodium ion accumulates and the osmotic pressure of the blood rises. Dietary reduction of salt can ameliorate some but not all of the problems. A wide variety of low-salt food products is now available.

2.2 Solubility

The total amount of a given element in the diet is not always the measure of its nutritional availability. Many trace metals readily hydrolyze to form polynuclear, frequently insoluble, hydroxides. Some metals, particularly iron, demonstrate dramatic differences in solubility as a function of their redox state. The maximum solubility of Fe^{II} at pH 7.0 is 10^{-2} M, while Fe^{III} is 10^{-17} M (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***; ***Iron Transport: Siderophores***). It is not surprising that Fe^{II} is more bioavailable than Fe^{III}. However, Fe^{II} readily autoxidizes and cannot be used to fortify foods because it causes rancidity.[7] Most di- and trivalent metals form insoluble complexes with inorganic and organic phosphates.

Iron pyrophosphate, both insoluble and inert, has been used to fortify foods. Phytic acid, hexaphosphoinositol, a constituent of many grains and vegetables, precipitates many metals. Precipitation of zinc is severe when calcium coexists with phytic acid.[14] Several naturally occurring fibers and polyphenols form insoluble complexes and render a metal less available. A remarkable example of this phenomenon is the recognition that a form of human dwarfism found in the Middle East was attributable to zinc deficiency. Individuals consuming some forms of whole grain containing high concentrations of fiber and phytic acids could not solubilize and absorb their dietary zinc. The ensuing metal deficiency prevented normal genital development. The condition could be reversed with proper diets and zinc supplementation.[15]

Low-molecular weight chelates, either secreted endogenously or provided exogenously in food, solubilize metals and facilitate their uptake. Sugars, amino acids, and organic acids can enhance metal solubility. Fructose and other reducing sugars and polyols bind Fe^{III}, lactose binds Ca^{II}, histidine complexes Cu^{II}, citrate, malate, and succinate complex Fe^{III}, Ca^{II}, Mg^{II}, Cu^{II}, and other metals. Ascorbic acid is unique for iron metabolism in that it both reduces Fe^{III} to Fe^{II} and becomes a powerful chelator, diketogulonic acid, as well. Plants secrete organic acids from their roots to solubilize and mobilize iron from the soil.[16] Frequently soluble complexes of metals with ethylenediamine-N,N,N',N'-tetraacetic acid (EDTA) or similar chelators are applied to soil or leaves to prevent iron deficiencies.[17]

The acid environment of the stomach provides a mechanism for solubilizing finely divided metallic iron as well as metal hydroxides prior to their entry into the small intestine. There, neutralization in the presence of suitable ligands makes the iron bioavailable. The oldest form of iron fortification employed iron filings added to sweet wine. Today, colloidal metallic iron, ferrum reductum, is still a widely used fortificant in food.

2.3 Permeability

Several mechanisms for the transport of ions are operative: (1) active transport of the ion against a concentration gradient by an ATP-driven membrane carrier, (2) passive carrier facilitated transport, (3) passive diffusion dependent upon the ability of the ion or complex to pass the membrane. Sodium,

potassium, calcium, and magnesium are actively transported across intestinal and cellular membranes. Calcium and magnesium can also passively diffuse as low-molecular weight complexes bound to membrane proteins. Movement of iron in microbial systems involves the active membrane transport of the Fe^{III} hydroxamate, followed by the intracellular removal of the metal and recycling of the chelator.[18] Many complexes of iron move passively across the intestinal membrane as a function of their size and permeability coefficient. Large polynuclear complexes of iron, manganese, chromium, and copper are impermeable.

2.4 Ligand Exchange

The observed inhibition of Cu^{II} and Zn^{II} uptake by large amounts of Ca^{II} suggests a competition of these metal ions for limiting amounts of solubilizing chelators in the intestinal lumen. Wilson's disease, a heritable disorder of copper overload, is treated by feeding high levels of zinc to block copper uptake (*see* ***Metal-related Diseases of Genetic Origin***).[19] The presence of adequate amounts of a metal in a soluble and permeable form is not sufficient to insure nutritional efficacy. Thus Fe^{III}–EDTA, an excellent source of iron for plants, is nutritionally less effective in mammalian systems. Although dietary Fe^{III}–EDTA readily enters the blood, it readily passes through the kidney tubules and into the urine. The rate of Fe^{III}–EDTA exchange with apotransferrin in the serum or with intracellular sites is slow.[20]

2.5 Transport

The bulk of monovalent elements are ionic and are localized in extra- and intracellular water. Some divalent metals, particularly Ca^{II} and Mg^{II}, exist both as free ions and bound to low- and high-molecular weight ligands. Transferrin, a serum β_1-globulin, has two highly selective binding sites with affinity constants of about 10^{36} for Fe^{III} (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). This protein solubilizes the Fe^{III} salt and transports it to the sites of assimilation. Absence of transferrin in a genetic disorder leads to pathological iron overload.[21] Serum albumin serves to bind and transport Cu^{II} and Zn^{II}. However, low-molecular weight chelators, including amino acids, may effectively transport these metals.[22–24]

2.6 Assimilation

Many metals are incorporated by equilibrium binding into their specific sites on their apoproteins. The rate of synthesis of the apoprotein by the cells or tissues controls the rate of incorporation. Most zinc and some copper proteins exhibit such behavior. The process of iron incorporation is far more complicated.[25] Uptake of heme into enterocytes occurs as an iron-protoporphyrin complex in an endosome process. Iron is released from heme by heme oxygenase to enter plasma from cytoplasm as inorganic iron. Ferric iron is absorbed via a β_3 integrin and mobilferrin pathway (IMP) specific for iron. Ferrous iron uptake is facilitated by a divalent cation transporter 1/divalent metal ion transporter 1 (DCT1/DMT1). DCT1/DMT1 has a broad substrate range that includes Fe^{II}, Zn^{II}, Mn^{II}, Co^{II}, Cd^{II}, Cu^{II}, Ni^{II}, and Pb^{II}. Many nutritional factors influence iron assimilation. Deficiencies in copper and vitamins B_{12} and B_6 inhibit cellular iron incorporation.

Intestinal absorption of copper is mediated by copper-transporting P-type ATPase 7A (ATP7A) or Menkes disease protein. Mutations in the ATP7A gene lead to Menkes disease in humans that is characterized by congenital impairment in intestinal transport of copper (*see* ***Metal-related Diseases of Genetic Origin***).[26]

2.7 Storage

A striking example of mineral storage is the skeleton. The apparent abundance of calcium available for mobilization is deceiving since loss of relatively little bone mineral density can lead to an increased incidence of serious fractures.[27] Significant amounts of magnesium are stored in bone and available for utilization.

Redox metals, particularly iron and copper, must be stored in a fashion to provide both available reserves of the metal and to sequester the metal in a form which prevents oxidative damage to the cells by Fenton-like reactions (*see Fenton Chemistry*; ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). For iron this is accomplished with the ubiquitous protein, ferritin. Polynuclear iron(III) hydroxide polymer containing from $2–4 \times 10^3$ iron atoms is surrounded by 24 protein subunits. Iron atoms can be mobilized from or enter into the core. The mechanisms governing iron movement are not definitively elucidated. Liver and spleen are the primary organs for ferritin storage. The concentration of serum ferritin can be used as a readily measurable indicator of adequate nutritional iron status. When iron concentrations exceed the ability of the cell to synthesize apoferritin subunits, iron(III) hydroxide polymers aggregate and precipitate, partially surrounded by protein. This material, hemosiderin, is a histological sign of iron pathology, and becomes a focus for oxygen-free radical generation (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***).[28]

The primary organs for copper storage are the liver and spleen, where the metal is found in the cytosol in superoxide dismutase (*see* ***Copper Proteins with Type 2 Sites***) or metallothionein (*see* ***Metallothioneins***).[29] In response to a copper challenge, yeast adaptively synthesizes metallothionein to detoxify the metal.[30] Copper is also bound, transported, and assimilated into tissues by ceruloplasmin.

Although metallothionein in liver binds zinc, there seems no apparent zinc storage in the body according to the kinetic analysis.[31]

2.8 Excretion

The primary organ for the regulation of sodium, potassium, calcium, and magnesium is the kidney. An intricate series of physiological sensing elements and hormonal response mechanisms maintains homeostasis. A variety of diuretic drugs can be used to enhance urinary output of various soluble salts, primarily sodium and potassium chloride. Profuse sweating is also a pathway of excretion for soluble salts and occasionally zinc.[32]

The trace elements iron, copper, zinc, and manganese, however, are excreted via the feces. Not only do the insoluble and unabsorbed dietary metals pass through the gastrointestinal tract, but also continual sloughing off of intestinal cells removes significant amounts of metal from the organism.

Biliary excretion of copper and iron is important. Major losses of iron can be caused by internal bleeding. Thus women during their menstrual periods will be in negative iron balance unless proper nutrition is observed. Blood loss via the gastrointestinal tract, as in ulcers or some forms of cancer, leads quickly to loss of utilizable or stored iron.[10]

Defects in the copper-transporting ATPase 7B (ATP7B) causes Wilson's disease. The ATP7B transporter eliminates copper through the bile and also transports copper into plasma ceruloplasmin (*see* ***Metal-related Diseases of Genetic Origin***).[26]

3 THE PATHOLOGY OF METAL OVERLOAD

As trace element deficiencies give rise to impaired growth and development, excessive uptake or aberrant deposition of some metals can be pathological. Iron storage diseases are of three primary origins: (1) genetic predisposition to increased absorption of dietary iron, hemochromatosis (*see* ***Metal-related Diseases of Genetic Origin***), (2) repeated transfusions of blood, transfusion siderosis, (3) nutritional iron overload. The pathological consequences of each are quite similar. Iron is deposited in liver, spleen, heart, skin, and other tissues. Free radical damage to the tissues is manifest in increased incidence of tumors and heart muscle damage.[33] In the majority of hereditary hemochromatosis cases, mutations in HFE gene (the approved gene symbol responsible for hereditary hemochromatosis by the HUGO Gene Nomenclature Committee) were identified. HFE proteins were found from the small intestine, liver, and placenta in humans. A possible function of HFE protein is the modulation of the transferrin receptor activity.[34]

Conventional treatments for hemochromatosis and for nutritional iron overload include reduction of dietary iron and periodic removal of blood (phlebotomy) until iron stores are reduced. In transfusion siderosis, it is necessary to eliminate iron via the urine by the intravenous infusion of highly specific chelating agents such as desferral (*see* ***Iron Transport: Siderophores***). This process is painful, laborious, and costly. The development of new orally effective iron chelators is expected.

An epidemiological study in a Finnish population indicated an association between moderate iron overload (measured by serum ferritin; *see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***) and increased incidence of coronary heart disease. This remarkable association has not been confirmed[35] and further investigation will be necessary to determine whether excessive iron storage may relate to coronary heart disease.[10]

One of the most common forms of accidental chemical poisoning is found among young children who swallow iron(II) sulfate pills, their mother's iron supplements, in the mistaken belief that they are candy. Such poisoning demands immediate response with emetic, gastric lavage, and treatment with desferral.

Copper toxicity has been observed, although it is not a function of dietary overload. Abnormally low levels of ceruloplasmin associated with the genetic disorder, Wilson's disease, lead to excessive deposition of copper in the central nervous system, ocular tissue, liver, and other organs. Severe psychotic symptoms are observed. Urinary excretion of the copper can be achieved with specific chelating agents such as British anti-lewisite (BAL, 2,3-dimercaptopropanol) or penicillamine, orally administered. Symptoms of the disease are reversed as the copper levels return to normal. Reduction of dietary copper uptake by competition with relatively high levels of oral zinc is also effective.[19]

Manganese toxicity has been observed in miners exposed to high levels of MnO_2 dust. The neurological symptoms mimic Parkinson's disease. Major changes were observed in the biogenic amines, dihydroxyphenylalanine (DOPA), and phenylalanine. Restoration of appropriate levels of these bioamines alleviated the symptoms. Chelation therapy has not been demonstrated as an effective strategy.[36]

4 SELENIUM AND NICKEL AS ESSENTIAL ULTRATRACE ELEMENTS

Selenium is an amphoteric element whose chemistry and biochemistry has much in common with sulfur. The essentiality of selenium in experimental animals was demonstrated in 1957. It was necessary that the animals be vitamin E deficient to manifest selenium deficiency. Selenium manifests antioxidant activity by its incorporation into selenocysteine and its subsequent participation at the

active site of glutathione peroxidase, a key enzyme in the detoxification of H_2O_2. Selenium is also found as selenomethionine, which is also incorporated into the peptide chain of proteins. Dietary selenium is present as the two seleno-amino acids and as inorganic selenite, which can be reduced and assimilated.[37] The nutritional status of selenium is best determined by measuring glutathione peroxidase levels in the blood.[38] Other important selenium-containing proteins include thioredoxin reductases (protein thiol redox regulation), iodothyronine deiodinases (thyroxin activation and triiodothyronine inactivation), selenoprotein P (selenium transport and antioxidant). Human selenium deficiency has been identified as the causal agent in Keshan disease. In some areas of China, soil selenium concentrations are so low that women of child-bearing age and children suffer cardiomyopathy.

Nickel belongs to the iron–cobalt group of metals and is found as a constituent in most meteorites and the nucleus of the Earth. The clear signs of nickel deficiency in experimental animals were demonstrated in 1975.[39] Nickel is decisive for life. Nickel occupies a metal center of urease as well as hydrogenase, carbon monoxide dehydrogenase and other enzymes in the primitive life forms, which have crucial roles in obtaining energy from hydrogen and carbon monoxide, presumably abundant in the primordial solar system (*see **Nickel Enzymes & Cofactors***). Nickel is believed to be essential for a chemoautotrophic origin of life.[40] Early studies of the essentiality of nickel indicated that nickel is beneficial for reproductive performance of experimental animals. Nickel deprivation during reproduction in rats is known to increase perinatal mortality.[41] Nickel deprivation of breeding goats significantly decreased the success rate of first insemination and conception rate, and increased the abortion rate.[42] The recent research in rats revealed that nickel deprivation decreased spermatozoa motility and density in the epididymides, epididymal transit time of spermatozoa, and testicular sperm production rate.[43] These findings can explain some parts of the decreased reproduction of nickel-deficient animals. Physiological concentration of nickel is known to potentiate CNG cation channels in the rod outer segments of retinae and to desensitize CNG cation channels of olfactory receptor cells.[9] Decreased spermatozoa motility of nickel-deficient rats may be attributable to the spermatic CNG channels that have a key role in activating flagellar movements. Further investigations of nickel functions in higher organisms including humans are awaited.

5 SUMMARY

In Greek mythology, when Phylacus was gelding rams, his son Iphyclus was frightened by his father's knife. After growing up, Iphyclus could not have children. The seer Melampus cured Iphyclus's male infertility or sexual impotency by having him drink rust scraped from his father's knife stuck on the sacred oak.[44] Perhaps this was one of the first manifestations of the belief system 'You are what you eat'. According to Guggenheim,[45] Thomas Sydenham (1624–1689) of London in 1661 treated chlorotic maidens with an iron syrup or a steel tonic, which he prepared from soaking steel filings in wine. This process presumably produced ferrous potassium tartrate. Hippocrates of Cos, in the fifth century BC, recommended the use of roasted flower of copper or copper ore ('chalcitis') with natron and other ingredients soaked in sweet wine for treatments of fistulae, ulcers, hemorrhoids, and other diseases.[46] Not long ago, table salt was a luxury item, heavily taxed and greatly coveted. Now some treat salt as a nutritional pariah. Paracelsus, one of the great alchemists, was a true believer in the efficacy of metal ions to cure and prevent disease. Paracelsus recognized 'sal' (salt or ash) as the active principle always found in all organisms as well as inanimate matters. He wrote one of the most prescient observations that serves us well today 'Only the dose makes the poison'.[47] It is our challenge to understand the optimal human mineral requirements and apply dietary strategies to ensure optimal health for all.

1 INTRODUCTION

The 1963 Nobel Prize in Chemistry was awarded to Karl Ziegler and Giulio Natta for their research on catalysts (*see Catalysis*) for the oligomerization (*see Oligomer*) and polymerization (*see Polymerization*) of alkenes under mild conditions of temperature and pressure. Their discoveries have grown into a multibillion dollar industry for the production of plastics, elastomers, and inexpensive feedstock chemicals for copolymers, surfactants, and other useful additives.[1,2]

Homogeneous oligomerization and polymerization catalysts were for many years in the shadows of their heterogeneous counterparts but began to attract the interest of industrial and academic chemists since the late 1970s. The term ‘homogeneous’, when applied to polyalkene catalysis, does not necessarily mean that catalysts, reactants, and products are in a single phase; soluble polymerization catalysts, for example, become heterogeneous if the polymer precipitates from solution. Instead, we define a ‘homogeneous’ polymerization as one having a single type of active site, resulting in far more uniform products than those possible with, in the case of polymerization, multisited heterogeneous Ziegler–Natta catalysts (*see Ziegler–Natta Catalysts*).

As economics and demands of the marketplace require more tailored preparations of polyalkenes, researchers continue to work toward turning the ‘art’ of polyalkene catalysis into a science. Understanding and controlling the active catalyst species and the processes by which alkene-based macromonomers are formed offers the opportunity for preparing products of targeted characteristics or with greater selectivity. This article examines the more important homogeneous polymerization and oligomerization catalysts, emphasizing well-characterized systems.

2 BACKGROUND

Oligomerization and polymerization are processes by which a monomer M or monomers M and N are coupled into higher molecular weight molecules consisting of repeating units (equation 1).

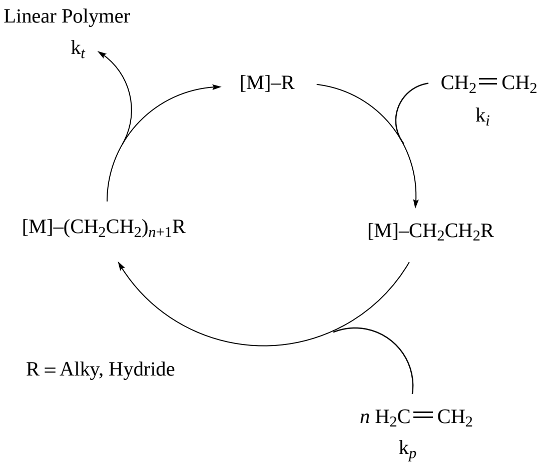
$$x\,\mathrm{M} \longrightarrow (\mathrm{M})_x$$
$$x\,\mathrm{M} + y\,\mathrm{N} \longrightarrow (\mathrm{M})_x(\mathrm{N})_y \qquad (1)$$

Dimerization occurs when x or $x + y = 2$. The products are considered oligomers when x or $x + y =$ from about 2 to 100. Molecules of more than about 100 monomer units are considered polymers. Homo-oligomers or -polymers result when one monomer is used. Co-oligomers or -polymers are formed from two or more different monomers. The distribution of comonomers in a co-oligomer or copolymer may be random (NMMNMMNMNMMNN), alternating (NMNMNMNMNMNMN), or blocked (NNNNNNNMMMMMM).

Branching can result from the chain-growth process or from branching groups in the monomers. For example, ethylene can be polymerized by a radical process to a highly branched low-density polyethylene (LDPE) or copolymerized with small amounts of α-alkenes like 1-hexene or 1-octene using a metal-mediated catalyst; the result is a linear polyethylene punctuated by short-chain branches and known as linear-low-density polyethylene (LLDPE).

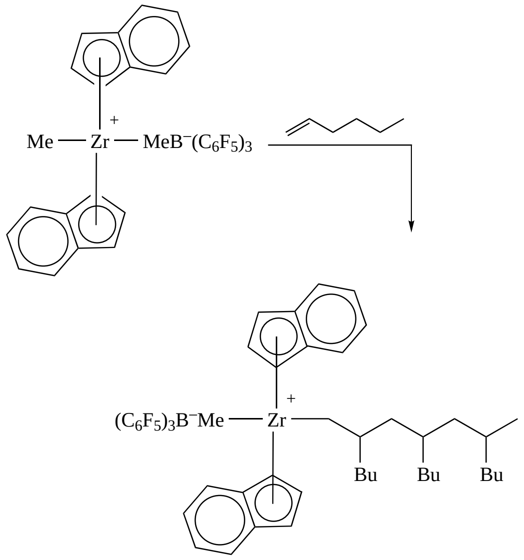
Oligomerization and polymerization catalysis by metal complexes comprises three steps: initiation, propagation, and termination. Chain growth proceeds at a coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) center having a metal–carbon or metal–hydride (*see* ***Hydride Complexes of the Transition Metals***) bond, usually generated by the interaction of a metal complex with an activating species such as an alkylaluminum cocatalyst. The first insertion of an alkene monomer into the metal–carbon or metal–hydride bond (chain initiation) is followed by repeated insertions

(propagation) until the chain is eliminated (termination), causing the cycle to start again (equation 2). Alkenes (cyclic olefins and α-olefins), dienes, and alkynes with terminal unsaturation make the most suitable monomers; internal alkenes are more difficult to polymerize, though certain nickel catalysts will polymerize *trans*-2-butene to poly(*trans*-2-butene).[3]



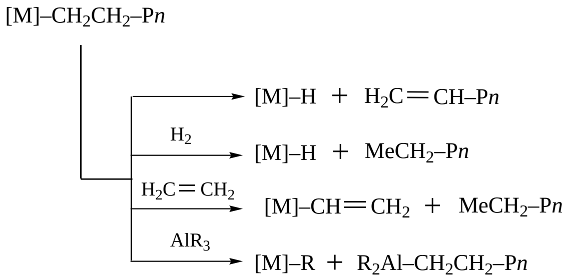
(2)

The mechanism of chain propagation now seems to be clear, following the Cossee (*see Cossee–Arlman Mechanism*) suggestion of chain growth by stepwise cis migratory insertion of the alkene into the metal–carbon bond.[4] Homogeneous catalysis has been invaluable in elucidating the chain-growth process, both in experimentation with model systems[5,6] and in theoretical calculations based on these complexes.[7] For example, the stepwise initiation and growth of a chain was observed by NMR spectroscopy using a precisely defined zirconium-based catalyst 1,2-Et(Indenyl)$_2$Zr$^+$Me(MeB$^-$(C$_6$F$_5$)$_3$) (equation 3);[8] such observations would have been impossible with the classic Ziegler–Natta catalyst systems.



(3)

The predominant chain termination mechanisms are (i) β-hydride elimination (*see Polymerization*), giving a chain with a terminal alkene; (ii) reaction with hydrogen, frequently used to control chain length; (iii) chain transfer to monomer by σ-bond metathesis (*see σ-Bond Metathesis*); and (iv) chain transfer to cocatalyst (equation 4).



(4)

The ratio of the rate of propagation (k_p) to the rate of termination (k_t) determines the molecular weight of the polyalkene:

- $k_p \gg k_t$ high polymers
- $k_p \approx k_t$ oligomers
- $k_p \ll$ kt dimers

Catalysts based on high-valent compounds of the early transition series (groups 3–5) and the lanthanides and actinides generally form high polymers; these electron-deficient (*see Electron Deficient Compound*) metal complexes are poor π-bases and have little ability to bond either into the σ^* orbital on the β-C–H bond or into the π^* of the bound alkene. The later transition metals (groups 9–10) are far more electron-rich; β-elimination (*see β-Elimination*) is much faster and dimers and oligomers are produced.

Chains with monodisperse molecular weight distribution (Mw/Mn = 1.00) can occur in idealized conditions when all polymerizing centers initiate instantaneously and chain termination is absent. In these cases the catalyst is actually an initiator. These 'living' polymerizations are quite rare among transition metal catalysts. More often, random chain termination leads to many chains formed per metal atom. A Schulz–Flory 'most probable' distribution of polyalkene molecular weights (Mw/Mn = 2.00) is the result.[9] In cases when more than one type of active site is present, bimodal or multimodal distributions of molecular weights result (Mw/Mn > 2.00).

Branched α-alkenes, most notably propylene, can insert in either a Markovnikov (secondary or 2,1) fashion or anti-Markovnikov (primary or 1,2) fashion (equation 5). Depending on the regioorientation of the next inserting monomer, this can lead to head-to-tail sequences (the most frequent in polypropylene), head-to-head or tail-to-tail. An illustration of the possible structures is shown in the catalytic dimerization of propylene by nickel catalysts (Figure 1). n-Hexenes, methylpentenes, and 2,3-dimethylbutene can be formed by the nickel hydride catalyst

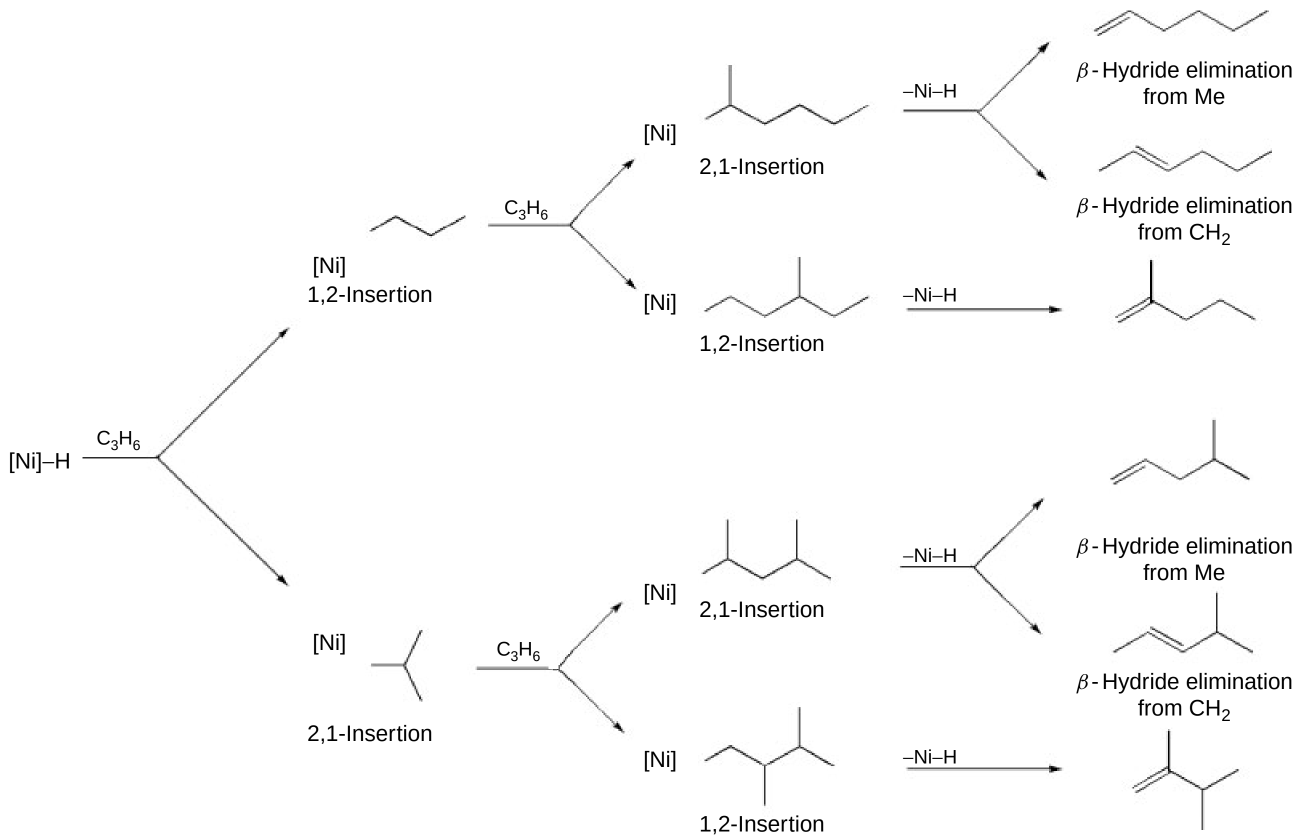


Figure 1 Regioisomerism in the dimerization of propylene

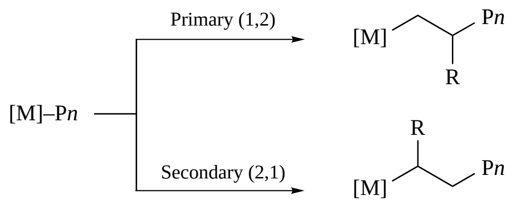
depending on the sequence of 2,1 and 1,2 insertions (*see Insertion*).



(5)

The regularity with which the branch groups of poly(α-olefins) are oriented leads to products of different properties. Propylene, for example, is prochiral and can polymerize with the methine carbons in either an (R) or (S) configuration. Two adjacent units with similar orientations are called a meso or m dyad while two adjacent units with different configurations are called rac or r dyads. Propylene in which the methyl groups are randomly oriented (random r and m dyads) is referred to as atactic, a rubbery material with limited commercial value (Figure 2). Isotactic polypropylene, where the methyl groups all have the same stereoorientation (all m dyads), is a crystalline material with many important applications. Syndiotactic polypropylene, with alternating sterocenters (all r dyads), can only be produced from homogeneous catalysts.

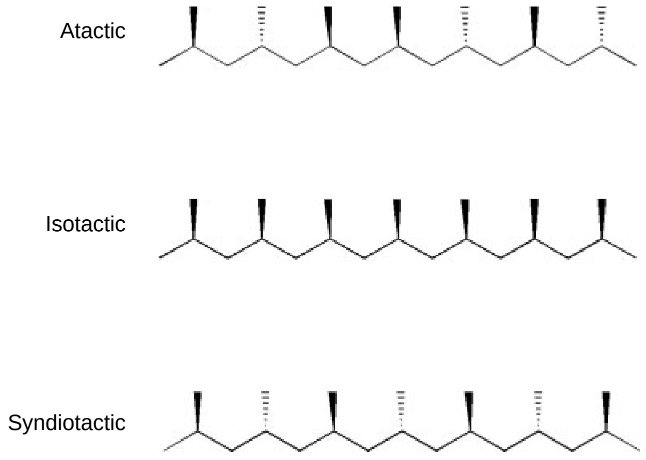


Figure 2 Structures of propylene polymers (with Bovey dyad notation)

1,3-Butadiene can be polymerized to four different microstructures: *cis*-1,4, *trans*-1,4, isotactic 1,2 and syndiotactic 1,2 (Figure 3). All four microstructures can be prepared

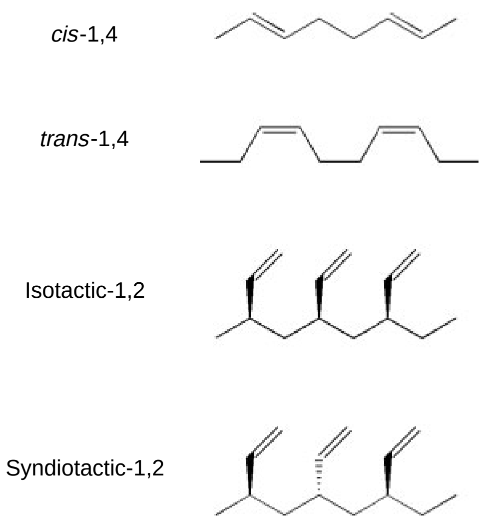

Figure 3 Structures of poly(1,3-butadiene)

to >95% selectivity using a wide variety of transition metal catalysts.[10]

Conventional heterogeneous catalysts have several drawbacks. Frequently a multiplicity of active sites (*see Active Site*) are generated by the interaction of the transition metal catalyst and the cocatalyst. Each type of active site has its own rates of initiation, propagation, termination, regio- and stereoregularity, and copolymerizing ability. The formation of complex mixtures of products containing undesirable species (chains with too many or too few branches, internal alkenes, high or low-molecular weight fractions, noncrystalline polymers) can give unwanted by-products, requiring costly separations or affording materials with inferior properties for a given application. Furthermore, the complexity of these catalysts limits our ability to understand and control their behavior.

Homogeneous polyalkene catalysts have three basic components: 1) a metal center; 2) a set of ligands (*see Ligand*) which react with cocatalyst and/or incoming monomer, and 3) a nonreactive ancillary ligand or ligands to limit the formation of multiple active catalyst species and control the electronic and steric environment around the active site. These catalysts afford much more uniform products than can be made from traditional heterogeneous systems. Alterations in the ancillary ligand set can be done rationally and molecular modeling can give insights into the response of the catalyst to the change.[7,11] An impressive array of instrumental techniques can be brought to bear in characterizing catalyst structures, catalytic mechanisms and products. High-throughput experimentation using automated process and data handling now allows researchers to screen a diverse array of catalysts far more quickly than serial testing.[12]

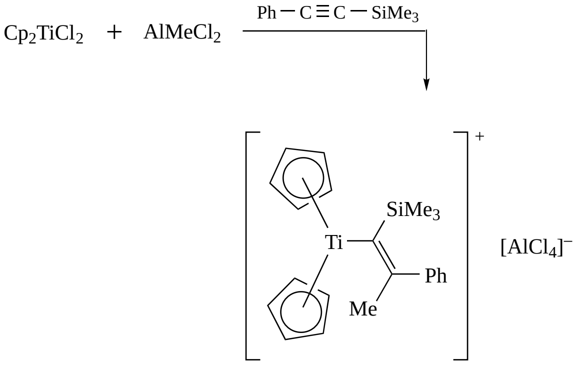
The ancillary ligands used in homogeneous polyalkene catalysis have become extraordinarily diverse, partly to exploit hitherto uninvestigated metals and partly to avoid the legal tangles associated with the industrial development of these systems. However, these ancillary ligands largely fall into three basic classes:

- Pi-bonded ligands, principally cyclopentadienyl (*see Cyclopentadienyl*) (especially in the earlier group metals) but also isolobal equivalents (*see Isolobal Analogy*) such as phospholes, boratabenzenes, and azaborolinyls.
- Sigma-bonded anionic ligands, usually chelating (*see Chelating Ligands*) ones such as β-diketenimides.
- Neutral ligands, which may be chelating or nonchelating.

All this does not suggest that homogeneous catalysts are prisoners of the laboratory. Homogeneous oligomerization and polymerization catalysts are now widely used industrially and new developments are constantly being brought into the commercial sphere.

3 GROUP 4 METALS

It was with the group 4 metals that homogeneous alkene polymerization catalysts began, almost contemporaneously with the discovery of Ziegler–Natta polymerization catalysts and cyclopentadienyl metal complexes. The Cp_2TiCl_2–$AlEt_2Cl$ catalyst discovered by Natta[13] and Breslow[14] was used extensively as a model system for heterogeneous polymerization catalysts, yielding many valuable insights into the mechanism of polymerization and active-site characterization. For example, electrochemical studies suggested the active polymerizing species was a $[Cp_2TiR]^+$ cation.[15] Subsequently, this species was characterized after trapping with a nonpolymerizable alkyne (equation 9).[16]



(6)

This catalyst is unsuitable for commercial applications because of its facile reduction to inactive Ti^{III} species in hydrocarbon solvents, its sluggish polymerization activity compared to conventional Ziegler–Natta catalysts, and its inability to polymerize propylene.

A breakthrough in the field took place in the mid-1970s when these group 4 metallocenes were combined with methylalumoxane, the product of the partial hydrolysis of trimethylaluminum (equation 7), to afford catalysts of vastly higher activity, especially of

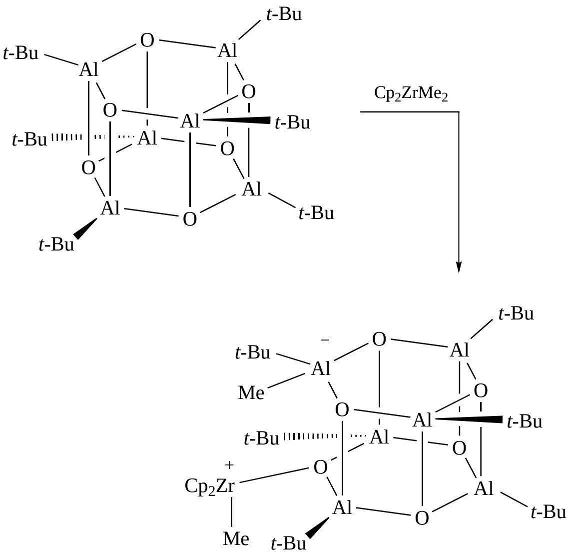
$$AlMe_3 + CuSO_4(H_2O)_5 \xrightarrow{\text{Toluene}} [AlOMe]_n \qquad (7)$$
$$n = 5{-}25$$

zirconocenes.[17] The subsequent discovery[18] that substitutions on the cyclopentadienyl ring had a profound influence on activity, polymer molecular weight (from waxes to ultrahigh molecular weight materials), reactivity toward comonomer (from elastomers to high-density polyethylene), and stereospecificity in α-olefin polymerization began the great industrial development of homogeneous polymerization catalysts of the group 4 metals. These have long been dominated by metallocenes (*see Metallocene Complexes*), but highly effective catalysts with novel ancillary ligands are now coming on stream.

Catalysts of the group 4 metals are much used in the commercial production of high olefin polymers, principally ethylene and propylene homo- and copolymers. When the polymer is particularly rich in comonomer (ethylene-propylene copolymers, ultra low-density ethylene copolymers), it is of low crystallinity and usually soluble in a hydrocarbon medium. For polymers of greater crystallinity (high-density polyethylene, isotactic polypropylene), the catalysts must be heterogenized on an inert support such as silica to ensure uniform morphology of the polymer particles, essential to smooth process operations. Many supports and supporting techniques have been developed to ensure high catalyst activity and good particle morphology without alteration of polymer properties.[19]

Almost all group 4 metal complexes require a cocatalyst to generate an active metal–alkyl cationic species.[20] Ordinary alkylaluminums – used in conventional Ziegler–Natta catalysts – are insufficient to activate these compounds on their own. The principal activator used is methylalumoxane (MAO), a structurally enigmatic material with a mixture of nuclearities.[21] Its purpose is to alkylate the metal dichloride and to abstract one of the reactive ligands to form the ion pair active catalyst. The interaction is dynamic and a large excess of MAO is needed for effective catalyst performance, thus inhibiting a comprehensive characterization of these catalysts.

By switching from $AlMe_3$ to $Al(t\text{-}Bu)_3$, alumoxanes of discrete nuclearities can be isolated. $(t\text{-}BuAlO)_6$ was structurally characterized and its interaction with Cp_2ZrMe_2 studied spectroscopically, indicating that the alumoxane abstracted a methyl group to generate a catalytically active tight ion pair with the oxygen atom of the alumoxane coordinated to the zirconium cation (equation 8).[22]



(8)

Highly active, yet completely characterizable catalysts are formed from Cp'_2MMe_2 and perfluorinated arylborates such as $B(C_6F_5)_3$[23] and $[Ct][B(C_6F_5)_4]$ ($[Ct]^+ = [HNMe_2Ph]^+$[24] or $[Ph_3C]^+$[25]). These form ion pairs with noncoordinating anions (*see Noncoordinating Anion or Cation*), which are largely resistant chemically to degradation by the strongly Lewis acidic metal cation. The neutral $B(C_6F_5)_3$ activator abstracts an alkyl group from Cp'_2ZrMe_2 to form $[Cp'_2ZrMe][Me(B(C_6F_5)_3)]$, adducts of which can be isolated and characterized crystallographically (*see X-ray Crystallography*).[23] The borane and borate cocatalysts also have the advantage of being used in near stoichiometric quantities with respect to the metal complex. In a further refinement, simple alkylaluminums can be used to alkylate the metal dichlorides before reaction with the activating boron cocatalysts (equation 9).[26]

$$[Cp'_2MR][RB(C_6F_5)_3]$$
$$\uparrow B(C_6F_5)_3$$
$$Cp'_2MCl_2 + AlR_3 \longrightarrow Cp'_2MR_2 + AlCl_2 \qquad (9)$$
$$\downarrow [Ct][B(C_6F_5)_4]$$
$$[Cp'_2MR][B(C_6F_5)_4]$$

The extent to which the metallocene framework can be modified is extraordinary indeed, with from one to four different substituents on each ring or a covalent bridging group like 1,2-ethylene or dimethylsilyl to lock the rings into one particular conformation and open the active site to varying degree. All these factors have an influence on catalyst performance and polymers produced.[27] An example

Table 1 Ethylene polymerization by 1,2-Et(Flu′)(Flu′)$ZrCl_2$–MAO catalysts

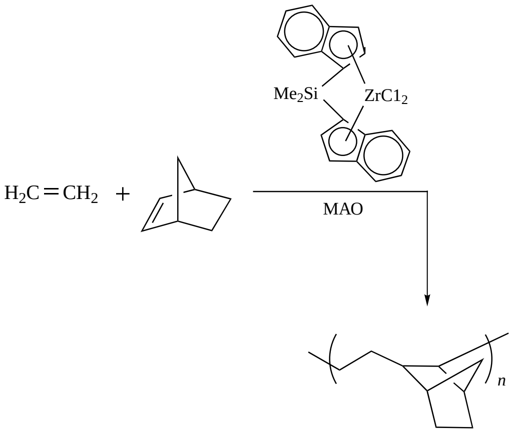
[a]Reference compound.

with just one class of substituted 1,2-ethylene bridged bis(fluorenyl)zirconium dichlorides is shown in Table 1, with catalyst activities and polymer molecular weights ranging over an order of magnitude.[28]

Metallocene group 4 catalysts are now used for the commercial production of ethylene/α-olefin copolymers with superior properties (clarity, tear strength, extractables) to those from conventional Ziegler–Natta catalysts. Metallocenes also excel in the copolymerization of ethylene with olefin monomers generally not reactive with Ziegler–Natta systems. For example, copolymers of ethylene with cyclic olefins like norbornene have desirably high glass transition temperatures (>100 °C). Conventional Ziegler–Natta catalysts



(10)

produce copolymers with unwanted unsaturation from ring opening. Metallocene catalysts afford high molecular weight products with high T_g without residual unsaturation (equation 10).[29]

It is in the stereospecific polymerization of propylene that metallocene complexes display their astonishing versatility.[30] Commercial Ziegler–Natta catalysts for isotactic polypropylene – based on combinations of $TiCl_4$, $MgCl_2$, Lewis bases and aluminum alkyls – depend on a metal-centered chirality which exists at specific edge and defect sites on the crystal lattice to direct the incoming monomer in a particular orientation. These catalysts produce small amounts of undesirable atactic material due to the presence of achiral active sites.

Until the mid-1980s, no homogeneous catalyst for the stereospecific polymerization of propylene existed: Cp_2ZrCl_2-MAO produces only atactic material. Isospecific polymerization in which the stereoorientation of the monomer is caused by the active polymerizing site can be induced by stereorigid metallocenes which have chirality centered at the transition metal. Such metallocenes have groups bridging the two cyclopentadienyl rings and substituents in the β-positions of the cyclopentadienyl groups. The steric constraints exerted by the ring substituents on the polymer chain force the chain into one particular orientation, which serves to direct the incoming monomer (Figure 4). The achiral meso complex has no orienting ability and gives atactic material. It is quite interesting that detailed mechanistic studies have established that stereoerrors (...mmrrmm...) are not the result of insertion of the wrong enantioface of the monomer but are caused by epimerization of the chiral center at the chain-end near the metal.[31]

The first catalyst to produce isotactic polypropylene at meaningful temperatures was the C_2-symmetric

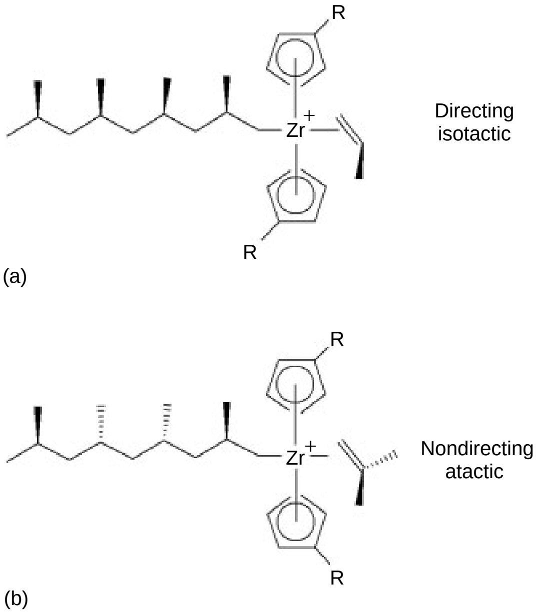


Figure 4 Polymer chain and monomer orientation in rac (a) and meso (b) isomers of stereorigid substituted zirconocene catalysts

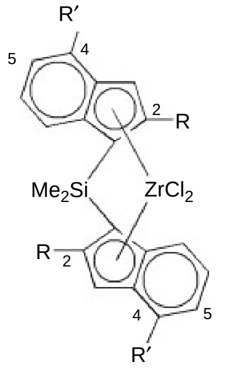


(**1**)

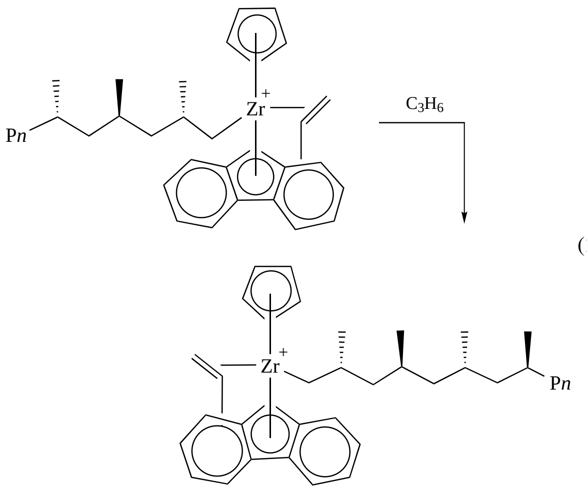
Figure 5 Structure of substituted dimethylsilyl-bridged bis(indenyl)zirconium dichlorides

complex *rac*-1,2-Et(4,5,6,7-tetrahydroindenyl)$_2$ZrCl$_2$ activated by MAO.[32] The polypropylene produced from this catalyst is of only modest molecular weight and isotacticity, but this disclosure served to set off a detailed search for more active catalysts to produce polypropylene of melting points and molecular weights produced by conventional Ziegler–Natta catalysts (mp = 165 °C, Mw = 900 000). This research effort, largely undertaken at Hoechst, made serial changes to the metallocene framework to improve its performance as a catalyst.[33] The use of a dimethylsilyl bridge (**1**, Figure 5) makes preparation of the complexes simpler and slightly improves activity, molecular weight, and stereospecificity. Adding a methyl group in the 2-position of the indenyl ring significantly increases the regioregularity of propylene insertions, increasing the melting point as well as the molecular weight. Substituents in the 4-position (or 4,5-benzoindenyl) have an enormous influence on catalyst performance (Table 2).

Syndiotactic polypropylene arises from the coordination of alternating enantiofaces of the incoming monomer. This can be induced by metallocene catalysts through the use of C_s symmetric metallocene catalysts such as Me$_2$C(Cp)(Fluorenyl)ZrCl$_2$–MAO (equation 11).[34] This material is now sold commercially, though the long crystallization time from the melt has limited its applications.

Table 2 Propylene polymerization by Me$_2$Si(Ind′)$_2$ZrCl$_2$-MAO catalysts

Ind′	Activity (kgPPmmol^{-1} Zr^{-1})	Mw ($\times 10^{-3}$)	M.p. (°C)
Indenyl	190	36	137
2-Methylindenyl	99	195	145
4-Isopropyl-2-methylindenyl	250	210	150
4-Phenyl-2-methylindenyl	550	730	157
4-(1-Naphthyl)-2-methylindenyl	880	920	161



(11)

Substituents in the distal position of the cyclopentadienyl ring in these cyclopentadienyl-fluorenyl catalysts has a profound effect on the polymer product produced. A small substituent like methyl produces a novel material, hemiisotactic polypropylene, in which methine carbons of specific conformation alternate with methine carbons of random conformation.[35] A larger substituent like *t*-butyl makes isotactic polypropylene (Figure 6).

Elastomeric polypropylenes with thermoplastic behavior can be prepared from conformationally dynamic metallocenes such as bis(2-arylindenyl)zirconium dichlorides.[36] These can exist in two conformations in the course of the chain lifetime: a chiral rac isomer which is stereodirecting and an achiral meso isomer which is aspecific. The resulting polymer consists of blocks of isotactic polypropylene alternating with runs of atactic material (equation 12).

(**5**)

Figure 9 Nonmetallocene single-site catalysts of the group 4 metals

Group 4 metal complexes without two cyclopentadienyl rings have figured more prominently in polyolefin catalysis in recent years. Substituting an amide for one cyclopentadienyl ring in a bridged complex form the family of ‘constrained geometry’ catalysts discovered by Exxon and Dow.[37,38] Unlike in bis(cyclopentadienyl) complexes, where zirconium is preferred to titanium or hafnium, in these cyclopentadienyl-amide catalysts, titanium complexes like (**2**) in Figure 7 are preferred, yielding catalysts of high activity and high reactivity toward α-olefins, producing high molecular weight low-density copolymers ($<0.88\,\mathrm{g\,cm^{-3}}$). These catalysts can reincorporate chains with terminal olefins, leading to polymers with long-chain branching, which is valuable in improving the processablity of the material.[39]

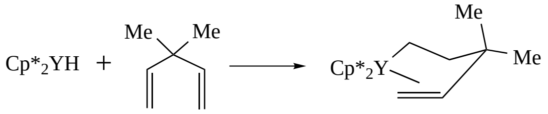
Monocyclopentadienyl complexes of titanium ($Cp'TiX_3$) perform poorly as catalysts for ethylene or propylene polymerization, but in the presence of MAO, they polymerize styrene to stereo- and regioregular syndiotactic polystyrene,[40] a crystalline material with very high melting point (273 °C) and glass transition temperature (100 °C).[41] In this case, the active polymerizing species is a Ti^{III} complex (Figure 8). Each styrene monomer inserts in a secondary manner and the stereoregularity is maintained by the conformation of the last inserted unit (chain-end control).

Nonmetallocene homogeneous catalysts of the group 4 metals have received no small amount of attention in recent years.[42] These largely fall into two main categories. One of them is isolobal equivalents to cyclopentadienyl, such as the boratabenzene complex (**3**) (Figure 9);[43] this catalyst can form

chains from oligomers to high polymers depending on the nature of the substituent R. The second class is chelating sigma-bonded anions. Two of the more commercially interesting of these are the class of phenoxyimine titanium and zirconium complexes (**4**), some of which exhibit high activities and, suitably substituted, are capable of polymerizing propylene to syndiotactic polypropylene.[44] The family of pyridine amide compounds (**5**) has also received considerable attention; the hafnium complex polymerizes propylene to isotactic polypropylene.[45]

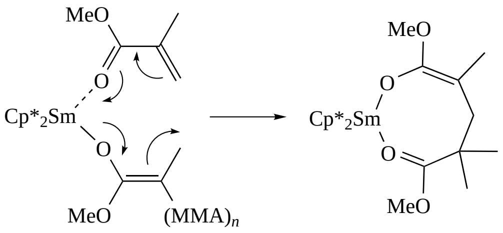
4 GROUP 3 METALS, LANTHANIDES AND ACTINIDES

The d^0 group 3 and lanthanide complexes Cp'_2MR are isoelectronic with the $[Cp'_2MR]^+$ catalysts discussed in the previous section. These nonionic complexes are soluble in most hydrocarbons and as one-component systems make ideal models for many of the fundamental processes in polymerization catalysis.[5] For example, an alkyl–alkene complex can be observed by NMR when $Cp*_2YH$ is allowed to react with an α,ω-diene (equation 13).[46]



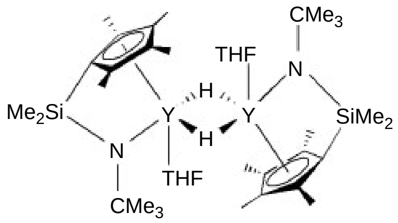
(13)

Neutral lanthanide-series metallocenes exhibit the remarkable ability to polymerize polar monomers such as methyl methacrylate to highly stereoregular polymers of extremely narrow molecular weight distribution ($Mw/Mn \approx 1$) (equation 14).[47] It is possible to prepare block copolymers of ethylene and poly(methyl methacrylate) by first adding MMA to $Cp*_2SmMe$ to produce a PMMA segment followed by addition of ethylene; the reverse order of addition fails to give block materials because the ethylene monomer cannot insert into the enolate.



(14)

Such bis(pentamethylcyclopentadienyl) complexes exhibit extremely high activities in ethylene homopolymerization but the steric constraint of the permethylated rings does not allow insertion by higher α-olefins. Less constraining ligand environments like that in (**6**) (Figure 10) result in dimerization with consequent loss of activity. Compound (**6**) is a more



(**6**)

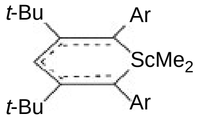
Figure 10 Cyclopentadienyl-amide hydride complex of yttrium

versatile catalyst, polymerizing styrene to atactic polystyrene and t-butyl acrylate.[48]

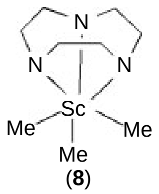
Ionic systems – less susceptible to deleterious dimerization – are accessible with a judicious choice of ancillary ligand. The β-diketoiminate scandium dimethyl complex (**7**) (Figure 11; Ar = 2,6-diisopropylphenyl), activated by $B(C_6F_5)_3$ leads to a structurally characterizable ionic complex which polymerizes ethylene.[49] The neutral 1,4,7-triazocyclononane ligand was used to prepare a scandium trimethyl complex (**8**), which polymerizes ethylene when $B(C_6F_5)_3$ is used as a cocatalyst.[50] A derivative pendant amide arm leads to the yttrium bis(trimethylsilylmethyl) compound (**9**), which exhibits modest activity in the presence of $[HNMe_2Ph][B(C_6F_5)_4]$.[51]

The actinide dimethyl complexes $Cp*_2MMe_2$ (M = Th, U) are virtually inert in ethylene polymerization but are far more active when adsorbed on dehydroxylated alumina (*see Alumina*).[52] Solid-state ^{13}C NMR studies suggest that surface bound $[Cp*_2MMe]^+$ species are generated (Figure 12).

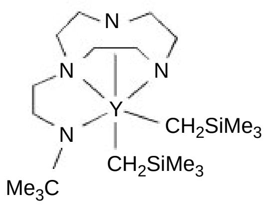
Because of the larger ionic radius of the actinide metals versus the group 4 metals (Th^{4+} = 1.08 Å vs. Zr^{4+} = 0.79 Å), organoactinides make good test compounds for the relative noncoordination of ionic activator anions.



(**7**)



(**8**)



(**9**)

Figure 11 Nonmetallocene single-site catalysts of the lanthanides

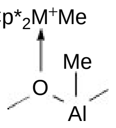


Figure 12 Proposed structure of $Cp^*_2MMe_2$ (M = Th, U) adsorbed on alumina

For example, the compound $[Cp^*_2ThMe]_2[(C_2B_9H_{11})_2Fe]$ is completely inactive in ethylene polymerization owing to strong coordination of the anion to each thorium center (the zirconium analog is an active catalyst)[53] but $[Cp^*_2ThMe][B(C_6F_5)_4]$ rapidly polymerizes ethylene.[54]

5 GROUP 5 METAL COMPLEXES

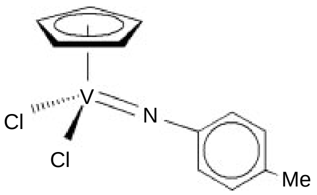
Vanadium-based homogeneous catalysts have found their greatest value in the commercial production of elastomeric ethylene-propylene copolymers.[55] Dienes such as dicyclopentadiene, 1,4-hexadiene, and ethylidenenorbornene are frequently used as termonomers for cross-linking, reducing the degree of unsaturation and making the material more resistant to environmental attack. While not highly active and prone to decomposition at elevated temperatures, these catalysts produce desirable copolymers owing to their lack of selectivity with respect to the individual monomers. Regio- and stereoirregularities produce a product with very little crystallinity arising from block distribution of comonomers and isotactic propylene segments.

$VOCl_3$ or V(β-diketonate)$_3$ in conjunction with alkylaluminums like $Al_2Et_3Cl_3$ appears to function as a single-site catalyst, giving a polymer with a low polydispersity. The paramagnetic (*see Paramagnetism*) nature of these systems and their low stability have inhibited their comprehensive characterization.

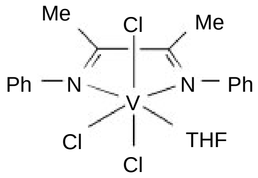
At $-78\,°C$, the soluble catalyst system $VCl_4/AlEt_2Cl$ polymerizes propylene to a predominantly syndiotactic polymer.[56] A secondary insertion of propylene into the V–C bond was invoked to explain this phenomenon, a hypothesis subsequently confirmed experimentally.[57]

These catalysts display less stereo- and regiospecificity than their isospecific counterparts and the directing effect is lost at higher temperatures, where atactic polymer is produced.

Recently, efforts have been made to expand the number of homogeneous vanadium catalysts using ancillary, nonreactive ligands. These catalysts may be in the +5, +4 or +3 oxidation states. The dianionic imido ligand is isolobal with cyclopentadienide and has been used to prepare diamagnetic, formally d^0 metal compounds like (**10**) (Figure 13) which, when activated by MAO, display modest activity for ethylene polymerization.[58] VCl_3 complexes of α-diimines

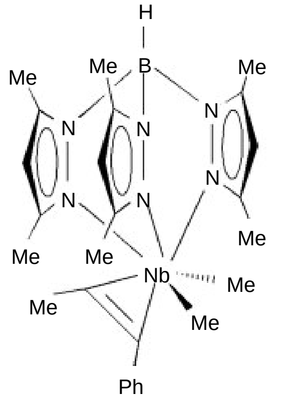


(**10**)

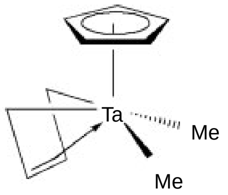


(**11**)

Figure 13 Nonmetallocene single-site catalysts of vanadium



(**12**)



(**13**)

Figure 14 Single-site catalysts of niobium and tantalum

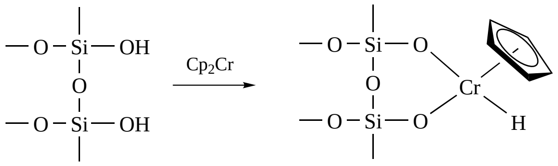
like (**11**) display well-resolved ^1H NMR spectra, their paramagnetism notwithstanding.[59] They polymerize ethylene in the presence of $AlEt_2Cl$, but MAO degrades the catalysts rapidly.

Just as imido ligands (*see Imide Complexes*) have been used as cyclopentadienyl surrogates in group 5 and 6 metals, the alkyne ligand can be used as an imido surrogate in a series of niobium catalyst precursors such as (**12**) (Figure 14). These can be activated by $B(C_6F_5)_3$ to generate active systems for ethylene polymerization.[60] The isolobal concept also allowed investigators to move down the group 5 series to tantalum. The formally dianionic η^4-1,3-butadiene fragment is isolobal to cyclopentadienyl and has been used to prepare tantalum systems like (**13**) for use as catalysts in ethylene, norbornene, or methyl methacrylate polymerizations.[61]

6 GROUP 6 METAL COMPLEXES

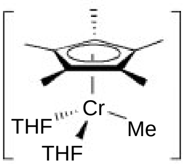
While molybdenum and tungsten catalysts are associated with metathesis polymerization (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***), chromium catalysts are widely used in the production of polymers. The best-known system is the so-called Phillips catalyst, Cp_2Cr (*see*

Chromocene) deposited on silica; reaction of the metallocene with hydroxyl groups on the silica surface generates the active catalyst (equation 15). These ill-defined heterogeneous systems give high-density polyethylene with broad molecular weight distributions, indicative of multisited catalysts.

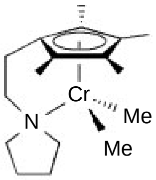


(15)

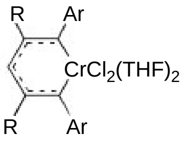
The commercial importance of chromium-based catalysts has inspired researchers to develop homogeneous systems that model the heterogeneous catalysts.[62] The cationic monomethyl complex (**14**) (Figure 15) represented the first working homogeneous analog for the Phillips catalyst, slowly polymerizing ethylene to linear polyethylene;[63] displacement of one tetrahydrofuran (THF) donor must take place for ethylene to react. The amino-substituted monocyclopentadienyl complex (**15**) activated by MAO exhibits high activity over a short polymerization time.[64] It also is capable of polymerizing propylene and 1-hexene, albeit at much lower rates. Complex (**17**), with a boratabenzene ligand (isolobal to Cp), is nearly as active as Cp_2ZrCl_2 under similar reaction conditions.[65] Strikingly, the activity of some of these 'model' systems is greatly increased when properly heterogenized; (**14**) $[BPh_4]$ has an activity of just 510 g PE/g Cr·hr by itself but supported on $Al_2O_3{\cdot}2AlPO_4$ increases to 233 000 g PE/g Cr·hr![66]



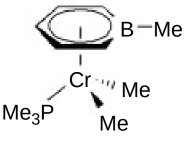
(**14**)



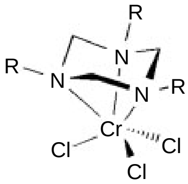
(**15**)



(**16**)



(**17**)



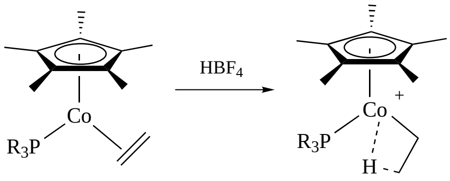
(**18**)

Figure 15 Homogeneous polymerization catalysts of chromium

Noncyclopentadienyl chromium complexes have also figured in polyolefin catalysis. The β-diketiminato chromium complexes like (**16**) polymerize ethylene and copolymerize ethylene and α-olefins in the presence of MAO.[67] The 1,3,5-triazacyclohexane complexes of $CrCl_3$ (**18**) polymerize ethylene in the presence of MAO or $[HNMe_2Ph][B(C_6F_5)_4]$/Al-*i*-Bu_3.[68] Some trimers are formed, resulting in butyl branches in the chain; higher α-olefins are trimerized.

7 IRON AND COBALT

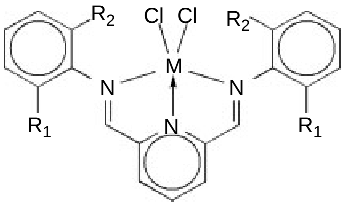
Cobalt complexes have been used as model systems for some of the chain-growth processes in olefin polymerization. Protonation of the ethylene complex $(C_5Me_5)Co(PR_3)(C_2H_4)$ with HBF_4 forms an ethyl cation with an agostic (*see Agostic Bonding*) interaction between the metal and the β-C–H bond, which can isolated and the structure determined crystallographically (equation 16); successive insertions of ethylene can be observed by NMR spectroscopy.[69]



(16)

Research into iron and cobalt compounds as oligomerization and polymerization catalysts has increased enormously since the disclosure that complexes of the metals with tridentate 2,6-diiminopyridine ligands (**19**; Figure 16) function as catalysts.[70,71] Fe(II) compounds with no substituents on the N-aryl rings ($R_1 = R_2 = H$) are inactive, those with one substituent ($R_1 = Me$, $R_2 = H$) yield oligomers and those with substituents in the 2- and 6- positions ($R_1 = R_2 = Me$) polymerize ethylene to high molecular weight material.

The Co(II) analogs are about an order of magnitude less active than the Fe(II) systems. They undergo reduction to Co(I) when alkylated and the actual active species appears to



(**19**)

Figure 16 2,6-diiminepyridine complexes (M = Fe, Co)

be an alkyl-free cobalt cation (equation 17).[72]

$$[\text{Lig}]\text{-CoCl}_2 \xrightarrow{\text{RMgX}} [\text{Lig}]\text{-CoMe} \xrightarrow{\text{B(C}_6\text{F}_5)_3} [\text{Lig-}]\overset{+}{\text{Co}}\text{-L} \qquad L = N_2, C_2H_4 \quad (17)$$

The performance of the catalysts is quite sensitive to the ligand environment.[73,74] For example, in the Fe(II) system, substituting pyrimidine for pyridine alters the activity only slightly while putting a furan or pyrrole group as the central donor almost completely shuts down activity.[75]

8 NICKEL AND PALLADIUM

Many MX_2, ML_2X_2, and ML_4 complexes (M = Ni or Pd; L = ancillary ligand; X = reactive ligand), activated by Lewis (*see Lewis Acids & Bases*) or Brønsted acids, or acting as single-component systems, are active for alkene oligomerization and polymerization.[76] Complexes with anionic ancillary ligands are usually single-component catalysts while those with neutral ancillary ligands exist as ion pairs (Figure 17). A judicious choice of ligands, solvents and conditions strongly influences chain lengths, linearity and α-alkene content. Polyalkenes ranging from dimers to ultrahigh molecular weight polyethylene can be prepared from suitably modified nickel and palladium catalysts of the same generic family.

Cationic allylnickel catalysts of the general formula $[(\eta^3\text{-}C_3H_5)NiL_2][X]$ have found wide use for studying ligand and anion effects in the polymerization of 1,3-butadiene.[77] Chain propagation occurs via *cis*-η^4 coordination of the butadiene monomer with insertion into a chain coordinated to the metal by an η^3 allyl. *Cis*-1,4- and *trans*-1,4-polybutadiene are formed from the η^3 allyl complexes in which the pendant chain is syn (thermodynamically preferred) or anti with respect to the metal (Figure 18). Large donors like (L = $P(OPh)_3$) favor the anti configuration with formation of *trans*-1,4-polybutadiene while smaller donors (L = MeCN) or no donor leads to selectivity for the syn configuration and the formation of *cis*-1,4-polybutadiene. Similarly weakly coordinating anions (PF_6^-, SbF_6^-) lead to the cis polymer while more strongly coordinating anions ($CF_3SO_3^-$) make the anti configuration preferable with trans polymer the product.

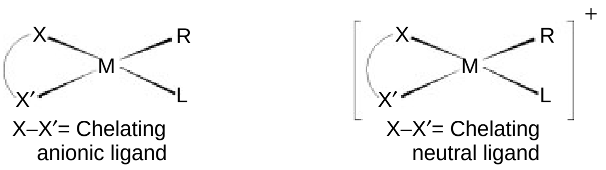


Figure 17 Structures of nickel and palladium complexes with neutral or anionic ligands

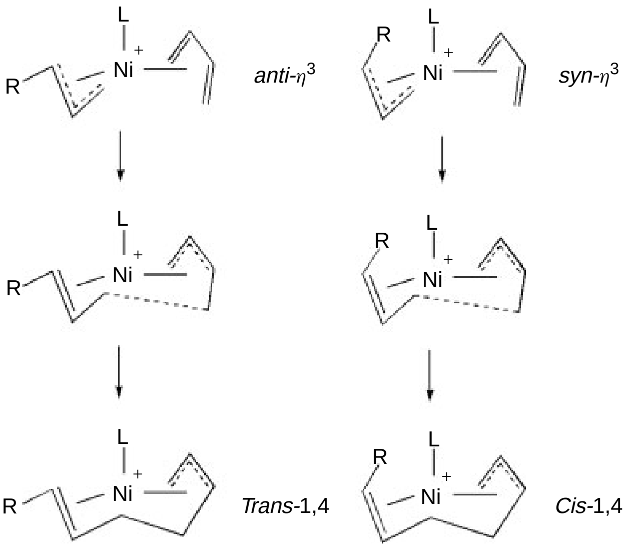

Figure 18 Transition states for formation of *cis*- and *trans*-poly(1,3-butadiene)

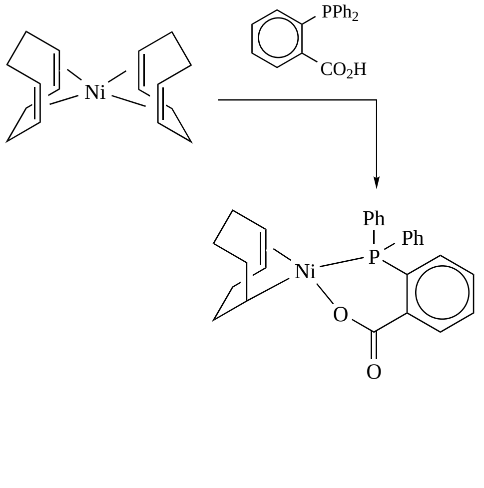
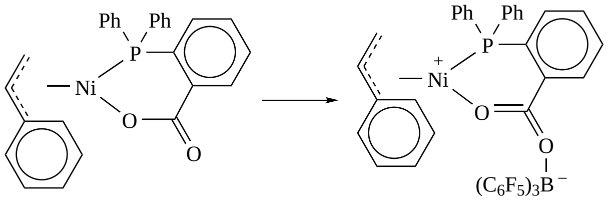
In the Shell Higher Olefin Process (SHOP), ethylene is oligomerized by single-component nickel catalysts which make α-alkenes of very high linearity (almost 99%) and high content of 1-olefin (96–98%). A mixture of C_4 to C_{40} alkenes is produced with the C_{12} to C_{20} fraction the most desirable. The light and heavy alkenes are removed and isomerized to internal alkenes in a separate reactor. The mixture is metathesized over a heterogeneous catalyst to desirable chain lengths.

The catalysts comprise a chelating ligand such as diphenylphosphinobenzoic or – acetic acid combined with nickel sources like (η^4-1,5-cyclooctadiene)$_2$Ni (equation 18) or $NiCl_2/NaBH_4$. A nickel hydride species is presumed to be the active catalytic species. On an industrial scale, the reaction is run in a polar solvent such as 1,4-butanediol, in which the catalyst is soluble but the olefin products are insoluble. Addition of $B(C_6F_5)_3$ to these systems converts them from neutral to zwitterionic (*see Zwitterion*) with a large increase in activity (equation 19).[78]

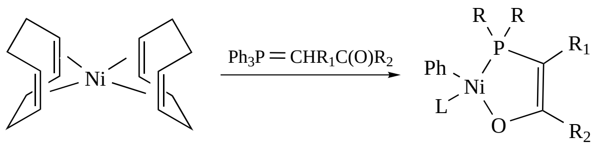


(18)



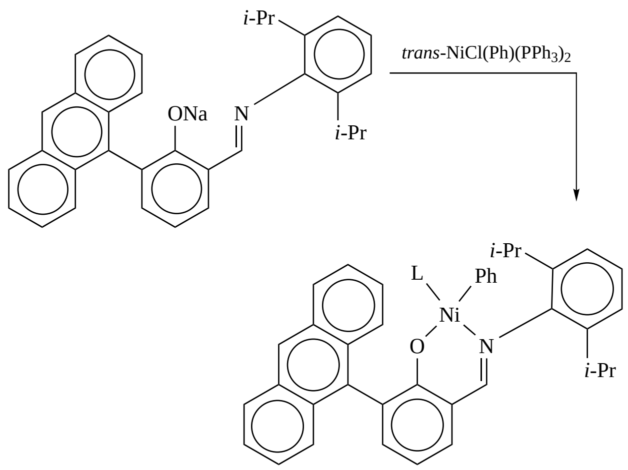
(19)

When phosphorus ylides (*see Ylide*) such as $Ph_3P{=}CH–C(=O)R$ are allowed to react with (η^4-1,5-cyclooctadiene)$_2$Ni or Ni(PR$_3$)$_4$ single-component catalysts are formed which polymerize ethylene to polyethylenes with molecular weights ranging from waxes (MW ≈ 1500) to ultrahigh molecular weight materials (MW > 10^6) and which are active even in polar solvents, including water (equation 20).[79] The molecular weight of the polymer can be modulated by choice of ligands and the use of phosphorus ylides affords particularly active catalysts.



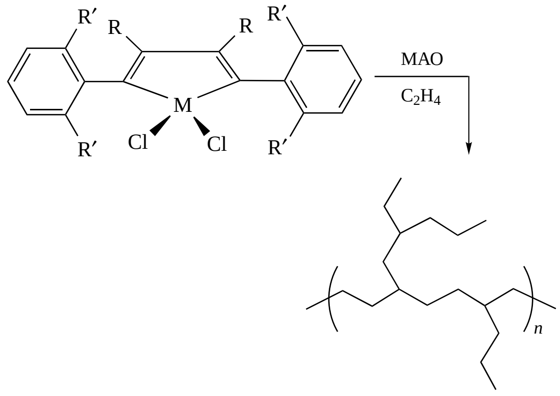
(20)

Another family of single-component catalysts uses salicylaldimides as ligands for nickel catalysts (equation 21).[80] Bulky groups like 9-phenanthryl in the 6- position on the phenyl ring inhibit chain termination and chain loss and encourage the formation of higher molecular weight polymer while using groups of smaller size (R = H) leads to the formation of waxes.



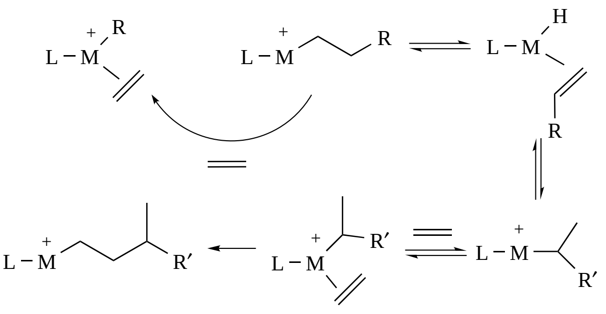
(21)

One of the more extraordinary recent developments in nickel and palladium polyalkene catalysis has been the development of α-diimines with bulky substituents as ligands in nickel and palladium complexes.[81] When bulky aryl groups are used (R′ = isopropyl), these catalysts polymerize ethylene with high activities to high molecular weight highly branched homopolyethylene (equation 22). In these catalysts, chain transfer is slowed by the large size of the



(22)

axial aryl groups. The highly branched nature of the polyethylene is ascribed to a 'chain walking' mechanism with occasional β-hydride elimination without chain loss followed by insertion of an incoming monomer (equation 23). The molecular weight of the polymer and branching are dependent on monomer concentration and axial substituents: polymers ranging from highly branched to highly linear can be produced. When the bulk of the axial substituents is reduced (R′ = H), oligomers are produced.[82]



(23)

Because of the relative rates of chain propagation versus chain walking, polymers from the bis(imine) catalysts can be quite different depending on the metal. Nickel complexes form polymers with mostly shorter-chain branches and more crystallinity while polyethylene from the palladium analogs is more highly branched, to the point it can be amorphous. The palladium complexes also have the ability to incorporate remarkably high (1–10 mole percent) amounts of polar monomers such as methyl acrylate and methyl vinyl ketone, though at considerable loss in activity.[83]

Palladium complexes figure prominently as well in the copolymerization of α-olefins with carbon monoxide.[84] Unlike the low molecular weight photodegradable random copolymers of ethylene and CO produced from a free-radical process, olefin/carbon monoxide copolymers produced from homogeneous palladium catalysts are perfectly alternating, the result of successive insertions of olefin and CO (Figure 19). Consecutive insertion of two similar monomers is either slow

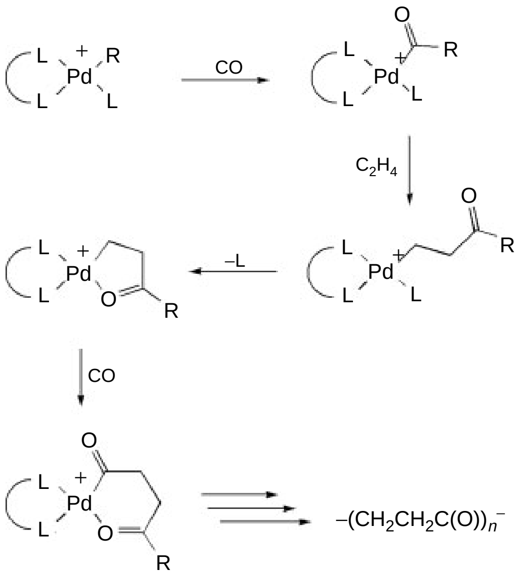


Figure 19 Alternating ethylene–CO polymerization by palladium catalysts

or nonexistent with respect to CO insertion into a metal–alkyl bond or olefin into a metal acyl linkage.

Neutral chelating bidentate ligands are used as ancillary ligands in these systems and greatly affect the catalyst performance and products. For ethylene/CO copolymerizations, bidentate arylphosphines such as 1,3-bis(diphenylphosphino)propane give the highest activities and polymer molecular weights. In the copolymerization of propylene and CO, catalysts with this ligand produce copolymer of low regioregularity, but this is much improved when alkylphosphines such as 1,3-(diisopropylphosphino)propane is used. The preferred ancillary ligand in styrene/CO copolymerization are N–N ligands such as 1,10-phenanthroline or 2,2′-bipyridine; the styrene/CO copolymers are not only highly regioregular but can also be made largely isotactic or syndiotactic depending on the choice of N–N ligand.[85]

9 OTHER METALS

Homogeneous polyalkene catalysis has progressed to the point where metals not generally associated with coordination polymerization can now be made to promote olefin chain growth and metals long ago associated with polyalkene catalysis have been given new life.

Copper complexes, which have never figured in coordination olefin polymerization, can be induced to polymerize ethylene by a judicious choice of ligand. The α-diimine compound (**20**) (Figure 20) in the presence of MAO shows modest activity in ethylene polymerization when R = Ph but not with R = *i*-Pr.[86] Cocatalyzed by MAO, the bis(benzimidzole) copper complex (**21**) homopolymerizes ethylene to polyethylene without detectable branches.[87]

Aluminum alkyls were first used by Ziegler in the early 1950s as olefin oligomerization catalysts (the ‘Aufbau’ catalyst). Within the last few years, aluminum is again receiving attention as a chain-growth system. Simple aluminum alkyls like $AlEt_3$, allowed to react with $B(C_6F_5)_3$, promote the polymerization of ethylene and propylene.[88] Aminotroponiminate complexes of aluminum such as (**22**) (Figure 21) are activated by $B(C_6F_5)_3$ or $[Ph_3C][B(C_6F_5)_4]$ to generate aluminum cations which polymerize ethylene with low activity.[89] The alkylaluminum and -gallium amidinates (**23**) similarly activated exhibit polymerization activity toward ethylene.[90]

1 INTRODUCTION

Synthetically important reactions employing transition metal–carbonyl complexes (*see* ***Carbonyl Complexes of the Transition Metals***) have been extensively developed and applied in total synthesis of complex organic molecules. Stoichiometric amounts of metal carbonyl complexes are usually employed, but the often significant increase in complexity going from starting material to product and the high stereoselectivity observed makes them very attractive reagents. In addition, reactions of transition metal–carbonyl complexes are frequently unique without any related reaction available for 'pure' organic compounds.

The following four types of complexes will be discussed in detail: (1) metal carbonyl–carbene complexes, (2) chromium tricarbonyl arene complexes, (3) iron tricarbonyl diene complexes, and (4) dicobalt hexacarbonyl alkyne complexes. A few examples of related transition metal–carbonyl complexes will be discussed under each heading. Only reactions of proven synthetic utility in which stoichiometric amounts of transition metal–carbonyl complexes have been used to mediate the reactions are included. Synthesis of the starting transition metal–carbonyl complexes will only be briefly discussed. Because of the vast amount of work published, the reactions selected for discussion will frequently be those that have been employed in total syntheses of natural products but important observations taken from methodological studies will also be discussed. Mechanistic considerations will be minimized to accommodate a larger number of examples of each reaction or complex type described (*see* ***Mechanisms of Reaction of Organometallic Complexes***). Reactions involving transient intermediates containing a metal–carbonyl bond or carbonylations of organometallic intermediates will not be covered. Reactions involving nucleophilic attack (*see Nucleophilic Addition: Rules for Predicting Direction*) on π-bonded alkene or alkyne metal–carbonyl complexes are discussed in an accompanying article (*see* ***Osmium: Inorganic & Coordination Chemistry***). In addition, catalytic reactions of transition metal–carbonyl complexes, such as hydroformylation (*see Hydroformylation*), reduction (*see Reduction*), alkoxycarbonylation (*see Alkoxycarbonylation*), hydrosilation (*see Hydrosilation*), hydrocyanation (*see Hydrocyanation*), and polymerization (*see Polymerization*) are covered elsewhere (*see* ***Carbonylation Processes by Homogeneous Catalysis***; ***Hydrocyanation by Homogeneous Catalysis***, and ***Oligomerization & Polymerization by Homogeneous Catalysis***).

2 METAL CARBONYL–CARBENE COMPLEXES

A very rapid growth of novel and synthetically useful reactions of Fischer-type carbene complexes (*see Fischer-type Carbene Complexes*) has occurred over the last decade. Reactions leading to cyclic and polycyclic compounds of high complexity and reactions wherein chirality has been transferred from the starting material to the product are of particular importance. A number of recent reviews on the chemistry of Fischer carbene complexes and their application in organic synthesis are available.[1–7]

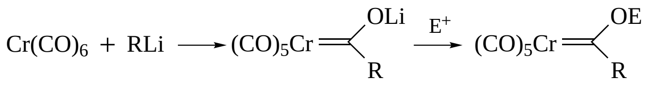
2.1 Formation and Elaborations of Fischer Carbene Complexes

Metal carbonyl–carbene complexes with a stabilizing heteroatom substituent on the carbene carbon (Fischer carbenes) can be prepared and further elaborated via a variety of methods. Methoxy- and ethoxy-substituted Fischer carbenes are generally prepared by reaction of metal carbonyl complexes with organolithium (*see* ***Alkali Metals: Organometallic Chemistry***) or dialkylzinc[8] (*see* ***Zinc: Organometallic Chemistry***) reagents forming a metal acylate. The metal acylate is usually unstable and is therefore directly alkylated with trimethyl- or triethyloxonium- tetrafluoroborates or methyl triflate (Scheme 1). This methodology is limited to methoxy- and ethoxy-substituted carbenes. Alkyl iodides can be used under phase-transfer catalysis conditions for the preparation of more substituted alkoxychromium carbenes. Other heteroatom substituents can be introduced via facile nucleophilic substitution of the alkoxy group upon reaction with thiols, selenols, primary and secondary amines, and aryllithiums. For example, carbene (**1**) reacts with pyrrole to give the pyrrole-substituted carbene (**2**) (Scheme 2).[9]

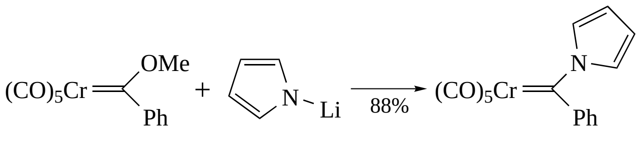
Lithium acylates are readily transformed to the substantially more thermally stable tetramethylammonium acylates by lithium-tetramethylammonium ion exchange. Reaction of tetramethylammonium salts with acid halides, usually acetyl chloride or bromide or pivaloyl chloride, affords thermally unstable acyloxycarbenes. These versatile complexes are transformed into alkoxy-, amino-, thio-, or seleno-substituted carbene complexes upon reaction with alcohols, primary and secondary amines, thiols, or selenols respectively (Scheme 3). In addition, direct alkylation of tetramethylammonium acylates can be achieved using alkyldiphenylsulfonium salts (Scheme 4).[10]

N,*N*-Disubstituted aminocarbenes can be prepared directly by reaction of chromium, tungsten, molybdenum pentacarbonyl, and iron tetracarbonyl dianions with tertiary amides in the presence of chlorotrimethylsilane (Scheme 5).

Reaction of 4-hydroxy-1-alkynes or 5-hydroxy-1-alkynes with chromium or tungsten pentacarbonyl compounds having a readily displaced ligand furnishes 2-tetrahydrofuranyl- and 2-tetrahydropyranylcarbenes respectively. This type of reaction was used in the synthesis of a number of natural products, including andirolactone and salinomycin[11] (Scheme 6). Related reactions of 4-amino- and 4-thiol-substituted alkynes furnishes dihydropyrroles, indoles, and dihydrothiophens. In contrast, the corresponding annulation using molybdenum carbonyls only affords dihydrofurans and dihydropyranes via elimination of the transition metal

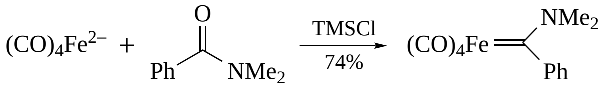


Scheme 1

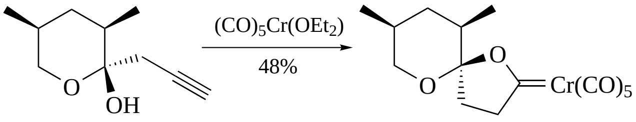


(**1**) (**2**)

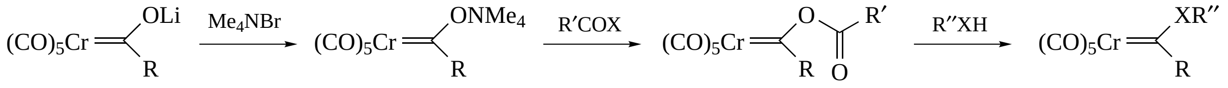
Scheme 2



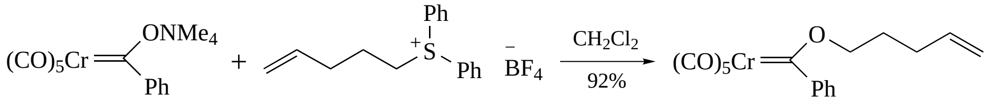
Scheme 5



Scheme 6



Scheme 3



Scheme 4

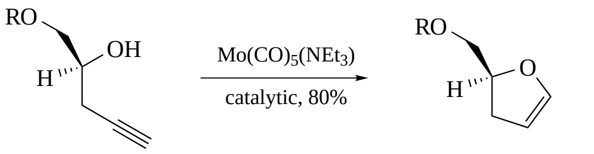
moiety.[12] The intermediately formed carbene is apparently not stable under the reaction conditions. The direct formation of cyclic ethers can be made catalytic in molybdenum (Scheme 7).

Reaction of enyne-esters and -amides and 2-alkynyl-substituted aromatic ketones in a related fashion led to pyrranylidene complexes (Scheme 8).[13] Compounds with a stabilized anion or a trialkylsilyl enolate in the 4- or 5-position relative to the alkyne can be used in related reactions to give carbocyclic products (Scheme 9).

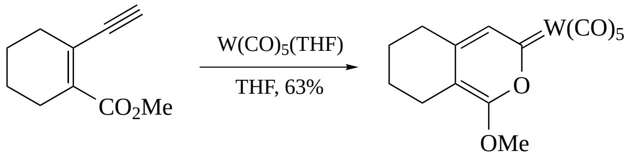
The relatively acidic α hydrogens of amino- and alkoxy-substituted Fischer carbenes are readily removed and the 'metal-enolate' formed participates in a number of carbon–carbon bond forming reactions. They can be alkylated using alkyl triflates, iodides, and tosylates, or benzyl bromides. Dialkylation of 'metal-enolates' is at times a competitive side reaction and can be used advantageously to introduce a cyclopropyl group α to the carbene carbon (Scheme 10). Alkylation of carbene anions with epoxides gives five-membered oxacyclic carbenes via an epoxide ring-opening-intramolecular alkoxy-exchange sequence. Reaction of optically active epoxides furnishes optically active carbene complexes. Allylic anions formed from α,β-unsaturated carbenes are alkylated with alkyl halides to give mixtures of α- (minor) and γ-alkylation (major) products. The same anion is exclusively or predominantly quenched in the α position using proton, deuterium, or chlorotrimethylsilane. It is interesting to note that N,N-dialkylhydrazino carbene complexes can readily be stepwise mono- and dialkylated in the α position (Scheme 11).[14] N,N-Dimethylamino-substituted tungsten and chromium acetylides undergo 1,2-additions to cyclohexenones.

Anions formed from group 6 and manganese Fischer carbene complexes undergo aldol condensations with aldehydes and ketones. Allylic carbenes exclusively react in the γ position with aldehydes affording dienyl-substituted carbenes. For alkoxy-substituted carbenes, the presence of an excess Lewis acid (*see Lewis Acids & Bases*), such as boron trifluoride etherate, titanium tetrachloride, or tin tetrachloride is required for the reaction to proceed in reasonable yield. The initial aldol product can be isolated without elimination (Scheme 12).[15]

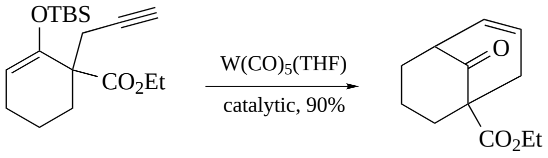
Anions of amino-substituted complexes are sufficiently reactive and do not require a Lewis acid in order



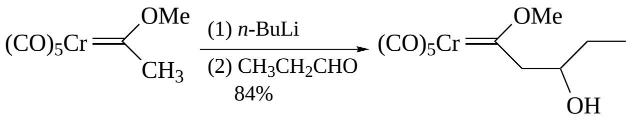
Scheme 7



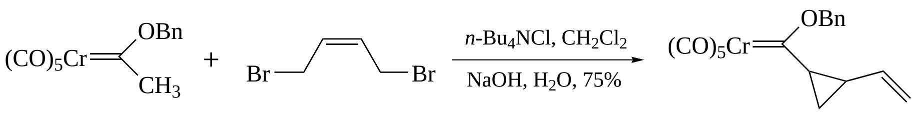
Scheme 8



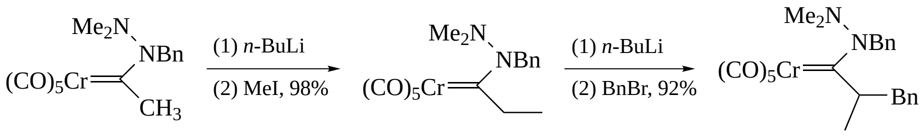
Scheme 9



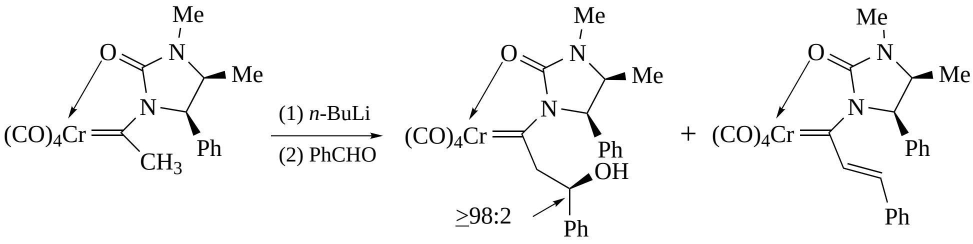
Scheme 12



Scheme 10

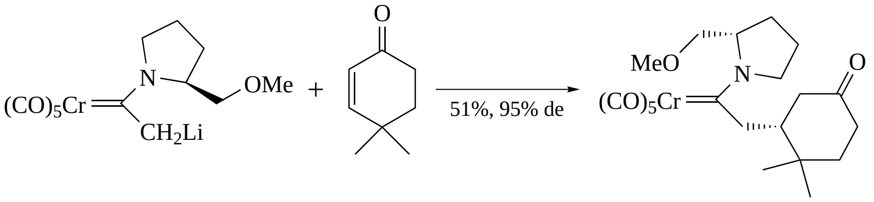


Scheme 11



(**3**) (**4**) (**5**)

Scheme 13



(**6**) (**7**) (**8**)

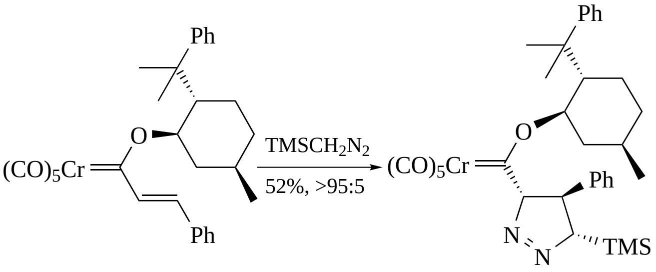
Scheme 14

to undergo aldol reactions with ketones and aldehydes. Highly diastereoselective reactions of chiral aminocarbenes are observed. For example, complex (**3**) reacts with benzaldehyde to give an essentially pure aldol product (**4**) together with the elimination product (**5**) (Scheme 13). 3-Hydroxy-substituted amino- and alkoxycarbenes are readily dehydrated by treatment with base, to give α,β-unsaturated carbenes of considerable synthetic value.

Deprotonation of carbene complexes followed by treatment with electron-deficient alkenes affords Michael addition products in fair to good yield. Reaction of the chiral pyrrolidine-substituted carbene (**6**) with 4,4-dimethyl-2-cyclohexen-1-one (**7**) furnishes the alkylkated product (**8**) in 95% de (Scheme 14).

α,β-Unsaturated complexes undergo a number of facile cycloaddition reactions to produce more elaborate complexes. For example, cycloadditions using diazoalkanes, nitrileimines, alkylnitrones, azomethine ylids (*see Ylide*), and imines are feasible. For example, reaction of the chiral carbene (**9**) with trimethylsilyldiazometathane gave the heterocyclic-substituted carbene (**10**) (Scheme 15).[16]

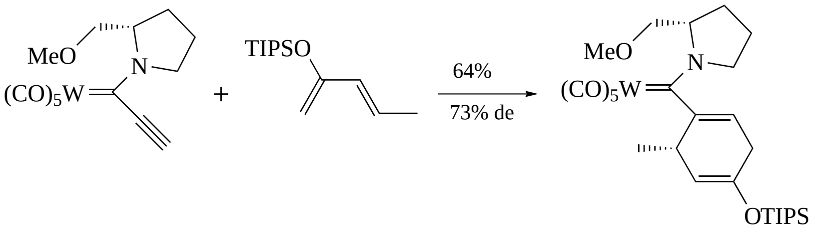
Alkene- and alkyne-substituted Fischer carbenes participate as dienophiles in Diels–Alder reactions. The conditions are usually mild and the reaction proceeds smoothly at room temperature. Similar isomeric ratio and rate acceleration is observed to that of Lewis acid–promoted Diels–Alder reactions between methyl acrylates and dienes when compared to the uncatalyzed reactions. The reactions are endo-selective. Asymmetric Diels–Alder reactions are observed using alkyne carbene complexes having a chiral amino group (Scheme 16)[17] or using a chiral diene (Scheme 17). Intramolecular Diels–Alder reaction can also be performed forming more complex bicyclic carbenes (Scheme 18).



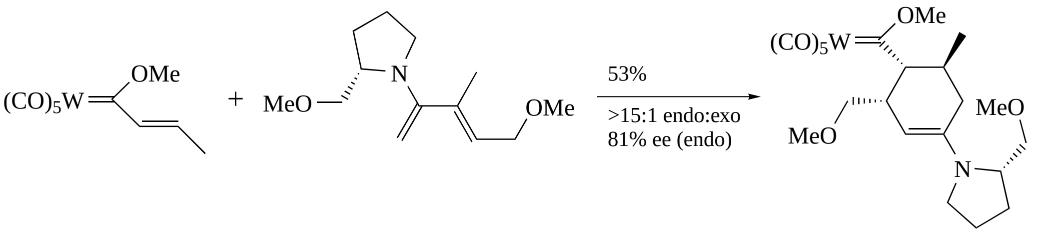
(**9**) (**10**)

Scheme 15

Depending on the size of the nucleophile, α,β-unsaturated carbene complexes either undergo 1,4-addition and/or 1,2-addition of the nucleophile. Michael addition is observed using relatively large carbanion nucleophiles, such as the enolates of cyclopentanone, isobutyrophenone, or dimethyl malonate. Enamines can also be employed as nucleophiles affording Michael-type adducts. Reaction of alkenyl (methoxy) carbene complexes with enolates derived from methylketones gave five- and seven-membered carbocycles under mild reaction conditions. For example, reaction of (**11**) with (**12**) gave cycloheptanone (**13**) or cyclopentane (**14**), depending on the nucleophile (Scheme 19).[18] Triethyl boron can be used to



Scheme 16

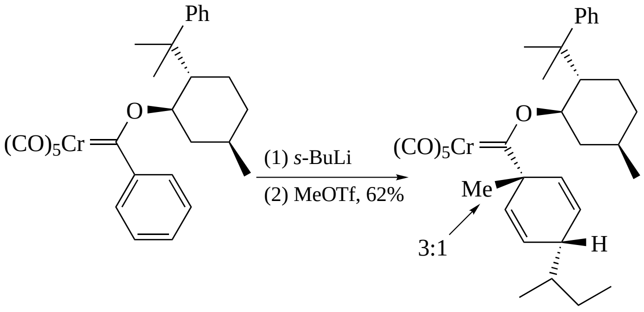


Scheme 17

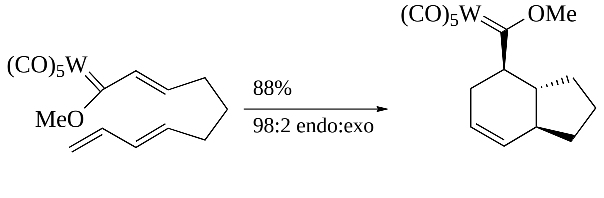
deliver an ethyl group to α,β-unsaturated alkoxy-chromium carbenes in a radical-type reaction using oxygen as the initiator. Asymmetric conjugate addition of organolithiums to aryl group of aryl-carbene complexes (Scheme 20) and to alkenyl-substituted carbenes can be achieved (Scheme 21). In the latter reaction, the addition reaction was accompanied by elimination of the metal carbonyl fragment. Hydrolysis of the enol ether affords an optically active aldehyde.

Several heteroatom nucleophiles, for example, amines, alcohols, thiols, carboxylates, and dialkylphosphines, undergo Michael addition reactions with alkene- and alkyne-substituted carbene complexes. Reaction of alkyne-substituted chromium carbenes with urea affords products derived from Michael addition and amine-alkoxy exchange (Scheme 22).[19] A Michael addition cyclization is observed upon reaction of hydrazine acetamide with alkynyl-substituted carbenes producing substituted pyrazoles (Scheme 23).

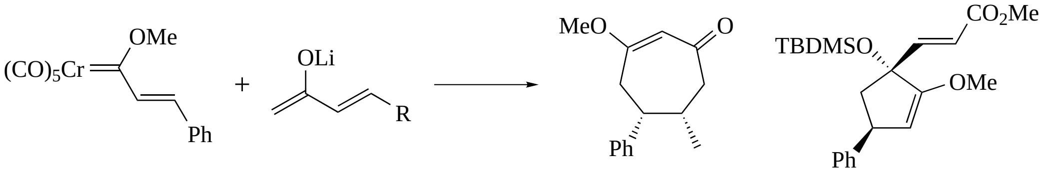
Chromium and tungsten carbene complexes containing an alkynyl or alkenyl substituent afford moderate to high yields of cyclobutene or cyclobutane complexes respectively via formal [2 + 2]cycloaddition with



Scheme 20

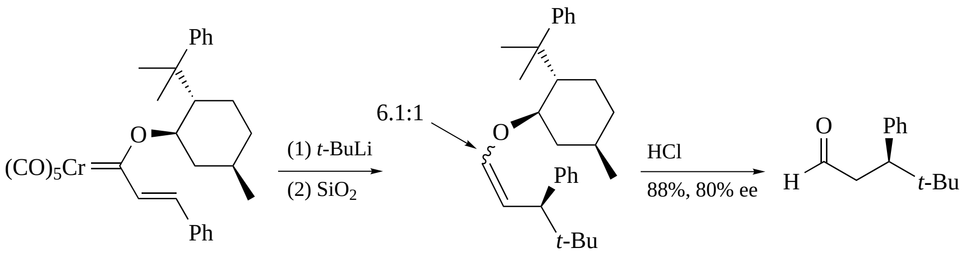


Scheme 18

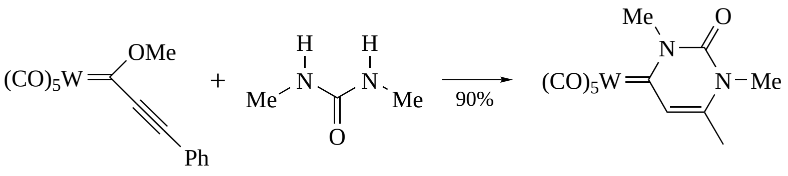


(**11**) (**12**) (R = Me, 51%, **13**) (R = CO_2Me, 72%, **14**)

Scheme 19

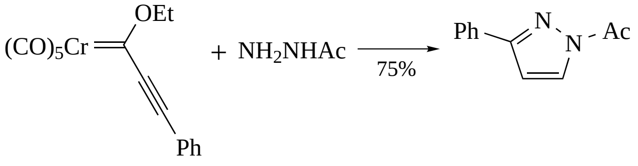


Scheme 21



Scheme 22

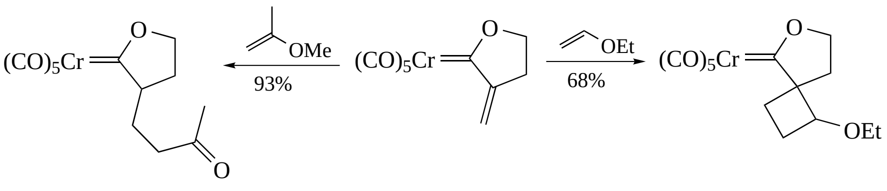
enol ethers and enamines (Scheme 24). In some cases, the ene reaction is a competitive pathway. This reaction path is exclusively seen using 1-substituted enol ethers and α-exomethyleneoxacyclopentylidene complex (**15**) (Scheme 24).[20]



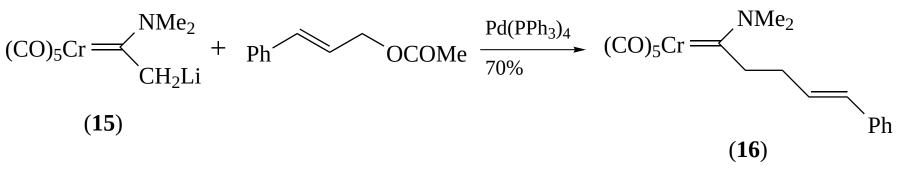
Scheme 23

Fischer-type carbenes can also be modified via transition metal catalyzed reactions. Fischer chromium aminocarbene complexes can be used as nucleophiles in palladium-catalyzed allylic substitution reactions with allylic acetates and carbonates, affording the corresponding allyl-substituted aminocarbenes. For example, reaction of the lithiated carbene (**15**) gives (**16**) in good yield (Scheme 25).[21]

Six- and seven-membered 2-oxacycloalkenylidene chromium complexes can be prepared via a ruthenium-catalyzed ring-closing metathesis using Grubb's catalyst (Scheme 26, *see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***). However, β-alkylated vinylcarbene complexes do not readily participate in the metathesis reaction.[22] Ene-yne functionalized carbenes undergo Pauson–Khand reactions (*see Pauson–Khand Reaction*) to



Scheme 24

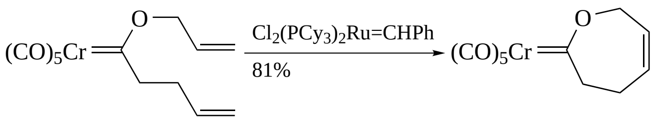


(**15**)

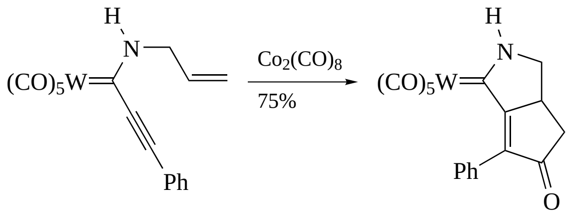
(**16**)

Scheme 25

give bicyclic complexes under mild reaction conditions (Scheme 27).



Scheme 26

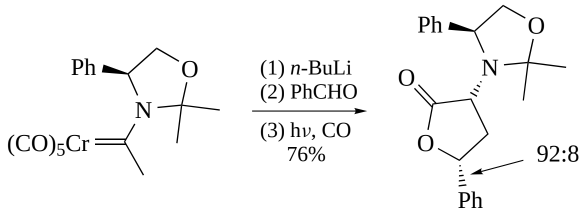


Scheme 27

2.2 Photolytic Reactions

Irradiation of Fischer carbene complexes generates, by insertion of carbon monoxide, a metal-bound ketene intermediate. Photolytic reactions of carbene complexes are synthetically attractive, in that the reaction conditions are mild and the reactions of ketene intermediates with a variety of reagents is of significant scope. A low concentration of metal-bound ketene is probably obtained and in the absence of a nucleophile, the starting material can usually be recovered even after prolonged irradiation. The ketene intermediates are readily trapped with nucleophiles; for example, dipeptides are formed in excellent yield and with very high diastereoselectivity upon irradiation of optically active carbenes in the presence of natural or ‘unnatural’ α-amino acids (Scheme 28). Dipeptides and PEG-supported amino acids and dipeptides can also be used as nucleophiles.

Photolysis of chiral amino carbene complexes in the presence of alcohols gives amino acid esters, again with a very high diastereoselectivity. Irradiation of aminocarbenes in the presence of 2,4,5-trichlorophenol produced optically active, activated, α-amino 2,4,5-trichlorophenoxide esters. Related intramolecular reactions of carbenes having a pendant alcohol afford lactones. For example, aldol condensation of (**17**)



(**17**) (**18**)

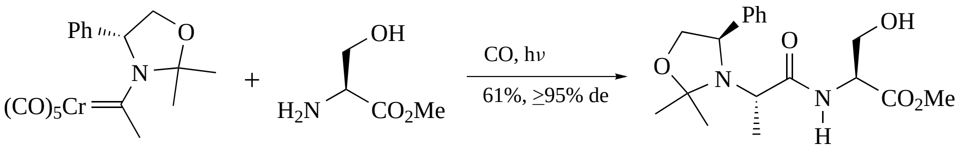
Scheme 29

followed by photolysis give (**18**) (Scheme 29). α-Hydroxy esters are prepared by irradiation of in situ generated hydroxy-substituted Fischer carbenes in the presence of an alcohol.

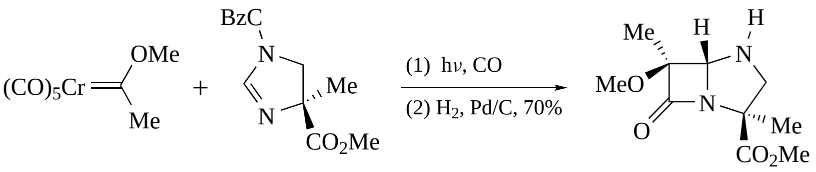
Photolytic reaction of chromium carbene complexes in the presence of cyclic and acyclic imines and iminodithiocarbonates produce β-lactams. This reaction is closely related to the well-precedented Staudinger reaction and the stereochemical outcome is the same. A large selection of free imines or the corresponding trimers, 1,3,5-triazines, can be used to form β-lactams. Several different classes of β-lactams can be synthesized using this methodology, including monocyclic β-lactams, cephams, oxacephams, carbacephams, penams, carbapenams, oxapenams, and azapenams. A wide range of optically active β-lactams can be made, in good to excellent yield with high diastereoselectivity, by photolysis of optically active aminocarbene complexes in the presence of imines or by reaction of achiral carbenes with optically active imines (Scheme 30).

Irradiation of alkoxycarbene complexes in the presence of alkenes and carbon monoxide produces cyclobutanones. A variety of inter- and intramolecular [2 + 2]cycloadditions have been reported. The regioselectivity is comparable with those obtained in reactions of ketenes generated from carboxylic acid derivatives. Cyclobutanones can be obtained with a high degree of diastereoselectivity upon reaction of alkoxycarbenes with chiral N-vinyloxazolidinones. For example, photolysis of (**19**) in the presence of (**20**) gives cyclobutanone (**21**) (Scheme 31).[23] In addition to alkoxycarbenes, carbenes having a thioether or pyrrole substituent can also be employed. Related intramolecular cycloadditions of γ,δ-unsaturated chromium carbenes afford bicyclo[2.1.1]hexanones (Scheme 32).

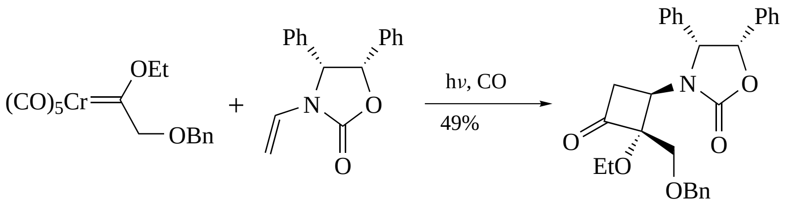
Nonstabilized phosphorus ylids (*see Ylide*) either deprotonate the relatively acidic α-position of chromium alkoxycarbenes or produce enol ethers by a formal metathesis reaction



Scheme 28

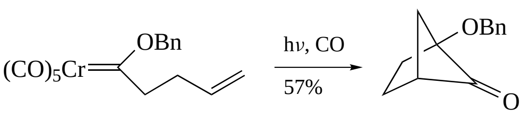


Scheme 30



(**19**) (**20**) (**21**)

Scheme 31

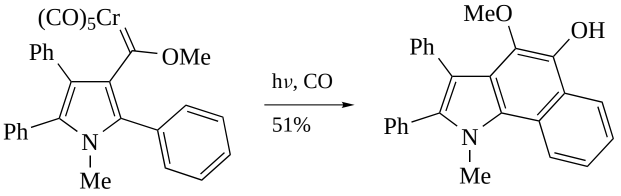


Scheme 32

with carbene complexes lacking α-protons. Photolytic reactions of alkoxycarbenes in the presence of carbonyl-stabilized sulfur ylids produce trisubstituted alkenes (Scheme 33).

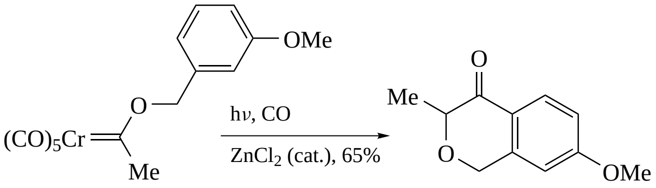
Polycyclic aromatic compounds are obtained upon irradiation of diaryl-substituted chromium carbenes under a carbon monoxide atmosphere. The reaction probably proceeds via the formation of a biaryl-alkoxy ketene followed by cyclization. For example, the pyrrole-substituted carbene (**22**) gave the tricyclic compound (**23**) (Scheme 34).[24] Related intramolecular Friedel–Crafts-type reactions of carbenes having tethered electron-rich aromatic rings are feasible, usually in moderate yields (Scheme 35). A Lewis acid catalyst such as zinc dichloride is required for optimum yields.

Photolysis of chromium alkoxycarbene complexes with aldehydes in the presence of a Lewis acid or base, and carbon monoxide, affords β-lactones in low to moderate yield. The intramolecular variation of this [2 + 2]cycloaddition using carbene complexes having a pendant aldehyde are considerably more efficient (Scheme 36).



(**22**) (**23**)

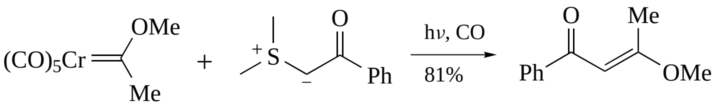
Scheme 34



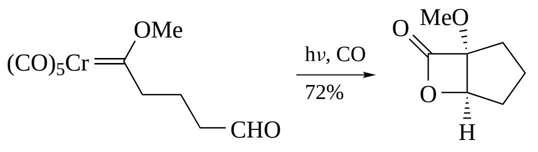
Scheme 35

2.3 Metal–Carbon Double Bond Cycloaddition and Further Reactions

Thermal reactions of Fischer carbenes with alkynes afford a variety of products depending on the substrates. The reactions can be visualized mechanistically as a [2 + 2]cycloaddition



Scheme 33



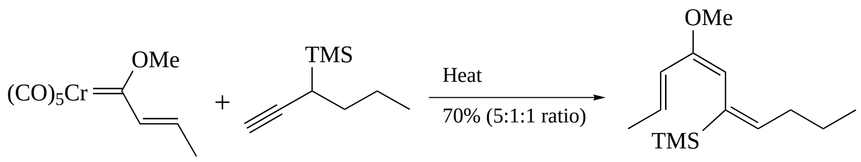
Scheme 36

between the alkyne and the carbon–metal double bond. The intermediately formed metallacyclobutene then undergoes a variety of reactions. Common 'termination' reactions include β-hydride elimination (*see β-Hydride Elimination*), insertion of carbon monoxide (*see CO Insertion*), forming a ketene, and reaction with nucleophiles. For example, dienes and trienes can be obtained from alkynes and Fischer carbenes via β-hydride elimination (Scheme 37). Alkynes having a pendant hydroxy group afford β- and γ-lactones (Scheme 38). Coupling of carbenes with 2-alkynylbenzaldehydes furnish isobenzofuran derivatives (Scheme 39).[25] Related reactions of 2-ene-4-yne-imines and 2-ene-4-yne-aldehydes give substituted pyrroles and furans respectively.

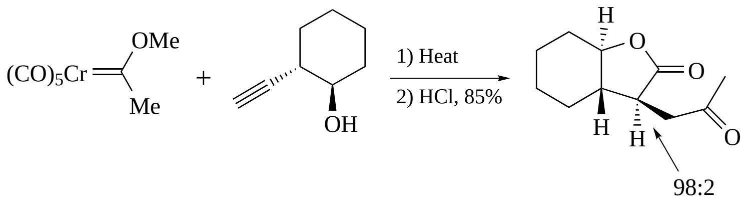
2.4 Benzannulation Reactions

Thermal reaction of alkoxy-substituted Fischer carbenes of group 6 metals with alkynes has been applied to the syntheses of a variety of polycyclic aromatic compounds. The reaction has been extensively developed into one of the more powerful reactions employing Fischer carbenes. Aryl-, alkenyl-, and alkynyl-substituted carbenes undergo benzannulation reaction furnishing cyclized products upon heating in the presence of an alkyne. A probable mechanism for the benzannulation involves [2 + 2] cycloaddition between the alkyne and the carbon–metal double bond forming a metallacyclobutene, metathesis to give a vinyl carbene, insertion of carbon monoxide to form a ketene followed by cyclization–aromatization. The regiochemistry of the initial cycloaddition puts the terminal end of the alkyne next to the initial carbene carbon. For internal alkynes, both cycloadducts are possible but the alkyne terminus containing the more sterically demanding group is usually connected to the metal. Oxidation of the 1,4-hydroxy-ether benzannulation products affords 1,4-quinones (Scheme 40). While the benzannulation of alkoxycarbenes results in the formation of new six-membered rings by insertion of carbon monoxide, as described above, aminocarbenes produce primarily indene derivatives, however this reaction has found little synthetic use. Cyclohexadienones are formed when tautomerization to an aromatic ring is not possible (Scheme 41).

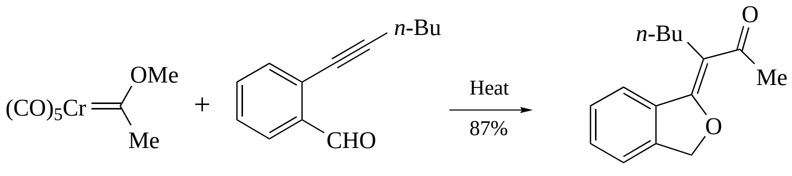
The benzannulation reaction can be promoted in a variety of ways including ultrasound, microwaves, and irradiation using a xenon lamp. Reactions are also possible on solid support such as, silica gel, magnesium sulfate, and aluminium



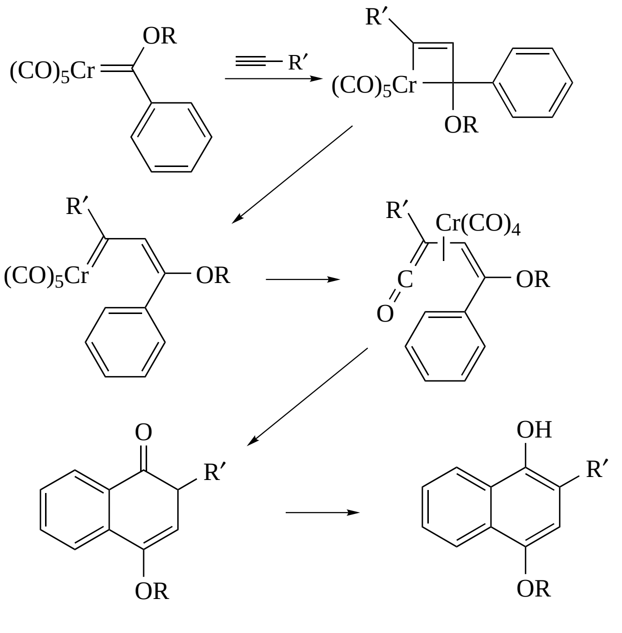
Scheme 37



Scheme 38



Scheme 39

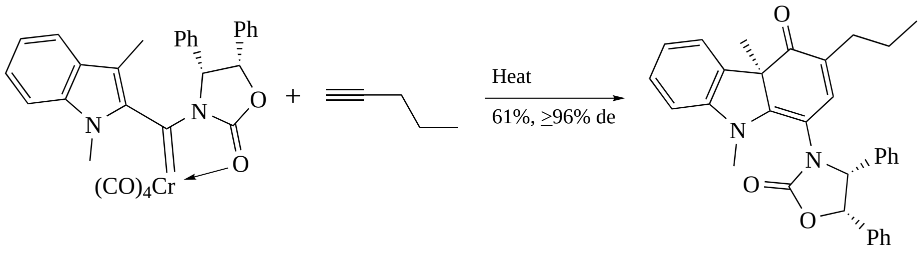


Scheme 40

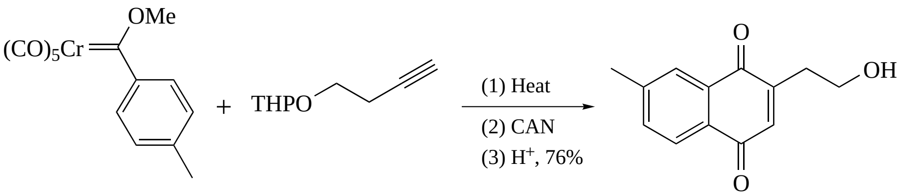
trioxide in the absence of a solvent. By tethering the alkyne via a silicon linkage, reversal of regiochemistry can be obtained (Schemes 42 and 43).

The aromatic products often contain an arene-complexed chromium tricarbonyl unit. The metal-free product is obtained by oxidation commonly using CAN or air under irradiation. The formation of complexed adducts can be used to prepare chiral chromium tricarbonyl arene complexes (Scheme 44, *see Arene Complexes*).

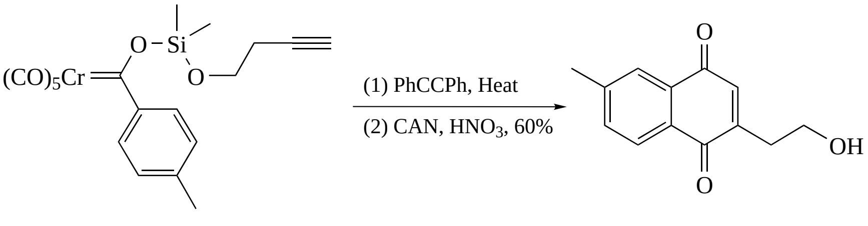
Many reactions afford, in addition to the naphthalene derivatives, mixtures of products. One of the major side reactions is the formation of indene derivatives directly from the metathesis intermediate without insertion of carbon monoxide. Other products frequently isolated as minor components are furans, cyclobutanones, and cyclopentenediones. The product distribution is dependent on numerous factors, including solvent, reaction temperature, concentration of the alkyne, and the nature of the aryl substituent. Molybdenum carbenes give, depending on the alkyne, either naphthols or indenes exclusively. The molybdenum Fischer carbenes can be tuned to give naphthoquinones by replacing one of the carbon monoxide ligands with a phosphine (Scheme 45).



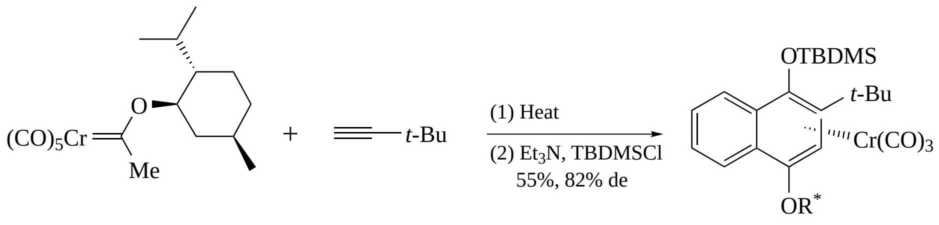
Scheme 41



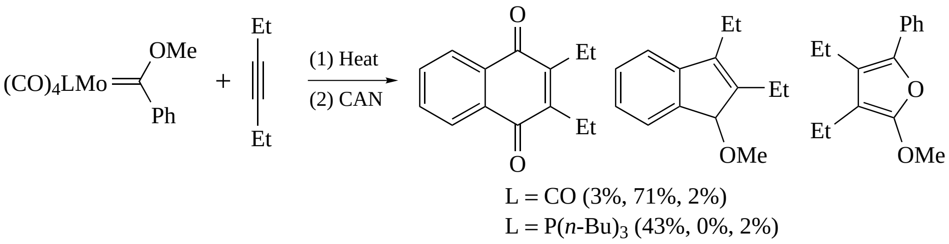
Scheme 42



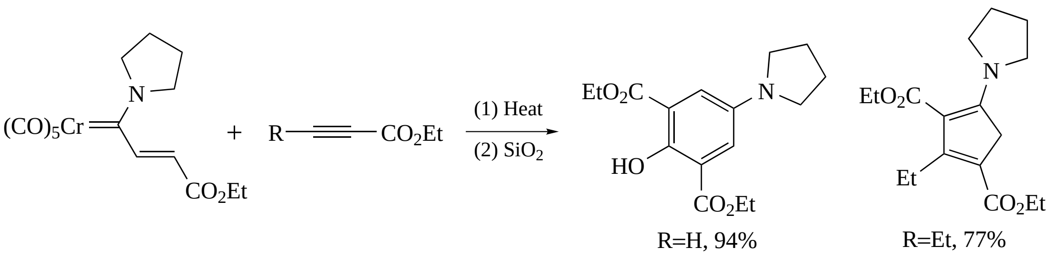
Scheme 43



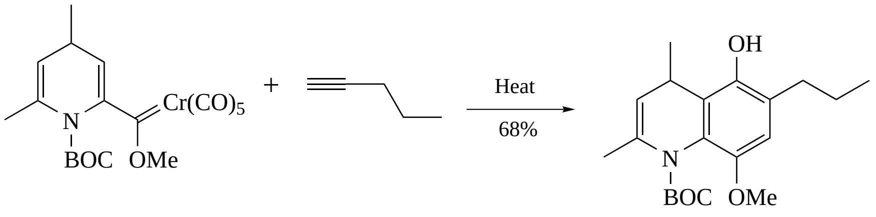
Scheme 44



Scheme 45



Scheme 46

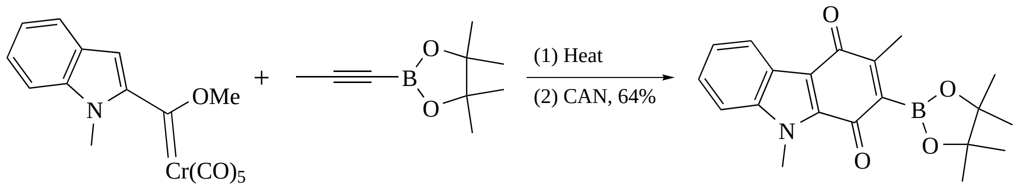


Scheme 47

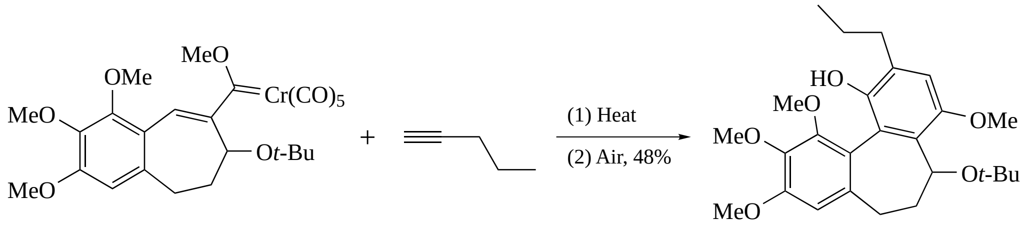
Depending on the alkyne, both six- and five-membered rings may be obtained upon reaction of ß-carbomethoxy-alkenyl-amino carbenes (Scheme 46).[26] Dihydropyridine and indole carbene complexes participate in benzannulation reactions (Scheme 47). Alkynes containing boronic esters may be used, affording boronic ester-functionalized quinones that can be used in palladium-catalyzed coupling reactions (Scheme 48).[27]

The benzannulation reaction of aryl- and alkenyl-substituted Fischer carbenes with alkynes has been used in several total syntheses. Some recent examples of benzannulation reactions used to synthesize advanced intermediates include, for example, allocolchicinoids[28] and menogaril (Schemes 49 and 50).[29]

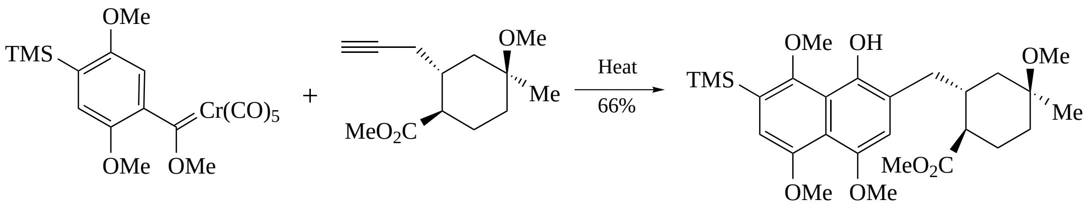
Related benzannulation reactions are also observed using isocyanides in place of carbon monoxide. It should be noted that the regiochemistry is opposite to that previously described. Reaction of complex (**24**) with *t*-butylisocyanide under thermal conditions produced naphthalene (**25**) used in total synthesis of the calphostins (Scheme 51).[30] Benzannulations



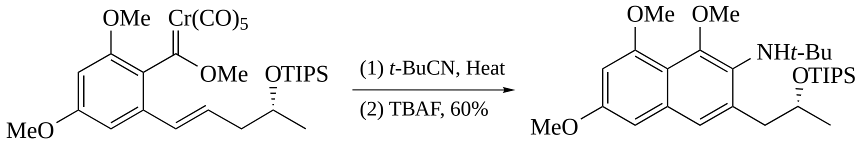
Scheme 48



Scheme 49

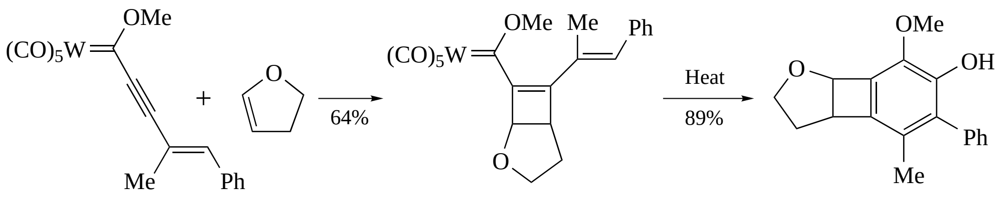


Scheme 50



(**24**) (**25**)

Scheme 51

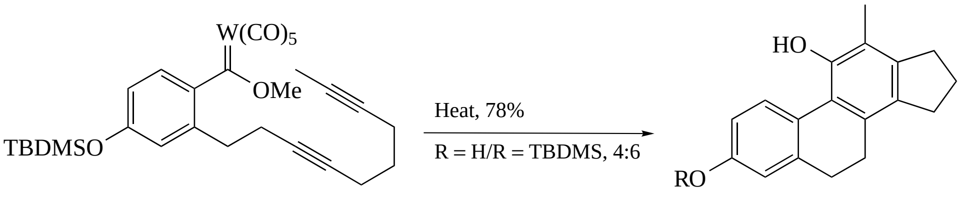


Scheme 52

of cyclobutenyl-substituted complexes, derived from [2 + 2]cycloaddition of alkyne-substituted complexes with enol ethers is also possible (Scheme 52).[31] A somewhat unusual annulation was employed to prepare the steroid skeleton (**27**) from (**26**) (Scheme 53).

2.5 Cyclopropanations

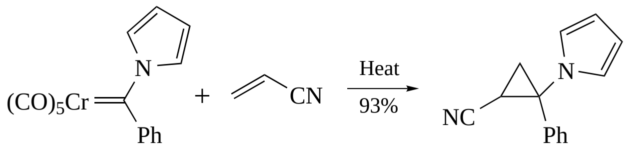
Several useful inter- and intramolecular reactions of chromium, molybdenum, tungsten, iron, or manganese Fischer carbenes with alkenes to form cyclopropanated products have



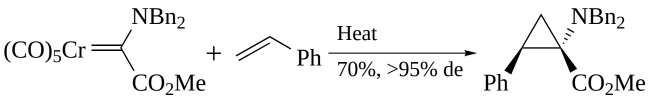
(26) (27)

Scheme 53

been developed. Thermal reaction of electron-deficient alkenes with group 6 carbenes affords donor–acceptor-substituted cyclopropanes. The geometry of the alkene is retained to a very high degree in the cyclopropane. Aminocarbenes usually do not produce cyclopropanated products upon thermolysis in the presence of alkenes. However, intramolecular reactions and the reaction of pyrrole-substituted carbenes give satisfactory yields of cyclopropanated products (Scheme 54). This is probably a result of a lower electron-donating ability, compared to amines, of the pyrrole nitrogen. Alkoxycarbonyldialkylaminocarbenes also cyclopropanate alkenes to give cyclopropane products in a high diastereomeric ratio (Scheme 55).[32] Reaction of carbenes with dihydropyridines transferring a hydride to the carbene carbon followed by cyclopropanation of alkenes, enol ethers, and enamines can be achieved (Scheme 56).[33]



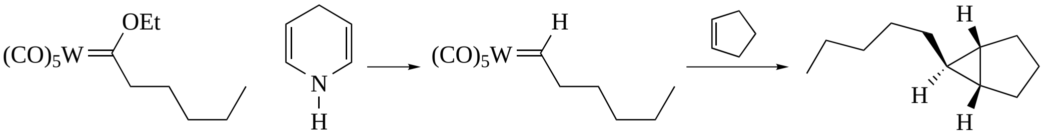
Scheme 54



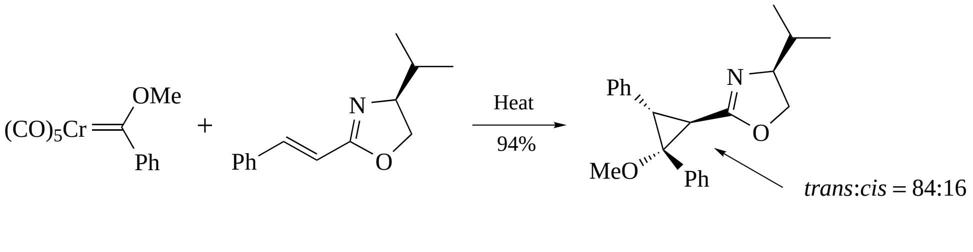
Scheme 55

Diastereoselective and enantioselective (*see Enantioselectivity*) cyclopropanations of chiral alkenes can be achieved (Scheme 57).[34] Unactivated alkenes usually do not participate in cyclopropanation reactions of Fischer carbenes. However, alkenyl- and heteroaryl-substituted group 6 alkoxy carbene complexes cyclopropanate unactivated alkenes in good yield (Scheme 58).[35]

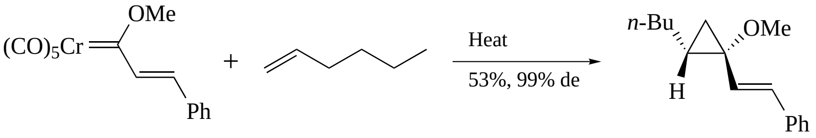
Intramolecular cyclopropanations of pendant alkenes are more favorable. Heteroatom-substituted 2-aza- and 2-oxabicyclo[3.1.0]hexanes, together with 2-oxabicyclo[4.1.0] heptanes, can be prepared from chromium and tungsten Fischer carbenes having a tethered alkene chain. An interesting carbene formation via a cationic alkylidene intermediate, nucleophilic addition (*see Nucleophilic Addition: Rules for Predicting Direction*), and intramolecular cyclopropanation is shown in Scheme 59. An intramolecular cyclopropanation via reaction of alkenyl Fischer carbene complex (**28**) and propyne was used in a formal synthesis of carabrone (Scheme 60).



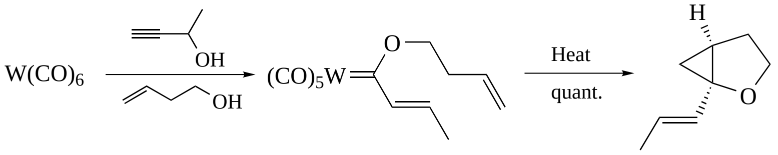
Scheme 56



Scheme 57



Scheme 58



Scheme 59

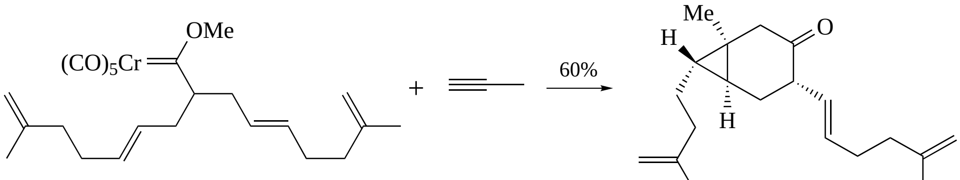
Cyclopropanation reactions of nonheteroatom-stabilized carbenes have also been developed. The most versatile are the cationic iron carbenes that cyclopropanate alkenes with high stereospecificity under very mild reaction conditions. The cyclopropanation reagents are available from a number of iron complexes, for example, *O*-alkylation of cyclopentadienyl dicarbonyliron alkyl or acyl complexes using Meerwein salts affords cationic Fischer carbenes. Cationic iron carbene intermediates can also be prepared by reaction of $CpFe(CO)_2^-$ with aldehydes followed by treatment with TMS-chloride. Chiral intermolecular cyclopropanation using a chiral iron carbene having a complexed chromium tricarbonyl unit is observed (Scheme 61).

2.6 Miscellaneous Reactions of Fischer Carbenes

Fischer carbenes react with silanes and stannanes to form alkoxy- or amino-stannanes and -silanes. For example, diastereoselective reaction of the chiral aminocarbene (**29**) with triphenylsilane or tri-*n*-butyltin hydride gave (**30**) and (**31**), respectively (Scheme 62).[36] Tin-substituted ethers can be prepared from α,β-unsaturated cyclic carbenes by treatment with tri-*n*-butyltin triflate in the presence of triethylamine (Scheme 63).[37] Reaction with lithiumdibromomethane and α-halo enolates affords carbonyl compounds (Schemes 64 and 65).[38]

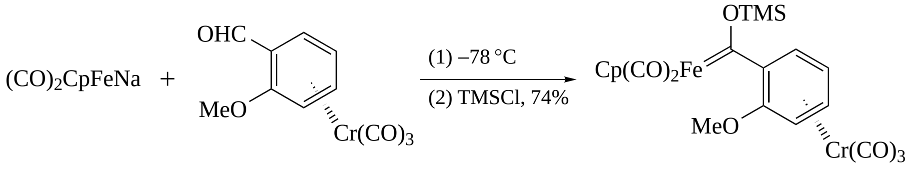
A variety of annulations leading to ring systems other than benzenes can be isolated from reactions of Fischer carbenes. Cyclopentenone derivatives are formed from a reaction of *Z*-ß-amino-α,β-unsaturated chromium carbenes with alkynes (Scheme 66). In contrast, *E*-ß-amino-α,β-unsaturated chromium carbenes reacts with alkynes to give cyclopentadienes (Scheme 67).

Formation of polycyclic ring systems via intermolecular reactions of Fischer carbenes with alkynes can be achieved. In a metathesis-type reaction, reactions of 1,6-enynes afford

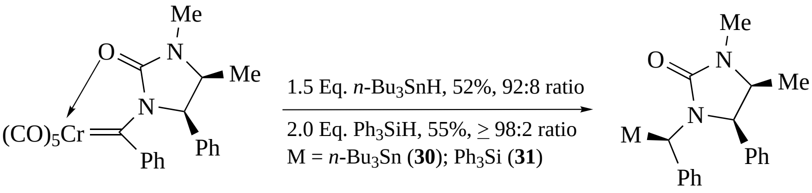


(**28**)

Scheme 60

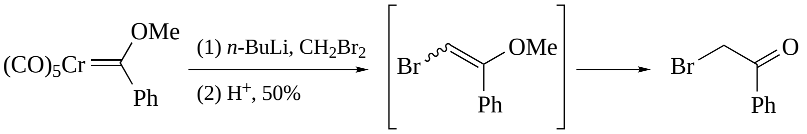


Scheme 61

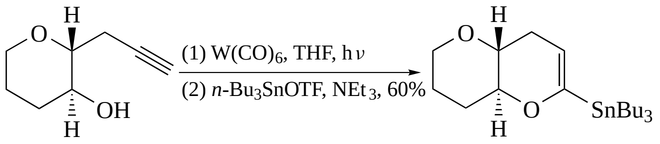


(**29**)

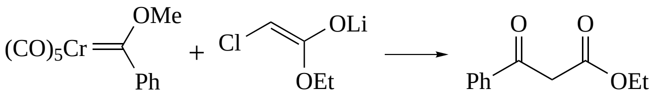
Scheme 62



Scheme 64



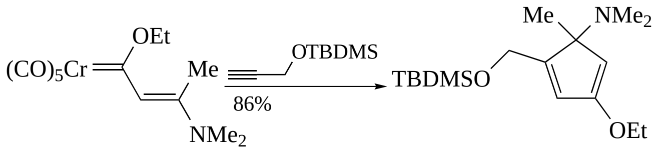
Scheme 63



Scheme 65

bicyclic ketones (Scheme 68). Related reactions of 3-ene-1,5-diynes afford polycyclic compounds (Scheme 69).[39] Reactions of other polyunsaturated compounds leading to complex molecules have also been reported (Scheme 70). Chromium-mediated β-lactone synthesis using ultrasonication or thermal reactions has been reported (Scheme 71).[40] The reactions are most likely initiated by a [2 + 2]cycloaddition.

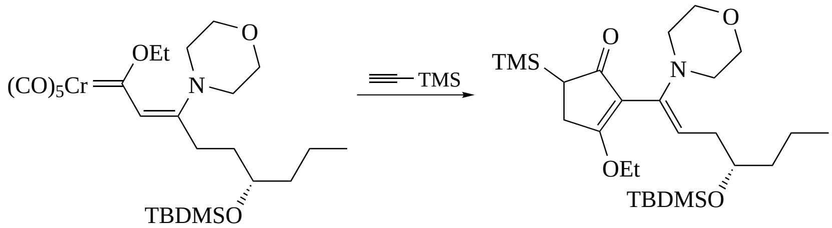
Interesting reactions wherein two carbon monoxides have been inserted into the final product have been



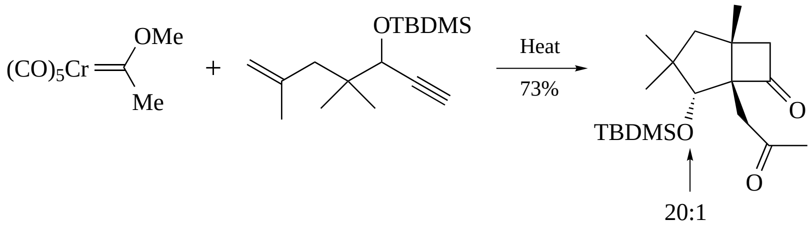
Scheme 67

described. For example, reaction of carbene (**32**) with N-phenyl-1,4-dihydropyridine affords the bicyclic lactone (**33**) (Scheme 72).[41] A possible mechanism is hydride transfer to the carbene carbon, carbon monoxide insertion, [2 + 2] and cycloaddition to give (**34**). Metathesis and ketene formation would form (**35**) followed by intramolecular lactone formation to give (**33**). Reaction of β-vinyl-cyclobutenyl-substituted carbenes with alkynes gives cyclooctatriene (Scheme 73).[42]

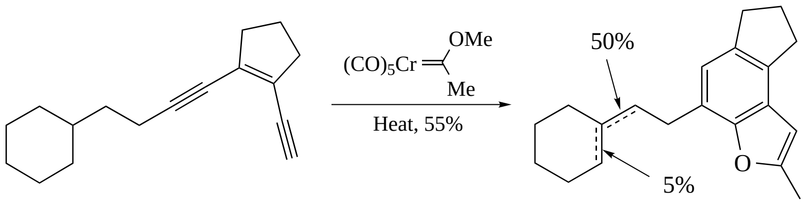
Fischer carbene complexes undergo elimination reactions under thermal conditions to form enol ethers, enol acetates, or enamines, depending on the heteroatom substituent on the carbene carbon and, depending on the conditions, aldehydes. High (Z) to (E) ratios of isomers are obtained in most cases. Although thermal reactions have been reported, this formal 1,2-hydrogen shift is in most cases facilitated by tertiary



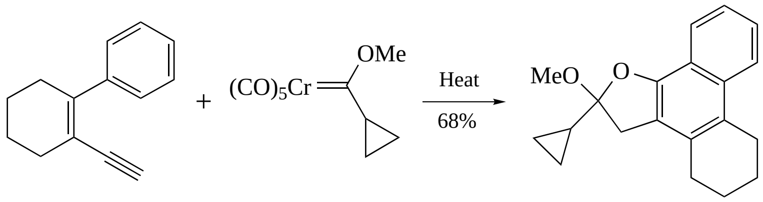
Scheme 66



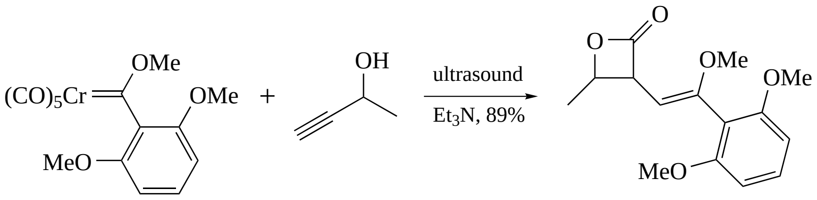
Scheme 68



Scheme 69



Scheme 70



Scheme 71

amines, pyridine, or alkoxides. An example of α-acylation-elimination forming an enol ether can be seen in Scheme 74.

Fischer carbene complexes are smoothly transformed by oxidation to esters or amides without racemization of α-substituents. Oxidizing agents frequently used includes, pyridine *N*-oxide, oxygen, dimethyloxirane, dimethyl sulfoxide, $[FeCl_2(DMF)_2][FeCl_2]$, hydrogen peroxide, and CAN. For example, cyclopropanation of (**36**) with chloroiodomethane to give (**37**) followed by oxidation give the trans-substituted cyclopropane (**38**) (Scheme 75).

Thermally induced ring-expansions of cyclopropyl-substituted chromium carbene affording 2-alkoxy-cyclopentenones or cyclopentadienones have been developed (Scheme 76). Reaction of a cyclopropylcarbene having a tethered alkoxyalkyne gives bicyclic systems (Scheme 77).[43]

Reactions of σ-alkynyltungsten complexes forming cationic carbene intermediates have been developed. Treatment of (**39**) with acetaldehyde in the presence of borontrifluoride etherate affords carbene (**40**) (Scheme 78). Treatment of (**40**) with base forms a new σ-alkynyltungsten complex (**41**). The σ-complexes are readily prepared from cyclopentadienyl(dicarbonyl)tungsten chloride and acetylides. A variety of potentially useful transformations can be made, for example, oxidation, reduction–oxidation, Michael addition, cyclopropanation–oxidation, and double alkylation (Scheme 79).[44]

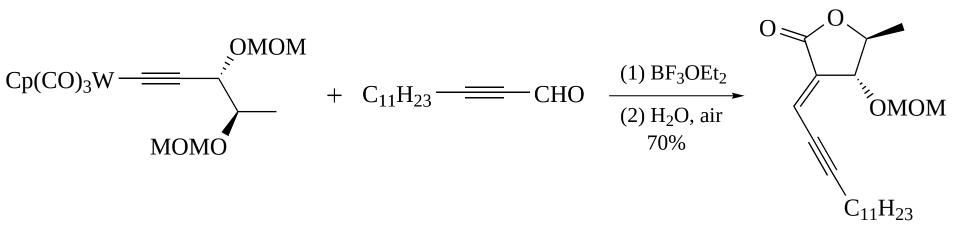
Scheme 79



Scheme 80

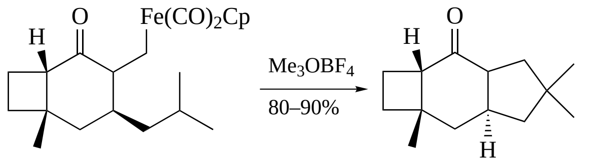
This methodology has been used to prepare a variety of natural products such as (+)-blastomycinone, (−)-listenolide C_1, and related lactones. The cyclization step for (−)-listenolide is seen in Scheme 80.[45]

Intramolecular C–H insertion reactions of (η^5-cyclopentadienyl)dicarbonyliron carbene complexes can be used to prepare complex polycyclic compounds. Carbon−hydrogen bond insertion using an iron carbene was used as a key step in the synthesis of sterpurene and pentalene (Scheme 81).[46]

3 METAL CARBONYL–ARENE COMPLEXES

A variety of transition metals, for example, chromium, molybdenum, tungsten, iron, vanadium, manganese, and rhodium can be used to prepare relatively stable η^6-arene complexes (*see Arene Complexes*). Reactions of η^6-arene chromium tricarbonyl complexes have been extensively examined, and numerous reviews are available.[47,48] Although chromium complexes are by far the most utilized in organic synthesis, complexes of iron and manganese are emerging as potentially useful alternatives.

A number of substituted benzenes, naphthalenes, indans, pyridines, and indoles form arene(tricarbonyl)chromium complexes upon thermolysis under an inert atmosphere, usually in a high boiling ether, or by irradiation of the arenes in the presence of chromium hexacarbonyl. The complexes are relatively air-stable and can usually be stored for long periods in the absence of light. Somewhat milder conditions can be used by transfer of the chromium tricarbonyl group from preformed naphthalene(tricarbonyl)chromium, tris(L)tricarbonyl chromium (L = acetonitrile, ammonia, pyridine), or tricarbonyl(η^5-1-methylpyrrole)chromium. Enantiomerically pure arene(tricarbonyl)chromium complexes having two different substituents, either ortho or meta can be prepared conveniently by classical resolution of racemic mixtures. Resolution of *ortho*-substituted benzaldehyde complexes has been achieved by formation of the aminal with chiral diamines, enamine from chiral amino alcohols, or from chiral semioxamazones, all followed by chromatographic separation and mild acid hydrolysis. Columns with chiral stationary phases can be used to directly separate enantiomers. Hydroquinone chromium tricarbonyl complexes can be prepared from Fischer carbene complexes via a benzannulation reaction (Scheme 82).



Scheme 81

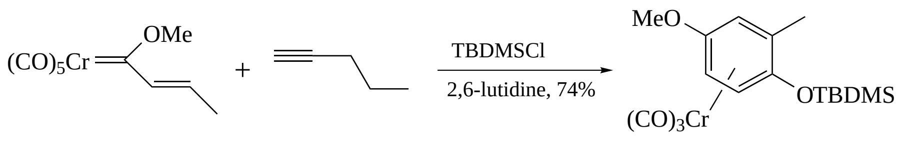
Arene(tricarbonyl)chromium complexes undergo a number of synthetically important transformations not usually observed for uncomplexed arenes. The chromium tricarbonyl moiety facilitates nucleophilic, electrophilic, and radical reactions at the benzylic position. Upon complexation, one side of the aromatic ring and adjacent functionalities is blocked by the metal carbonyl moiety and highly stereoselective reactions are usually observed even at relatively remote positions. In addition, the protons of the complexed aromatic ring have a substantially higher acidity and are readily removed and further substituted by electrophiles. Finally, the aromatic ring is activated toward addition reactions using a variety of nucleophiles.

Decomplexation to liberate the organic ligand is usually achieved by oxidation of the metal employing hydrogen peroxide, iodine, CAN, or photolysis in the presence of oxygen.

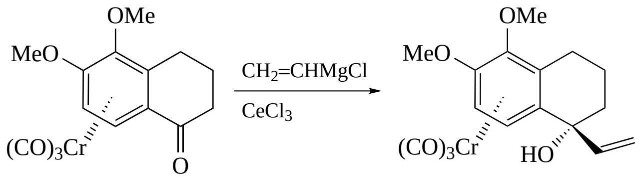
3.1 Arene Chromium Tricarbonyl Complexes as a Stereodirecting Group

The large chromium tricarbonyl ligand is a powerful stereodirecting group and nucleophilic, electrophilic, and radical reactions occur exclusively or with a very high selectivity from the *exo* side, relative to the metal, of the complexed ring. Nucleophilic addition to benzaldehyde complexes with a high degree of stereoselectivity is observed using silyl enol ethers, trimethylsilyl ketene acetals, hydrides, stabilized nucleophiles, and a variety of organometallic nucleophiles. High erythro selectivity is observed in aldol reactions of complexed benzaldehydes.

In a similar fashion, chromium tricarbonyl complexes of aryl ketones are exclusively alkylated and reduced from the *exo* face relative to the metal. For example, addition of vinyl magnesium chloride to the substituted tetralone complex (**42**) affords the alcohol (**43**) exclusively with an antirelationship between the incoming nucleophile and the chromium tricarbonyl group (Scheme 83).[49] This was used in a synthesis of 11-epi-helioporin B. 2-Trimethylsilyl-substituted benzaldehyde complexes undergo an interesting



Scheme 82



(**42**) (**43**)

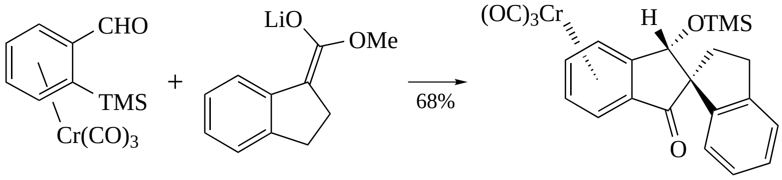
Scheme 83

alkylation-silyl-migration and cyclization upon reaction with ester enolates (Scheme 84).[50]

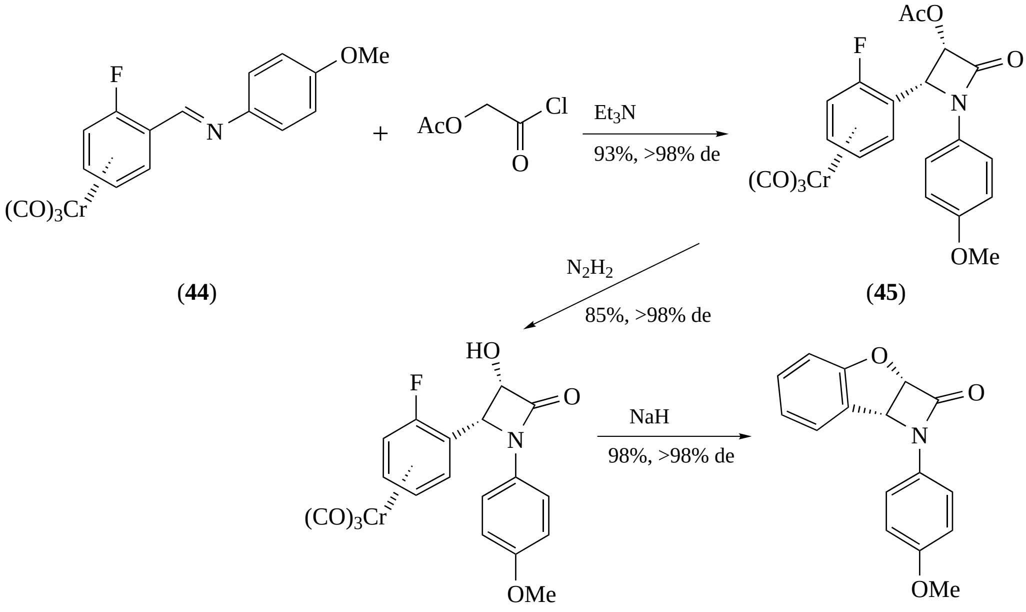
Enantiomerically enriched or pure benzaldehydeimine complexes react with nucleophiles such as Grignard (*see Grignard Reagents*) and organozinc reagents, and they participate in a number of cycloaddition reactions. Enantiopure tricyclic β-lactams can be obtained from stereoselective $[2+2]$cycloaddition between a complexed chiral benzaldehyde imine and a ketene (Scheme 85).[51] For example, reaction of (**44**) with acetoxyketene gives (**45**). The acetoxy group was hydrolyzed using hydrazine to give (**46**). Nucleophilic substitution of the fluorine atom produced the tricyclic β lactam (**47**). A diastereoselective aza-Diels–Alder reaction was used in a synthesis of (−)-lasubine (I). Tin tetrachloride–mediated reaction of complex (**48**) with Danishefsky's diene afford 2,3-dihydro-4-pyridone (**49**) as a single diastereomer (Scheme 86).[52] Chiral benzaldehyde imines can be allylated with high diastereoselectivity to give optically active homoallylic amines (Scheme 87).

Stereoselective, conjugate allylation of more remote positions using allyl trimethylsilane and $TiCl_4$ is possible. Further transformation by nucleophilic addition and ring-closing metathesis affords fused polycyclic ring systems (Scheme 88).[53] Stabilized anions and organocopper (*see* ***Copper: Organometallic Chemistry***) reagents also participate in Michael-type additions to complexed α,β-unsaturated aromatic enones.

The stereodirecting power of the chromium ligand does not only apply to reactions at the benzylic position or using rigid ring systems, but also to more remote sites. Reaction of mesylate complex (**50**) with sodium acetate affords (**51**) with



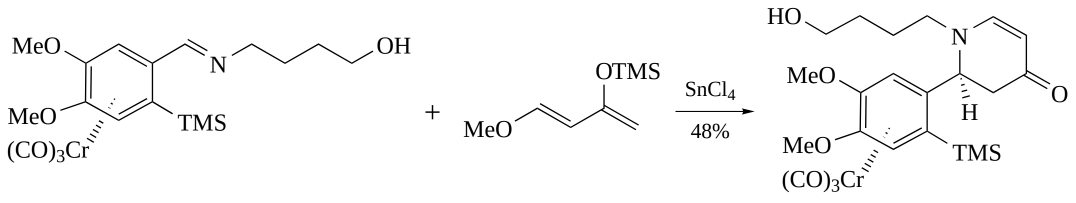
Scheme 84



(**44**) (**45**)

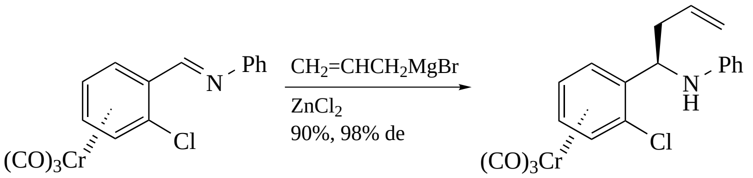
(**46**) (**47**)

Scheme 85

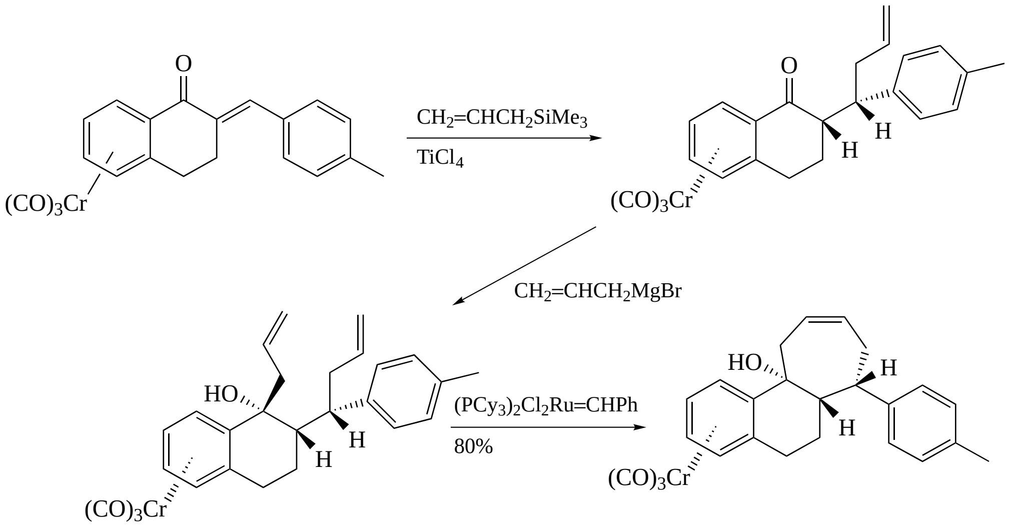


(**48**) (**49**)

Scheme 86

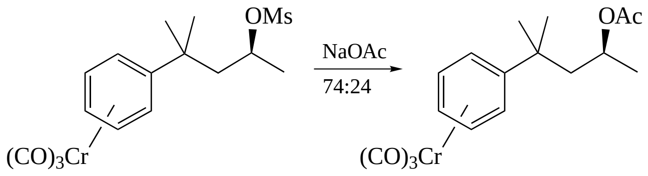


Scheme 87



Scheme 88

retention of stereochemistry (Scheme 89). In contrast, the uncomplexed substrate gave mostly inversion (Scheme 90).[54] A quinolizidinone (**53**) was obtained as a single diastereomer in an intramolecular radical cyclization reaction (Scheme 91).



(**50**) (**51**)

Scheme 89

3.2 Stabilization of Benzylic Anions and Cations

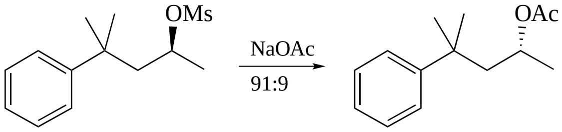
A synthetically very powerful property of chromium tricarbonyl arene complexes is the ability to stabilize a negative charge at both the α- and β-positions of an alkyl side-chain. Deprotonation of the benzylic position using sodium hydride, *t*-butyl lithium, or potassium *t*-butoxide followed by addition of an electrophile affords alkylated products. The steric requirement of the chromium tricarbonyl group again forces the incoming electrophile to be added from the *exo* face of the complex. Only one diastereomer is isolated upon

reaction of complexes wherein the benzylic position is part of a ring such as indans, 1,3-dihydroisobenzofuran, 1,2,3,4-tetrahydroisoquinoline and tetrahydrobenzazepine, and 1,3-dihydroisobenzothiophen. Furthermore, acyclic systems are commonly alkylated with a high diastereoselectivity.

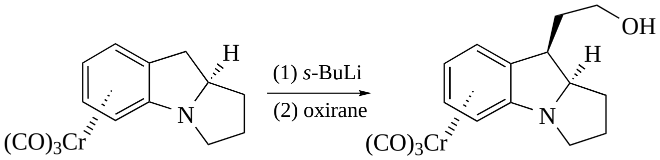
A variety of common electrophiles can be used in conjunction with deprotonation of the benzylic position of complexed alkylbenzenes. This includes alkyl iodides, aldehydes, ketones, and epoxides. Mitosanes can be prepared by deprotonation of the tricyclic complex (**52**) followed by addition of oxirane (Scheme 92). Depending on the substituent on the complexed aromatic ring, both regio- and stereoselective benzylic alkylations are observed. For example, deprotonation and alkylation of the benzylic position meta to the dimethylamino group of (**53**) is exclusively observed (Scheme 93).

Chromium tricarbonyl complexed to benzaldehyde acetals can be reduced using lithium 4,4′-di(t-butyl)biphenyl to give benzyllithium complexes that can be further functionalized using electrophiles (Scheme 94).

Examples of benzylic alkylation, aromatic ring deprotonation, and nucleophilic addition to a β-position were used in a synthesis of (+)-20-methoxy-serrulat-14-en-7,8-diol.[55] Deprotonation of the optically active complex (**54**) followed by reaction with chloromethyl methyl ether affords (**55**) (Scheme 95). The trimethyl silyl-protecting group was removed using tri-n-butylammonium fluoride (TBAF) followed by lithiation and methylation forming (**56**). Addition of phenyl methyllithium sulfone gave a 94% de after decomplexation (**57**).

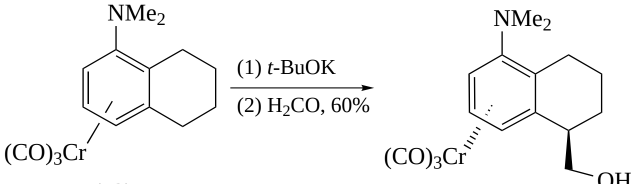


Scheme 90



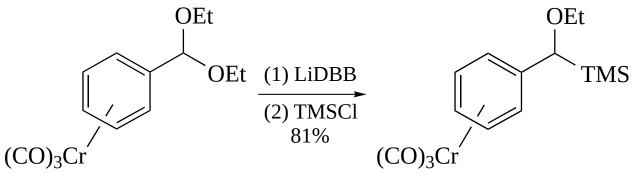
(**52**)

Scheme 92



(**53**)

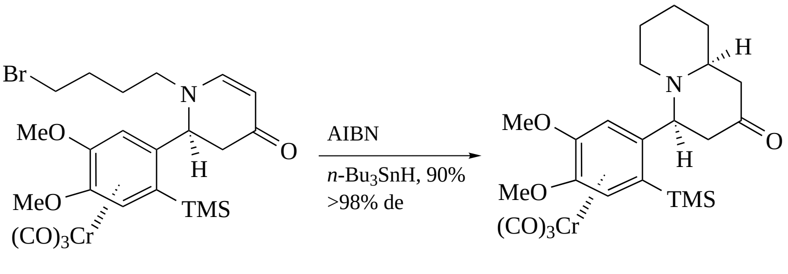
Scheme 93



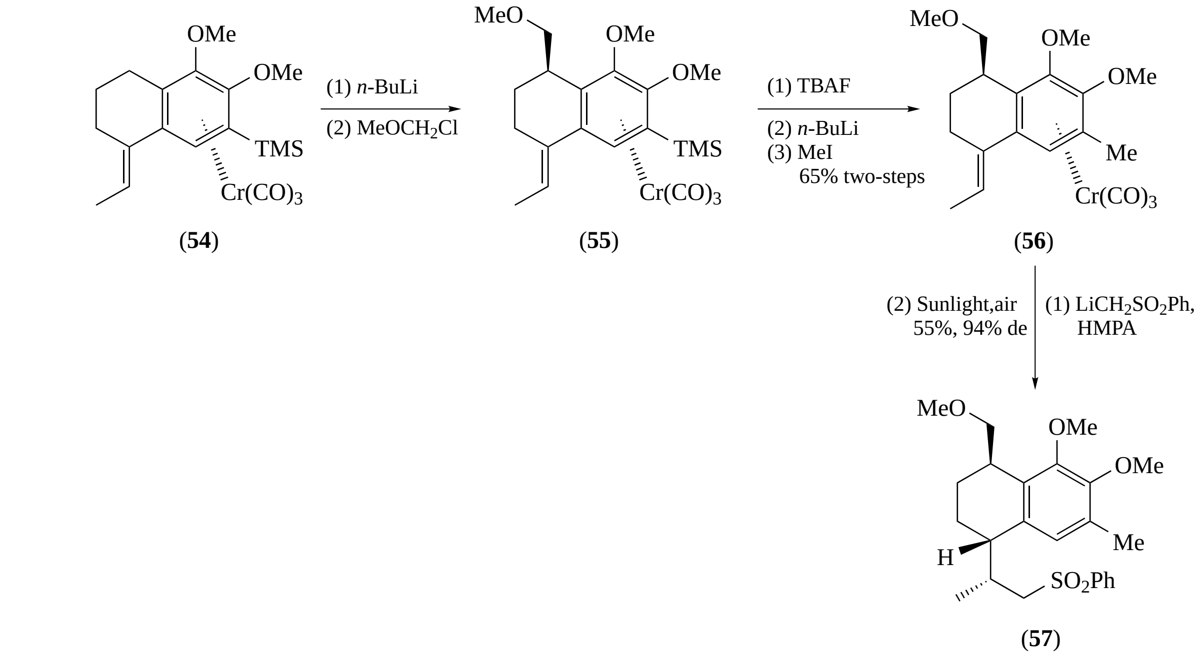
Scheme 94

Benzylic carbocations are also stabilized by complexation to chromium and a number of interesting reactions have been reported. Again, reaction of the carbocations with nucleophiles occurs from the *exo* face of the complex, relative to the metal. Carbocations are readily formed by treatment of benzylic alcohols with a strong acid, such as sulfuric acid, tetrafluoroboric acid, or borontrifluoride etherate. The cation can be trapped with water, alcohols, nitriles, and mono- or disubstituted amines to form alcohols, ethers, amides, and di- or trisubstituted amines respectively. Scheme 96 illustrates the formation of a benzylic carbocation followed by intramolecular trapping, resulting in a net inversion of stereochemistry. Benzylic acetates react with trimethyl aluminium introducing a methyl group from the opposite face of the metal.

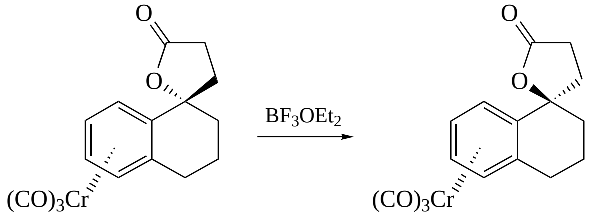
A dimethylamino group can be transformed into a chloride using 2-chloropropionylchloride (Scheme 97). The chloride in turn is readily replaced by a diphenyl



Scheme 91



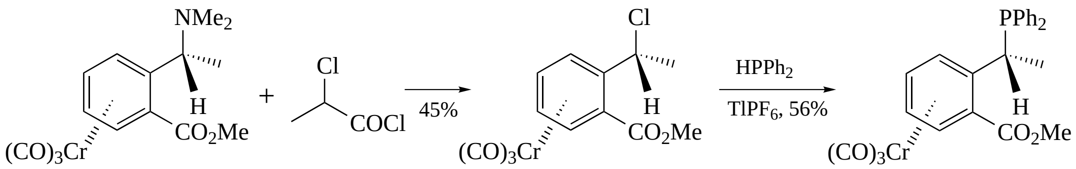
Scheme 95



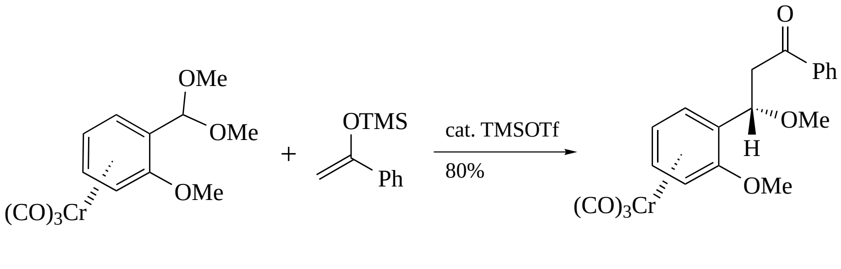
Scheme 96

phosphino group using thallium hexafluorophosphate. These transformations are again highly stereospecific due to the stereodirecting power of the bulky chromium tricarbonyl group.

Acetals and ethers can also be used to produce benzylic carbocations by reacting with a Lewis acid. Treatment of acetals derived from chiral 2-substituted benzaldehyde chromium tricarbonyl complexes with trimethylsilyl triflate followed by reaction with a silyl enol ether give diastereomerically pure alkylation products (Scheme 98).[56] Benzylic alcohols can be



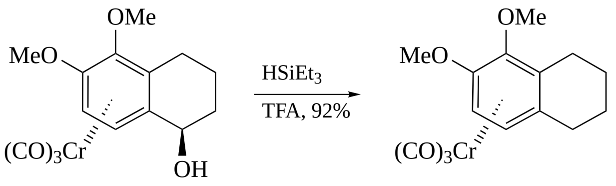
Scheme 97



Scheme 98

readily reduced using triethylsilane and trifluoro acetic acid (Scheme 99).

Asymmetric benzylic functionalization using a chiral base can be achieved. For example, reaction of complex (**58**) with the chiral base (**59**) and methyl iodide produce complex (**60**) in high yield and enantiomeric excess (Scheme 100).[57] Asymmetric benzylic alkylation can also be obtained using the chiral complex (**62**) derived from enantioselective deprotonation of (**61**) (Scheme 101).[58] High enantiomeric excess is observed upon deprotonation and alkylation of isobenzothiophen complexes with a chiral base (Scheme 102).

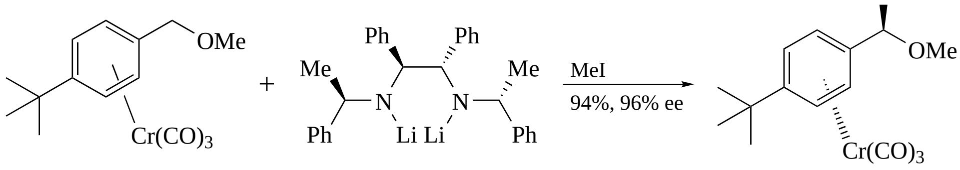


Scheme 99

3.3 Lithiation of the Aromatic Ring

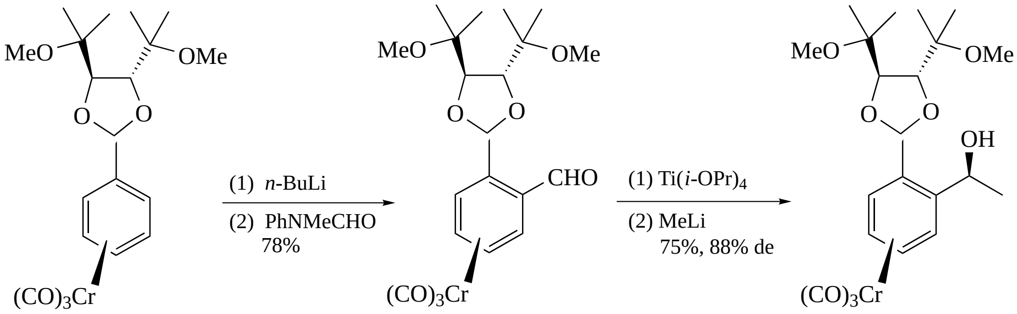
The ring protons of arenes, when complexed to a chromium tricarbonyl group, have enhanced acidity and are readily deprotonated to form, for example, lithiated (η^6-arene) complexes. Reaction of these anions with electrophiles affords substituted arene tricarbonyl complexes. A wide range of common electrophiles can be used including ketones, iodomethane, iodine, carbon dioxide, trialkyltin chlorides, trimethylsilyl chloride, chloro triphenylphosphine, disulfides, chloroformates, sulfur, diphenyldiselenide, and 1,2-dibromoethane. The latter reagent introduces a bromine atom. Lithiation of the chiral dimethylamine–substituted complex (**63**) with *t*-butyllithium followed by addition of Mander's reagent affords the ester-functionalized complex (**64**) (Scheme 103). Depending on the base and the amount of base used, *t*-butylsulfonylbenzene chromium tricarbonyl affords a variety of substituted products (Scheme 104).

Substituted aromatic rings usually produce mixtures of products upon lithiation-electrophilic addition. Fluorine, chlorine, and alkoxy groups in monosubstituted chromium



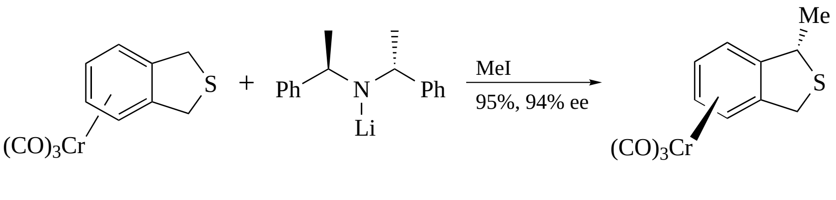
(**58**) (**59**) (**60**)

Scheme 100

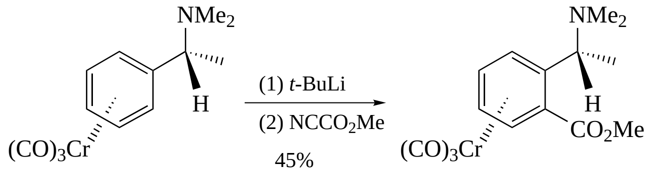


(**61**) (**62**)

Scheme 101



Scheme 102



(**63**) (**64**)

Scheme 103

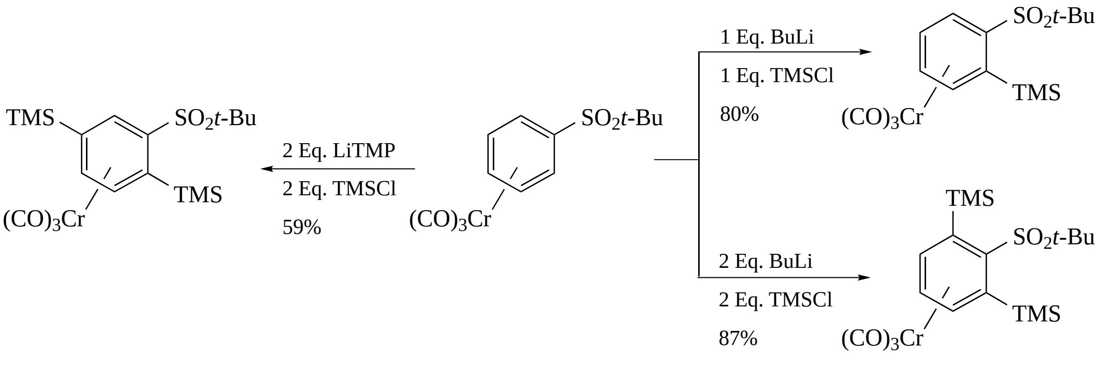
benzene complexes direct lithiation to the ortho position, and alkylation occurs exclusively in this position. Alkyl groups afford lithiation predominantly at the meta position. Lithiation using a chiral base, such as butyllithium/(−)-spartein, give in some cases products in high enantiomeric excess (Scheme 105).[59]

Optically active chromium tricarbonyl complexes can be lithiated and subsequently functionalized by a wide array of electrophiles with high diastereoselectivity. For example, reaction of (**65**) with a base and benzophenone gave (**66**) (Scheme 106).[60] The sugar-derived complex (**67**) was lithiated and reacted with diphenyldisulfide to give the chiral complex (**68**) (Scheme 107).

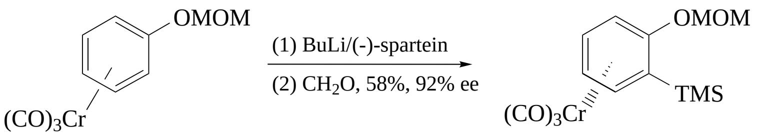
3.4 Miscellaneous Reactions of Arene Chromium Tricarbonyl Complexes

Although many oxidizing reagents remove the chromium tricarbonyl group, benzylic alcohols can be oxidized to benzaldehydes using dimethyl sulfoxide with acetic anhydride, trifluoroacetic anhydride, or sulfurtrioxide with minimal decomplexation. Asymmetric oxidation of alkylthio-substituted complexes can be achieved using titanium tetraisopropoxide and an optically active tartrate ester (Scheme 108). Dimethyloxirane can also be used to oxidize sulfides to sulfoxides.

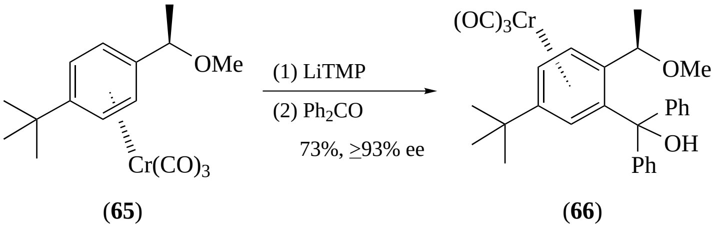
Fluoro- and chloro-substituted tricarbonyl chromium arene complexes can be reductively coupled with ketones, in the presence of samarium iodide, to give tertiary alcohols (Scheme 109).[61] A related reaction of a tethered alkoxyimine furnished a tricyclic compound (Scheme 110).[62] Samarium also promotes the formation of a benzylic ketyl



Scheme 104

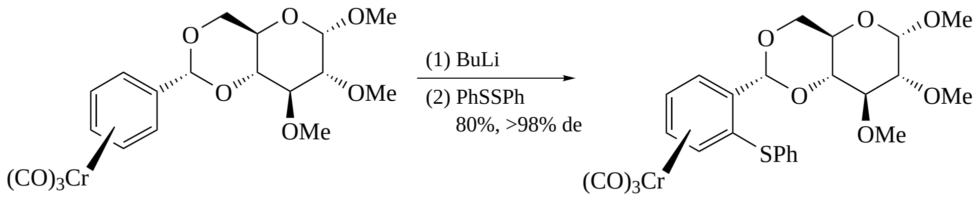


Scheme 105



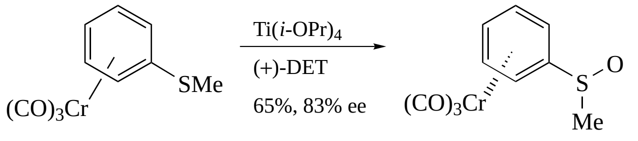
(**65**) (**66**)

Scheme 106

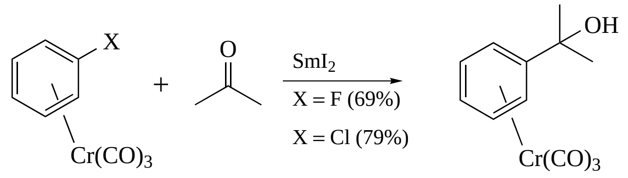


(**67**) (**68**)

Scheme 107



Scheme 108



Scheme 109

radical followed by Michael-type addition-lactone formation (Scheme 111).[63]

Iodo-, bromo-, and chloro-substituted chromium-complexed benzenes undergo a variety of palladium-catalyzed reactions. Complexed aryl halides readily react with alkynes, organoboron, organotin, organofluorosilane, and organozinc reagents under palladium catalysis. A significant enhancement in reactivity of the otherwise fairly unreactive chlorobenzenes is obtained upon complexation. Sterically hindered aryl bromides are readily coupled with arylboronic acids. Diastereoselective coupling of chiral chromium-complexed aryl bromides can be achieved (Scheme 112). In addition to reactions of transmetallating reagents, the aryl halides can be carbonylated to form benzoic acids, esters, and amides. Intramolecular alkene insertion followed by carbonylation furnishes substituted indanes (Scheme 113).[64] Aryl ketones are formed upon reaction of chromium tricarbonyl–complexed trialkylstannylbenzene. It is interesting to note that no external carbon monoxide is required.

An interesting [6 + 4]cycloaddition of thiephin-1,1-dioxide chromium tricarbonyl complex (**69**) with diene (**70**) was used in a synthesis of (+)-estradiol (Scheme 114).[65]

Scheme 115

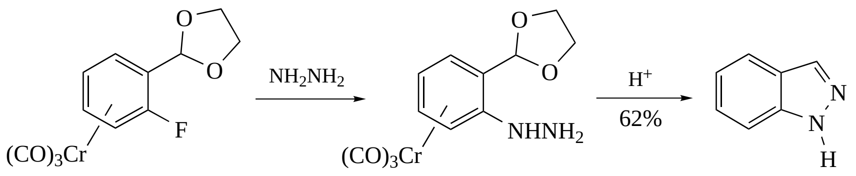
3.5 Nucleophilic Addition to the Aromatic Ring

Chromium tricarbonyl–complexed aryl fluorides undergo nucleophilic substitution reactions. The substitution is not a straightforward S_NAr mechanism as can be seen using, for example, 4-methoxy-1-fluorobenzene complex (**71**). Reaction of (**71**) with acetylide (**72**) gives a 1:2 mixture of the 1,2 and 1,3 products (**73**) and (**74**) (Scheme 115). Other leaving groups include halogens, alkoxides, and amines. Indazoles can be prepared by reaction with hydrazine followed by acidic deprotection–decomplexation (Scheme 116).

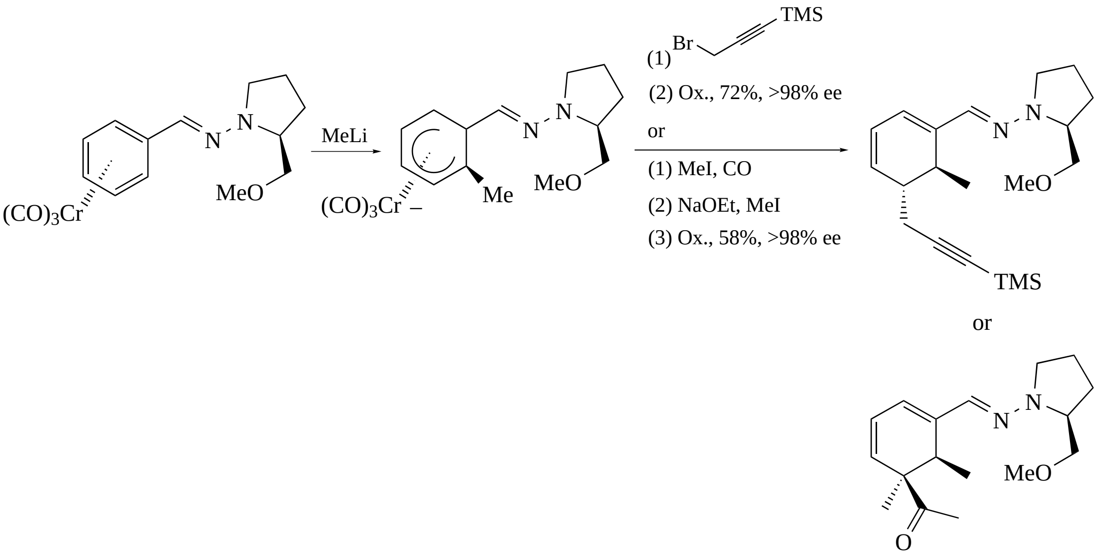
Sequential addition of organolithium reagents to enantiomerically pure tricarbonyl chromium arene complexes having a chiral oxazoline, hydrazone, ether, or imine functionality, followed by quenching with an electrophile form highly substituted, optically active cyclohexadienes (Scheme 117).[66] Depending on the conditions, two or three alkyl groups can be introduced.

The chemistry outlined above was used in a synthesis of (+)-ptilocaulin (Scheme 118). Lithiation of (**75**) followed by addition of copper chloride and an electrophile gave (**76**). Highly diastereoselective nucleophilic addition of 2-lithio-1,3-dithiane followed by treatment with TMS-chloride, oxidation, and hydrolysis produced the intermediate (**77**).

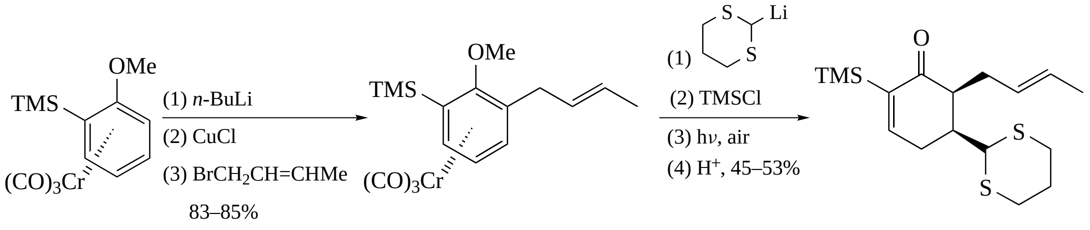
Cationic arene tricarbonylmanganese complexes of phenols can be deprotonated to give neutral η^5-cyclohexadienyl



Scheme 116



Scheme 117

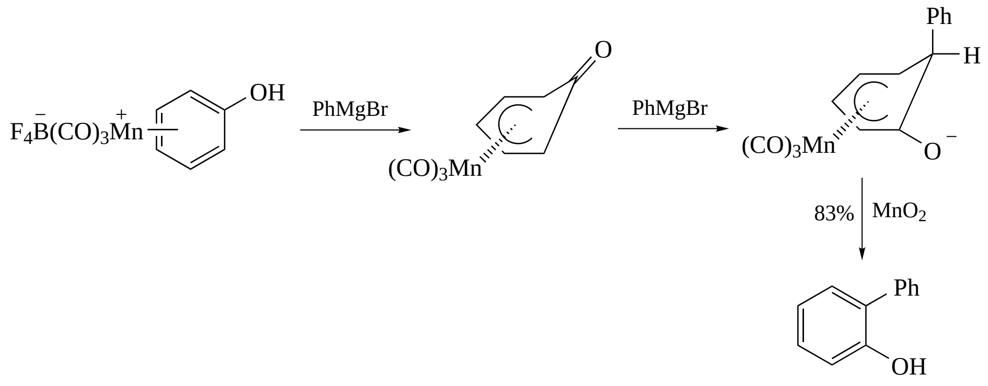


(**75**) (**76**) (**77**)

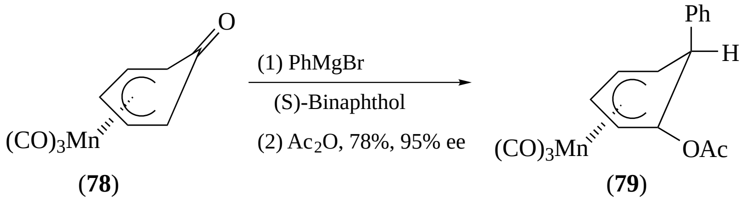
Scheme 118

complexes. These complexes undergo nucleophilic addition reactions (*see Nucleophilic Addition: Rules for Predicting Direction*) to give a new η^5-complex that can be decomplexed to form substituted phenols (Scheme 119).[67] It is noteworthy that the nucleophile does not add to the carbonyl carbon. Chiral arene-manganese complexes can be obtained by addition of the nucleophile in the presence of a chiral ligand. For example, reaction of (**78**) with phenyl magnesium bromide in the presence of (S)-binaphthol produced (**79**) after acetylation (Scheme 120).

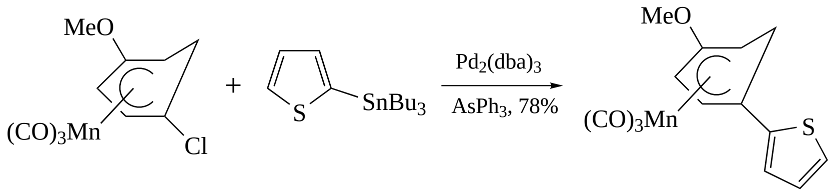
Organozinc reagents can also be added to the cationic manganese arene complexes. Neutral η^5-1-chlorocyclohexadienyl manganese complexes undergo palladium-catalyzed couplings with organotin compounds (Scheme 121, *see Stille Coupling*). Alkylation of cationic manganese complexes of amino-substituted arenes affords neutral cyclohexadienyl complexes. The latter complexes can be further transformed into substituted cyclohexenones by ligand exchange, hydrolysis, and hydride reduction (Scheme 122). 2-Lithio-2-chloro- and 2-lithio-2-bromopropanoates can be used as nucleophiles in alkylations of cationic manganese arene complexes. Only the complex resulting from meta alkylation was observed using toluene and anisol complexes. Alkylation of chiral cationic manganese complexes having a 2,5-dimethylpyrrolidine group



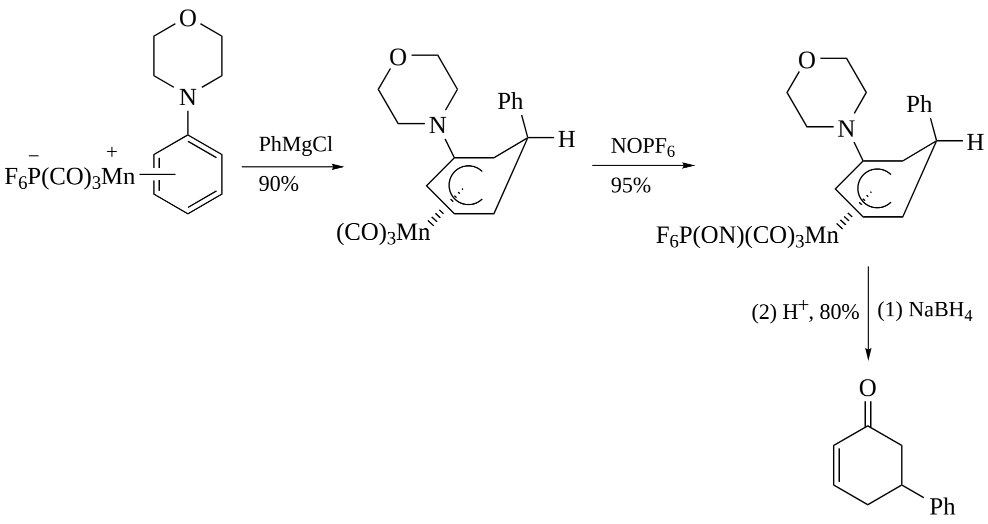
Scheme 119



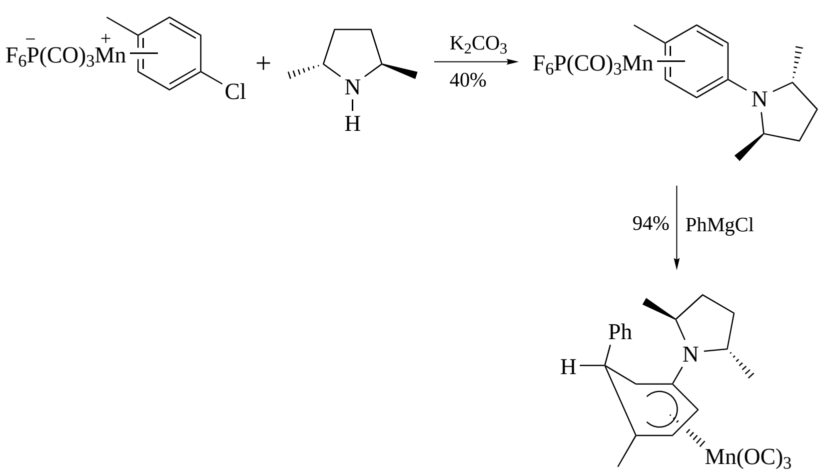
Scheme 120



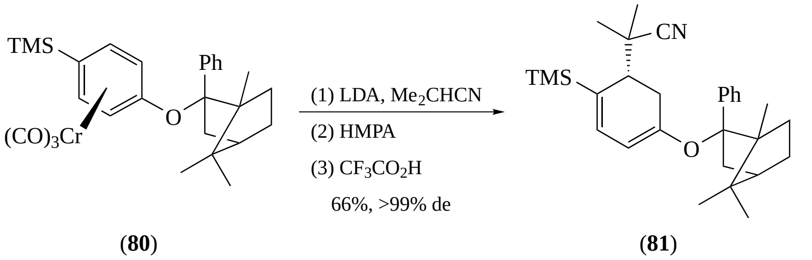
Scheme 121



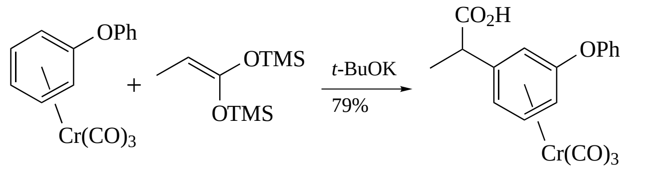
Scheme 122



Scheme 123



Scheme 125



Scheme 124

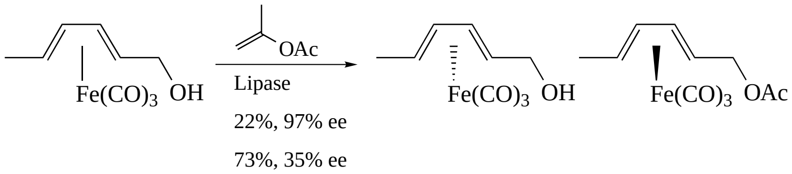
produce products with diastereoselectivities up to 94% (Scheme 123).

Direct nucleophilic addition of potassium enolates derived from bis(trimethylsilyl)ketene acetals to aromatic chromium-complexed aromatic ethers affords meta substituted products (Scheme 124).[68] A very high degree of asymmetric induction is obtained upon reaction of chiral arene chromium tricarbonyl complexes. For example, alkylation of complex (**80**) gave (**81**) after decomplexation (Scheme 125).[69]

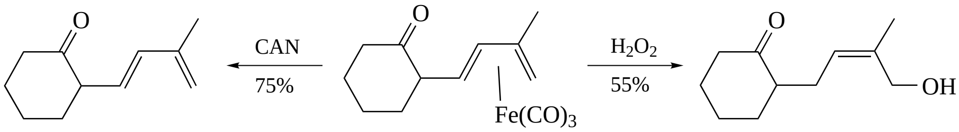
4 IRON TRICARBONYL COMPLEXESOF CONJUGATED DIENES

The use of cyclic and acyclic diene iron tricarbonyl complexes (*see Diene Complexes*) in organic synthesis of complex molecules has continued to grow over the last decade.[70,71] The relatively stable iron tricarbonyl diene complexes are easily prepared on a multigram scale from readily available starting materials. Other transition metals, such as molybdenum, cobalt, iridium, and rhodium also form complexes of this type but still remain relatively unexplored. The significant synthetic utility of iron tricarbonyl diene complexes relies heavily on four important features: (1) the stereodirecting power of the bulky iron tricarbonyl group; (2) optically active complexes can be prepared by fractional crystallization or chromatography of diastereomeric mixtures; (3) through complexation, the diene system is stable towards a large number of reagents and the iron tricarbonyl fragment can be used as a protecting group for diene systems; and (4) the metal can be removed from the dienes in high yields under mild conditions.

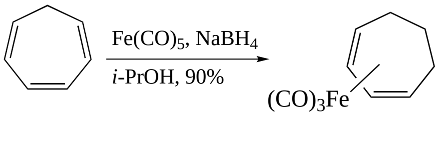
Diene iron tricarbonyl complexes are prepared by thermal or photochemical reaction of conjugated dienes with iron pentacarbonyl in the presence of TMANO, triiron dodecacarbonyl, (η^4-benzylidenacetone)iron tricarbonyl, diiron nonacarbonyl, or diiron nonacarbonyl absorbed on silica gel in the absence of solvent. The latter method is particularly useful for the preparation of complexes from polar electron-rich dienes and heterodienes. A reductive complexation of cycloheptatrienes using iron tricarbonyl and sodium borohydride to give cycloheptadiene iron tricarbonyl has been developed (Scheme 126).



Scheme 127



Scheme 128

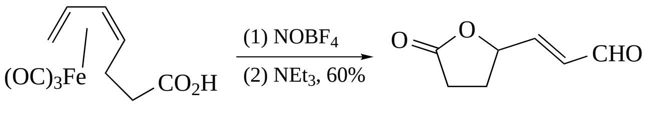


Scheme 126

Unsymmetrically substituted diene iron tricarbonyl complexes are formed as racemic mixtures of compounds having planar chirality. Optically pure diene iron tricarbonyl complexes can been prepared by classical chromatographic separation of diastereomeric mixtures of α-methylbenzylamine and ephedrine salts, and of semioxamazones and oxazolidines derivatives. Direct asymmetric complexation to cyclic dienes can be achieved 73% ee using iron pentacarbonyl in the presence of a chiral 1-aza-1,3-butadiene.

Kinetic resolution of racemic dienal iron tricarbonyl complexes by reduction using baker's yeast has been developed. Porcine pancreatic lipase-catalyzed transesterification of hydroxymethyl-substituted complexes have also been used to kinetically resolve diene complexes (Scheme 127).

Oxidative removal of the iron tricarbonyl group can be achieved using iron trichloride, copper dichloride, CAN, hydrogen peroxide under basic conditions, 3-chloroperbenzoic acid, or TMANO. The latter oxidant is frequently the reagent of choice. Depending on the reagent, decomplexation may occur with or without concomitant transformation (Scheme 128). It is important to note that no racemization of optically active compounds is detected upon decomplexation. Reductive decomplexation to form an alkene is observed upon UV irradiation in acetic acid. Tricarbonyl complexes with a pendant carboxylic acid undergo decomplexation to form lactones containing an unsaturated aldehyde (Scheme 129).

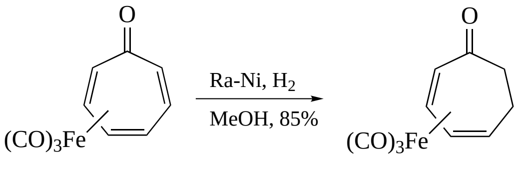


Scheme 129

4.1 Reductions and Oxidations

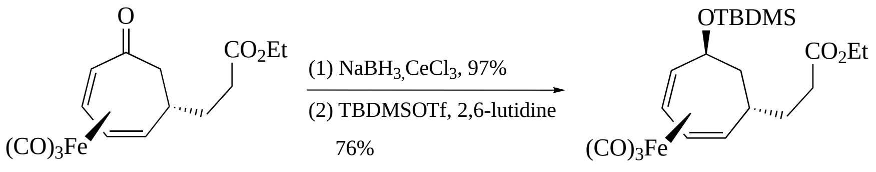
Conjugated dienes are protected toward a variety of reagents by coordination to an iron tricarbonyl moiety. For example, diene iron tricarbonyl complexes are stable to a number of reducing reagents, such as lithium aluminium hydride (LAH), diborane, diisobutylaluminum hydride (DIBAL-H), zinc in hydrochloric acid, heterogenous hydrogenation, Raney-nickel hydrogen gas, and borohydrides. For example, cycloheptatrienone complex (**82**) was reduced to the corresponding cycloheptadienone complex (**83**) using Raney-nickel hydrogen gas (Scheme 130). Stereoselective Lluche-type reduction of the ketone in (**84**) is observed using, for example, sodium borohydride in the presence of cerium trichloride (Scheme 131).

Epoxidation of allylic and homoallylic alcohols not part of the diene complex can be achieved using the Sharpless t-butyl hydroperoxide/vanadium acetylacetonate protocol. Dihydroxylation of alkenes adjacent to the diene complex using osmium tetraoxide-t-butyl peroxide has been reported

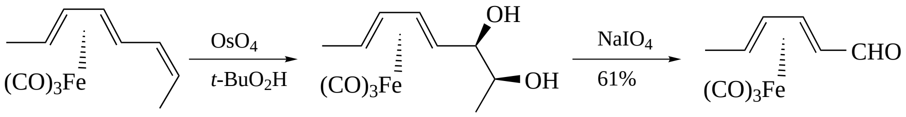


(**82**) (**83**)

Scheme 130



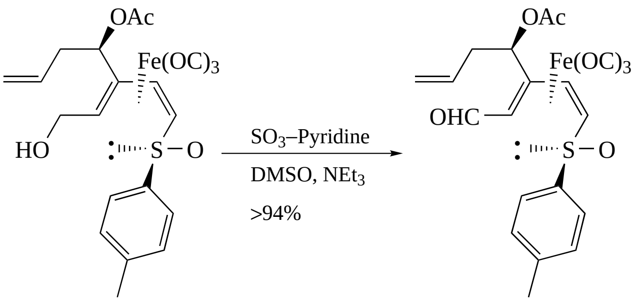
Scheme 131



Scheme 132

(Scheme 132). Sodium periodate oxidatively cleaves the diol without decomplexation of the diene moiety.

A number of oxidizing reagents can also be used to modify side-chain groups. For example Swern oxidation, pyridinium dichromate (PDC), and sulfur trioxide-pyridine/dimethyl sulfoxide (DMSO)/triethylamine oxidations are all possible without affecting the complexed diene (Scheme 133). Remote alkenes can be transformed to epoxides using DMDO (Scheme 134) and to allylic alcohols using photooxygenation and triphenylphosphine reduction. This again exemplifies the protective ability of the diene–iron tricarbonyl complex.

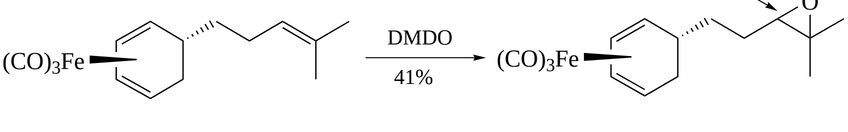


Scheme 133

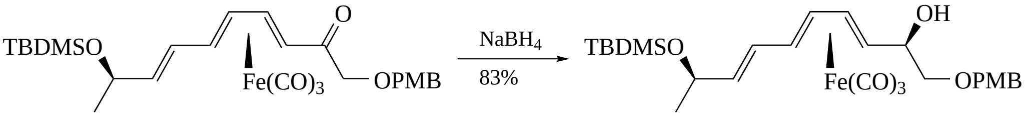
4.2 Reactions with Nucleophiles

Because of the stability of iron tricarbonyl diene complexes, conjugated dienals are protected from polymerization when complexed, while other reactions can be carried out at the aldehyde functionality. A number of synthetically attractive nucleophilic transformations of the aldehyde can be performed on these complexes. These include, aldol reactions, Michael additions, reactions with organozinc, -silicon, -boron, and -tin reagents, or Wittig-type reactions. Stereospecific reduction of adjacent ketones to give alcohols with very high stereoselectivity is observed (Scheme 135).

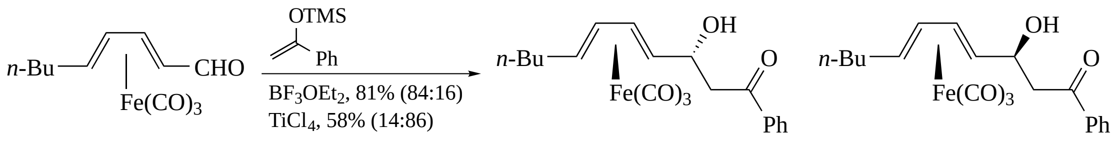
Aldol reaction of dienal complexes usually gives diastereomeric mixtures of readily separated *exo*- and *endo*-alcohols in good yields. The diastereoselectivity is highly dependent on the reaction temperature, the metal counterion of the nucleophile, and the presence



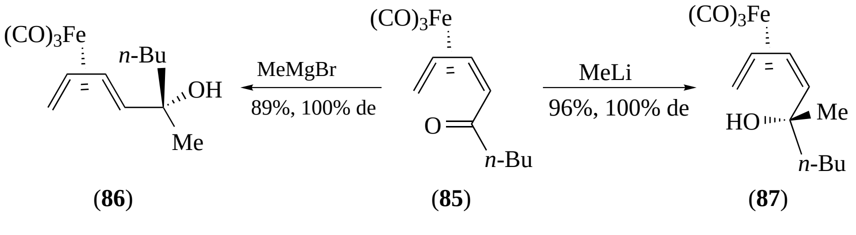
Scheme 134



Scheme 135



Scheme 136



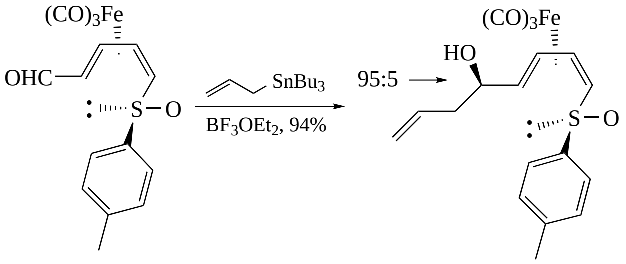
Scheme 137

or absence of electrophiles. The diastereoselectivity can be reversed using nucleophiles containing the second-row metals copper, titanium, and aluminum, in contrast with that observed with lithium and magnesium reagents. In addition to the nucleophile, reversal of selectivity can be obtained depending on the Lewis acid used (Scheme 136).

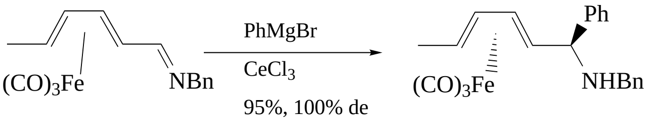
Reactions of the corresponding ketones have been much less studied, but alkylation reactions appear to be highly antiselective relative to the metal. Some alkylations resulting in the isomerization of the diene geometry have been observed. For example, reaction of (**85**) with methyl magnesium bromide gives (**86**) but reaction with methyl lithium affords (**87**) (Scheme 137). Related reductions of dienone iron complexes with sodium borohydride are also highly antiselective.

Diastereoselective allylation of optically pure sulfinyl dienal complexes using tributyl allyltin can be obtained (Scheme 138). 2,4-Hexadien-1,6-dial iron tricarbonyl complex (**88**) undergoes nucleophilic addition reactions with dialkylzincs in the presence of a catalytic amount of an optically active amino alcohol (Scheme 139). Very high enantio- and diastereoselectivity is observed. Related reactions of (**88**) with chiral allyl boronic esters give allylated alcohols in very high enantiomeric excess.

Imines formed from dienal complexes not surprisingly undergo stereoselective nucleophilic additions. Particularly



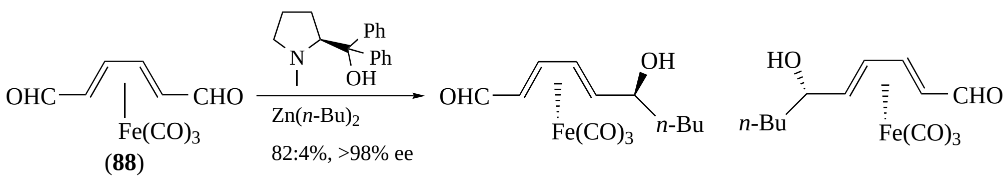
Scheme 138



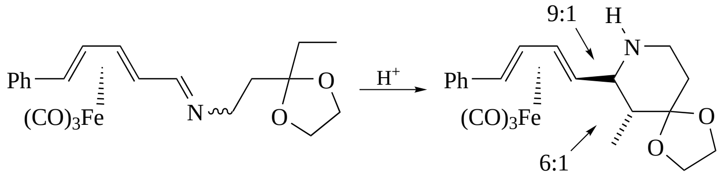
Scheme 140

selective nucleophiles are organocerium and Grignard reagents (Scheme 140). An intramolecular Mannich-type cyclization was used in a synthesis of dienomycins (Scheme 141). Imine complexes also undergo Diels–Alder reactions with Danishefsky's diene (Scheme 142).

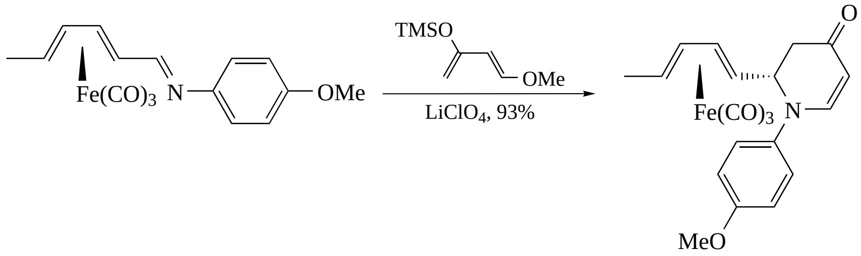
Isomeric products are obtained upon complexation of polyenes. Instead, these complexes are usually prepared



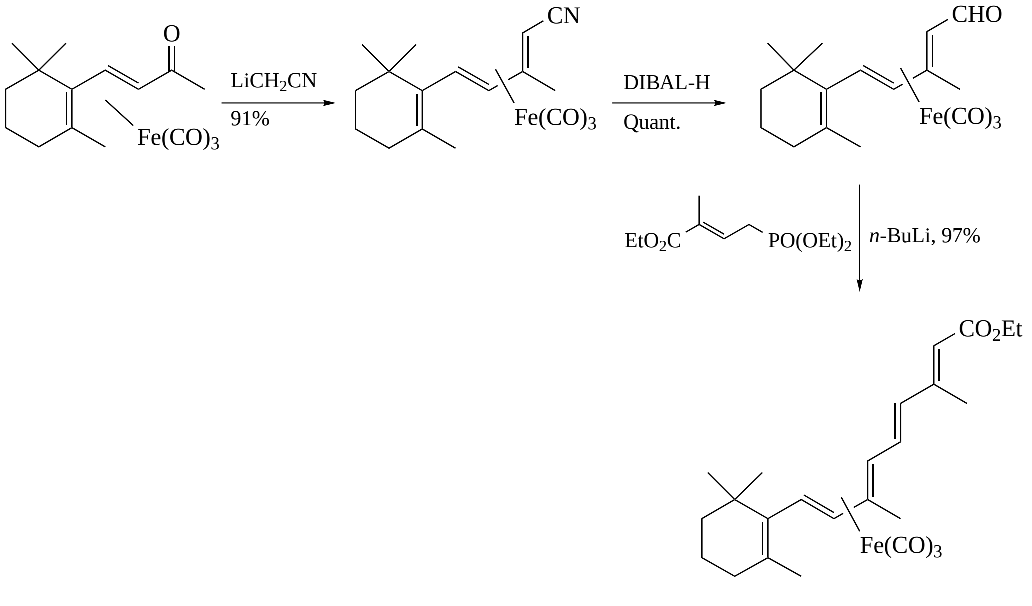
Scheme 139



Scheme 141



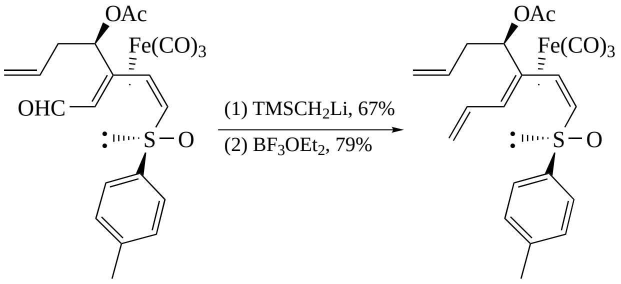
Scheme 142



Scheme 143

via standard alkenation procedures of dienal complexes. The most useful reactions in this context are Wittig-type reactions (*see Wittig Reagent*). Complexed dienals react readily with both stabilized and nonstabilized phosphoranes, as well as with phosphonate carbanions, to give E-alkenes. The inverse reaction, that is, adding aldehydes to diene complexes containing phosphorane groups, also affords the corresponding alkenes. Reactions of complexed dienals with ketone and ester enolates or $LiCH_2CN$ afford alkenation products in which the iron tricarbonyl moiety has shifted towards the electron-withdrawing group. This type of shift occurs both in the presence of a strong base or a Lewis acid. A synthesis of retinoic acids utilized the migration of iron followed by reduction and a Horner–Emmons reaction (Scheme 143). It should be noted that the migration of iron does not occur in the last phosphorous-based olefination. Petersen olefination also afford products without migration of the metal (Scheme 144).

Alkylidene malonate substitute complex (**89**) undergoes diastereoselective Michael-type additions with a number of nucleophiles including organolithiums, Grignards (*see Grignard Reagents*), allyl tributylstannane, and ketene silyl



Scheme 144

acetals (Scheme 145). Related conjugate addition reactions using dialkylzinc reagents is also possible.

Stereoselective Michael addition of functionalized zinc–copper reagents to cycloheptatrienone iron tricarbonyl complexes is observed (Scheme 146). A pendant nitrile can participate in an alkylation reaction of the intermediate enolate forming a fused bicyclic ring system (Scheme 147). Addition in a 1,2- or 1,4-fashion depends on the nucleophile. Harder nucleophiles tend to form 1,2-adducts (Scheme 148).

Reaction of complex (**90**) with methyllithium followed by acid and carbon monoxide affords a mixture of acylated complexes (Scheme 149). Reaction of an oxime complex with organocuprates followed by acetic anhydride, carbon monoxide, and potassium carbonate gives *meta*-acylaniline derivatives (Scheme 150). In both cases, the nucleophile probably initially adds to the metal followed by an acyl transfer.

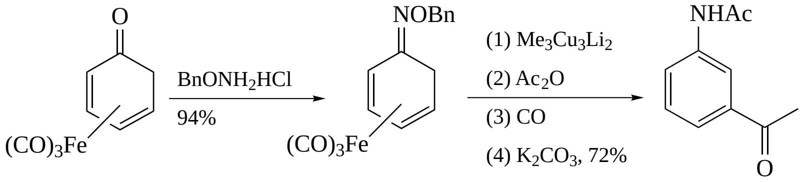
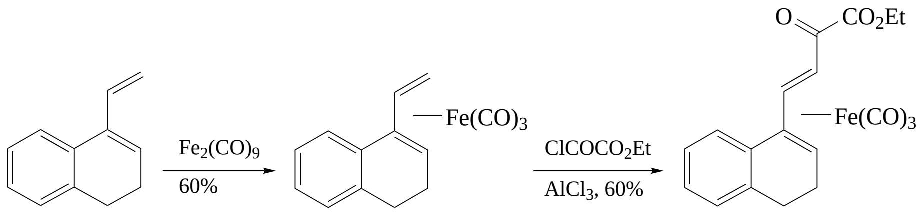
Scheme 149



Scheme 150

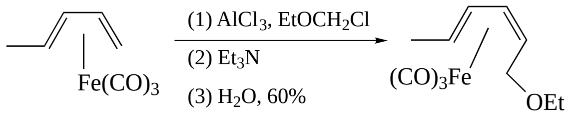


Scheme 151

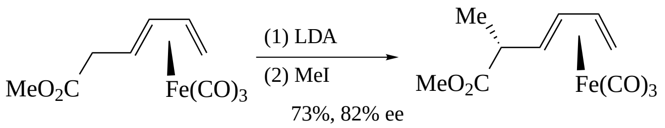
4.3 Reactions with Electrophiles

Friedel–Crafts acylation of complexed dienes can be accomplished on the nonsubstituted terminus without isomerization. An example of a complexation–acylation can be seen in Scheme 151. The cis–trans complex is often obtained as the major product from Friedel–Crafts acylations (Scheme 152). Acid-catalyzed isomerization furnishes the thermodynamically more stable trans–trans complexes.

Highly enantioselective alkylations α to acyclic diene complexes have been developed. Deprotonation of (**91**) with LDA to form an ester enolate, followed by reaction with iodomethane, gives the alkylated product (**92**) in excellent yield with 82% ee (Scheme 153). Stereospecific remote alkylation was used in a synthesis toward macrolactin A (Scheme 154).[72] In the synthetic sequence, the primary



Scheme 152

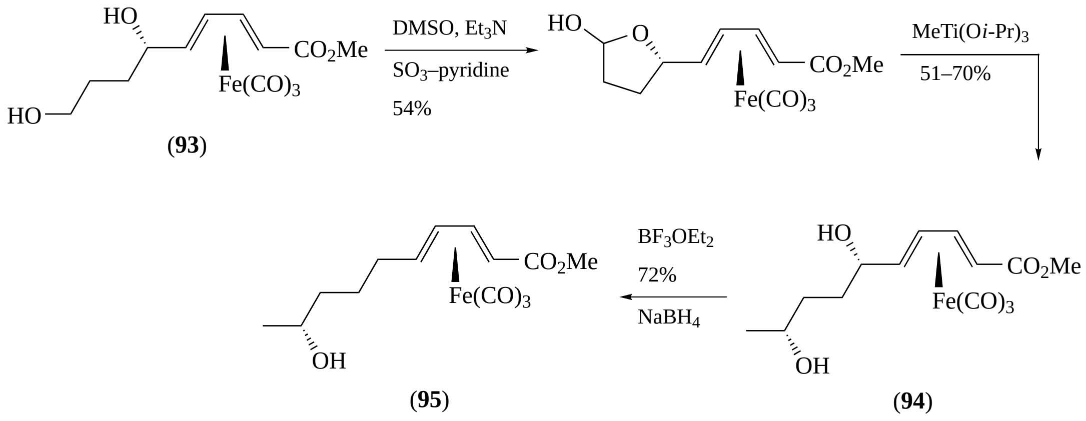


(**91**) (**92**)

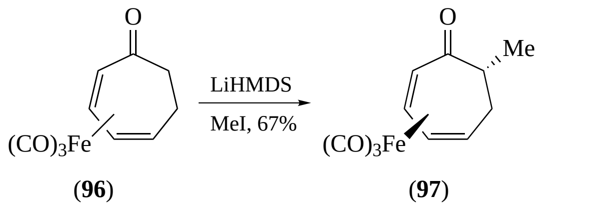
Scheme 153

alcohol of (**93**) is oxidized to an aldehyde. Reaction of the formed acetal with methyl trisopropoxytitanium furnishes the alkylation product (**94**). The α-hydroxy group is removed using sodium borohydride in the presence of boron trifluoride etherate to give (**95**). Cycloheptadienone complex (**96**) is readily deprotonated to form an enolate followed by stereospecific alkylation to give (**97**) (Scheme 155). Treatment of 1-aza-1,3-diene iron tricarbonyl complexes with a strong base followed by addition of methyl iodide, allyl bromide, or benzyl bromide affords *N*-alkylated 1,3-diene complexes (Scheme 156).

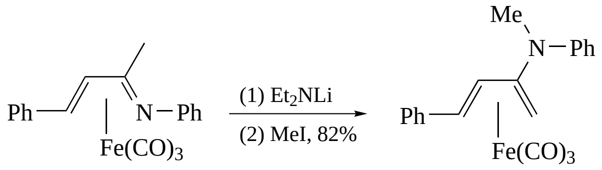
Regioselective deprotonation of ironphosphonate complexes have been reported. Depending on the phosphonate, 1,3-migration of phosphonate or ring alkylation of the anion is observed (Schemes 157–158).



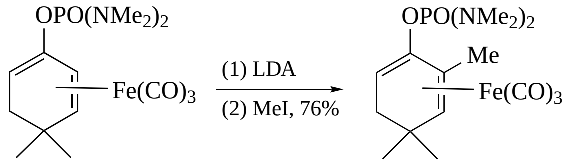
Scheme 154



Scheme 155

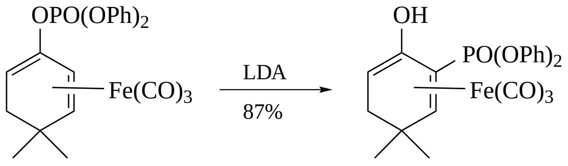


Scheme 156



Scheme 157

A number of the reactions discussed above were used in a synthetic sequence. Friedel–Crafts acylation of (**98**) gives (**99**) after isomerization of the diene geometry using sodium methoxide. Bromination of aTMS-enol ether, formed from (**99**), with DBA was nonstereospecific; however, the isomers were readily separated (Scheme 159). The pure α-bromoketone is stereospecifically methylated and transformed into an epoxide. Lewis acid–mediated isomerization of the epoxide affords an optically pure ketone (**100**).



Scheme 158

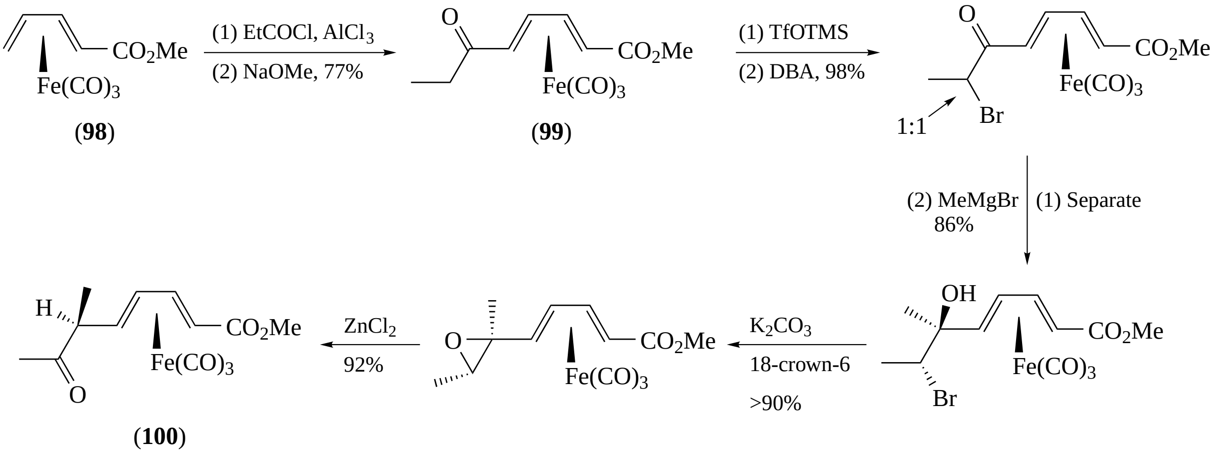
4.4 Annulations

Dienes coordinated to iron tricarbonyl do not undergo Diels–Alder reactions and a number of interesting annulation reactions of groups attached to iron tricarbonyl diene complexes have been developed. Cyclohexadiene iron tricarbonyl complexes having a pendant alkene undergo annulation reactions to form spirocyclic compounds (Scheme 160). Related reactions of allylic thioesters afford spirocyclic thialactones.

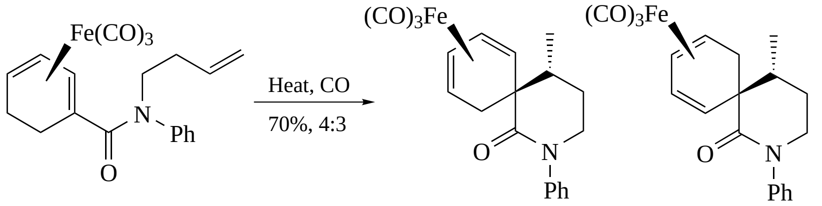
Double bonds adjacent to complexed dienes can be cyclopropanated using diazomethane, methyl diazoacetate, or sulfur-based ylids. Cycloheptatriene iron tricarbonyl undergo a $[2+2]$cycloaddition with chloroketene derived from trichloroacetyl chloride (Scheme 161).

Diene complexes containing alkene or diene substituents undergo Diels–Alder reactions in good yields. Hetero-Diels–Alder reactions have also been reported. Chirality transfer is observed upon reaction of chiral diene iron tricarbonyl complexes.[73] Reaction of the chiral complex (**101**) with cyclopentadiene in the presence of a Lewis acid give (**102**) with a relatively high chirality transfer from the metal complex (Scheme 162).

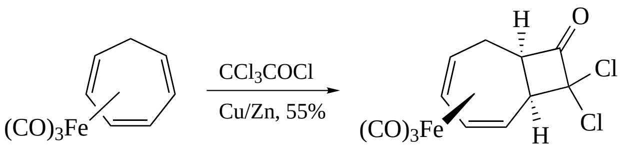
Alkene-functionalized 1,3-diene complexes undergo regio- and stereoselective 1,3-dipolar cycloaddition reactions with nitrile N-oxides. Related cycloadditions of nitroalkanes in the presence of triethyl amine and phenylisocyanate afford dihydroisoxazoles. This type of cycloaddition was used in a synthesis toward macrolactin A (Scheme 163).



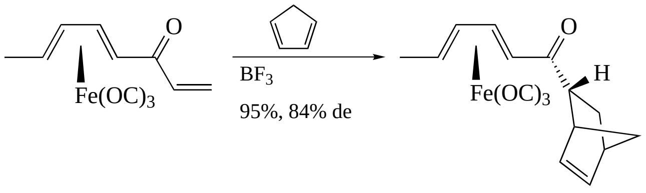
Scheme 159



Scheme 160



Scheme 161

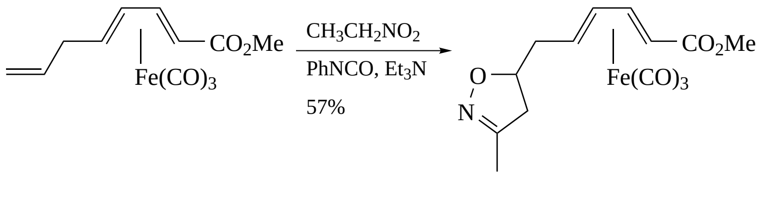


(101) (102)

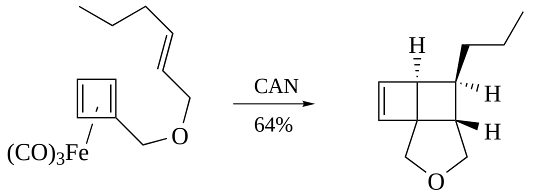
Scheme 162

Cyclobutadiene iron tricarbonyl complexes can be isolated and have been utilized in organic synthesis. Both intra- and intermolecular [2 + 2]cycloadditions of alkenes with cyclobutadiene complexes are observed upon decomplexation using CAN or TMANO (Schemes 164–165).[74] The stereochemistry of the alkene is retained in the product. Iron tricarbonyl diene complexes are compatible with metathesis reactions using ruthenium catalysts (Scheme 166, *see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***).

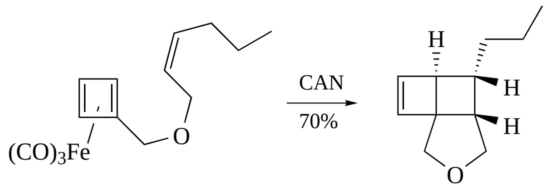
Benzannulated products are obtained via thermolysis of α-diazo ester-substituted complexes. For example, formation of diazo ketone complex (**103**) via a tosyl hydrazone followed by thermolysis gave (**104**) (Scheme 167).[75]



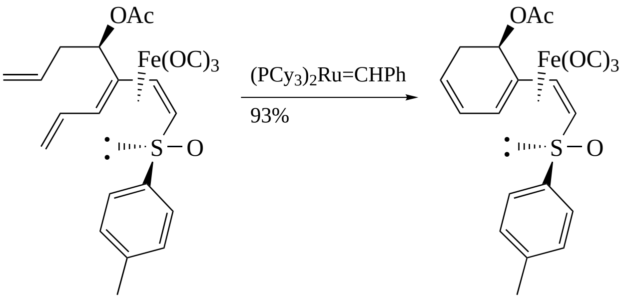
Scheme 163



Scheme 164



Scheme 165



Scheme 166

The chemistry of diene iron tricarbonyl complexes described above has been in a number of total syntheses. An iterative stereospecific 1,3-migration of the iron tricarbonyl moiety was used to prepare compounds with multiple chiral centers. An example of one iteration can be seen in Scheme 168.[76] Ester hydrolysis of (**105**) and protection of the resulting alcohol gives (**106**). Reduction of the nitrile with DIBAL-H followed by olefination furnished (**107**). Treatment of (**107**) with a base resulted in the migration of iron toward the nitrile to give (**108**). The uncomplexed double bond can be dihydrolylated and transformed to ketal (**109**). Triethylsilane–Lewis acid reduction of the carbon adjacent to the diene system affords a new complex (**110**) completing the sequence.

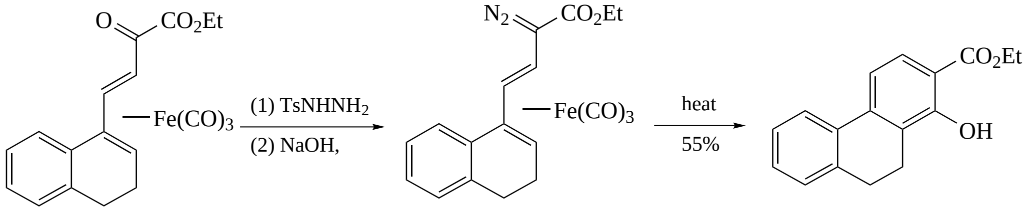
A synthesis of α-lipoic acid and derivatives has been reported. The pendant alkene of complex (**111**) was transformed to a primary alcohol (**112**) via hydroboration-oxidation sequence. Mitsunobu coupling of (**112**) with thiobenzoic acids to give (**113**), followed by desilylation and nucleophilic substitution again employing thiobenzoic acid gave the advanced intermediate (**114**) (Scheme 169).

4.5 Cationic η^5-dienyl Iron Complexes

Hydride abstraction from dienyl tricarbonyl iron complexes furnishes cationic dienyl tricarbonyl iron complexes. For example, reaction of the diene–iron tricarbonyl complex (**115**) with triphenylmethyl hexafluorophosphate followed by trimethylsilyl cyanide furnished with excellent regio- and stereoselectivity a new diene–iron tricarbonyl complex (**116**) (Scheme 170). Excellent regio- and stereoselectivity is seen upon reaction of the cationic complex (**116**) with trimethylsilyl cyanide (TMS-CN) (Scheme 170). Reduction of the nitrile affords a spirocyclic lactam complex. Intramolecular cyclization of in situ formed enols furnishes spirocyclic compounds again with excellent stereocontrol (Scheme 171). An interesting example of hydride transfer from a cyclohexadiene ring to a pendant aldehyde followed by nucleophilic addition is seen in Scheme 172.

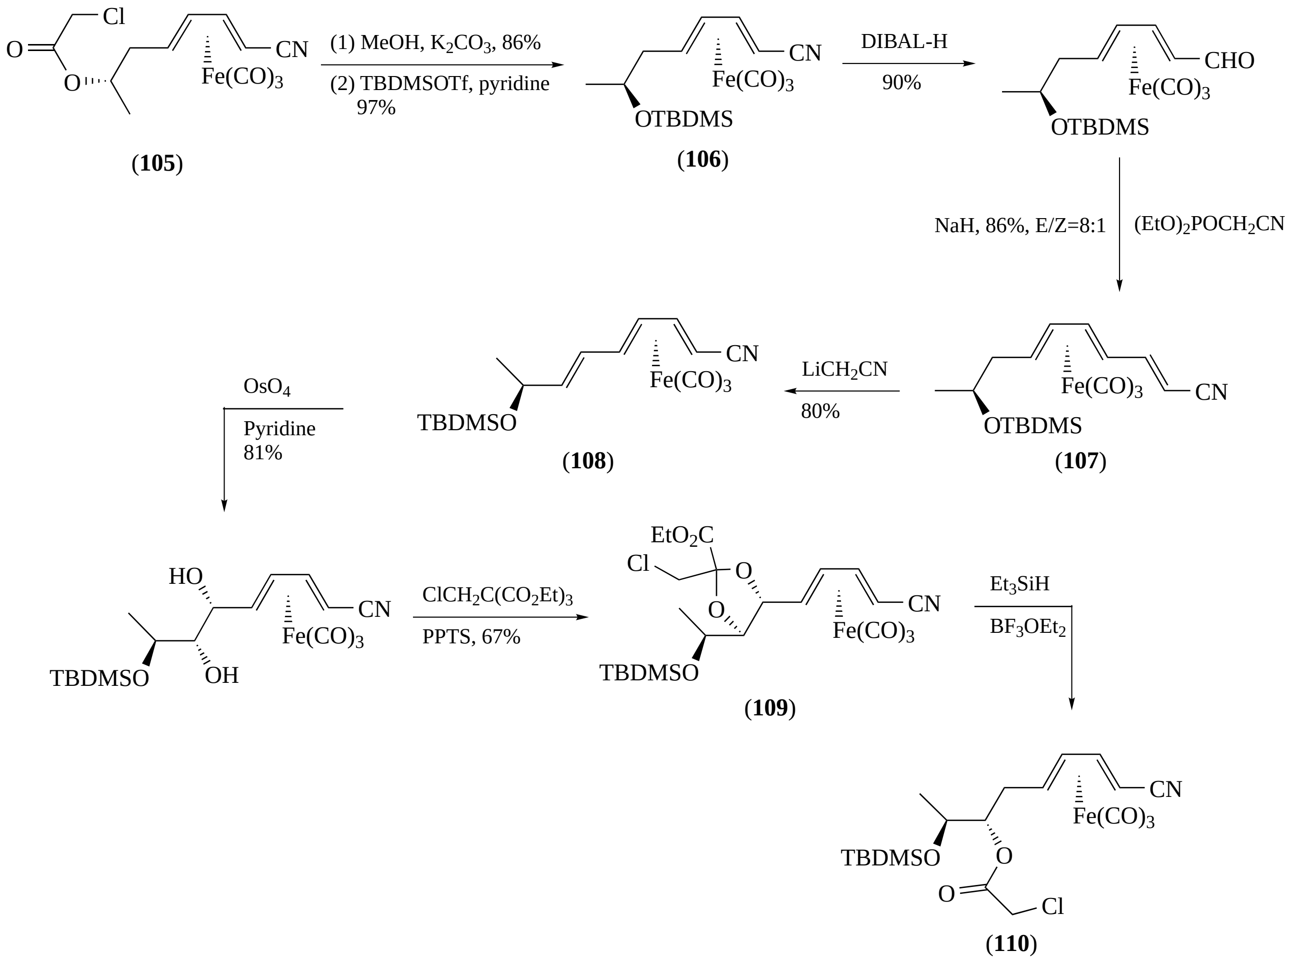
Addition of stabilized nucleophiles to complex (**117**) affords (**118**) via addition of the nucleophile to the face opposite the metal (Scheme 173).[77] Oxidative decomplexation of (**118**) results in the formation of a stereodefined vinylcyclopropane (**119**). Vinyl ketene complexes insert electron-deficient alkenes and undergo related cyclopropanations upon oxidation (Scheme 174). Harder nucleophiles such as Grignard reagents (*see Grignard Reagents*) usually add to the terminal carbon of the dienyl system (Scheme 175). Depending on the cation and ligand on iron, either addition of a stabilized nucleophile to the ring or a Michael-type reaction is observed (Schemes 176–177).

Cationic complexes formed from acyclic diene iron complexes react in a fashion very similar to dicobalt hexacarbonyl stabilized propargylic cations. The cations can

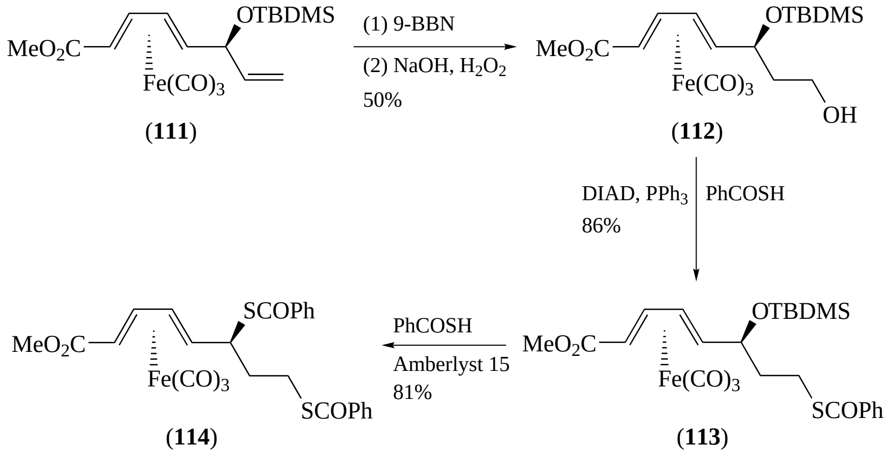


(**103**) (**104**)

Scheme 167

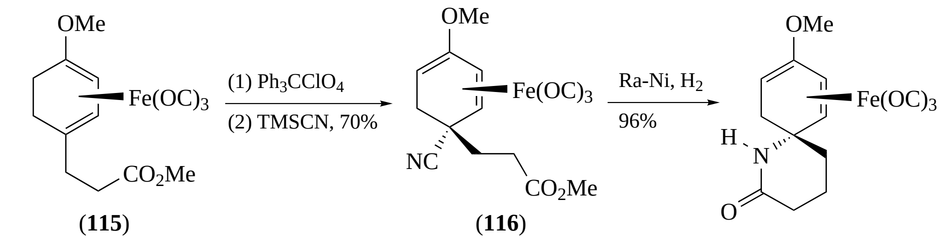


Scheme 168

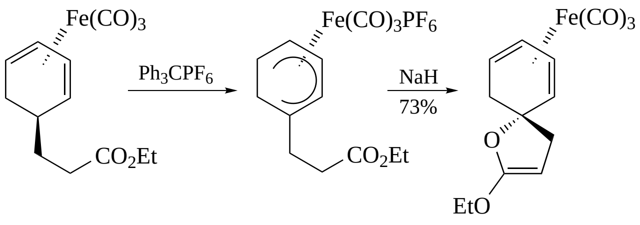


Scheme 169

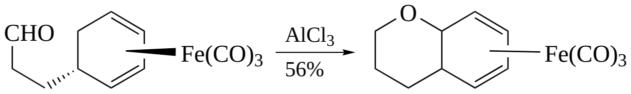
be formed by reaction of an adjacent alcohol or an ester group with a Lewis acid. The cationic species undergo reactions with a variety of nucleophiles to give products from addition to the face opposite the metal. Nucleophiles include trialkylaluminum, ketene silylacetals, allyltributyltin, allyltrimethylsilane, and trimethylsilylazide (Scheme 178).



Scheme 170



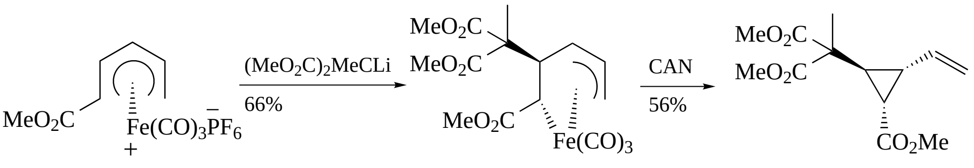
Scheme 171



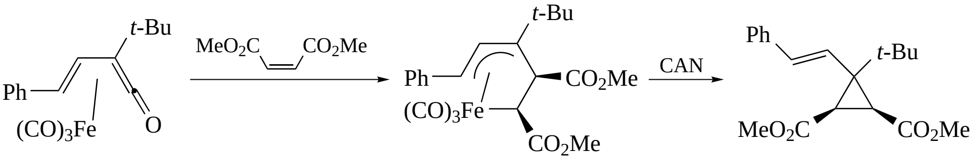
Scheme 172

Highly stereospecific additions of thio-groups are also seen and this was used as a key step in the synthesis of halicholactone (Scheme 179).[78] Treatment of dienol iron tricarbonyl complexes with DAST introduces a fluorine atom with complete retention of stereochemistry. Stereospecific cyclization reactions involving pendant alkenes or electron-rich aromatic rings can be achieved (Scheme 180).[79] The incorporation of a fluoride atom from boron trifluoride is usually observed from reaction with alkenes. The carbocation can also be generated from a double bond adjacent to the diene moiety. For example, reaction of (**120**) with formic acid gave (**121**) via stereoselective interception of an intermediately formed secondary carbocation (Scheme 181).[80]

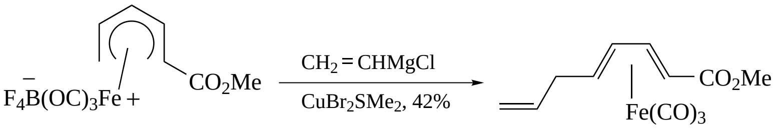
A very high stereoselectivity is observed upon formation of a dienyl carbocation (**123**) from the enantiomerically pure complex (**122**) followed by nucleophilic addition. An



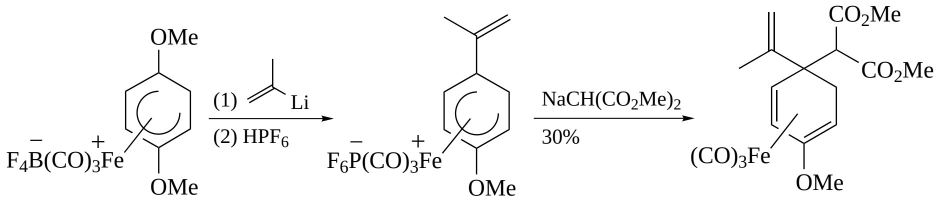
Scheme 173



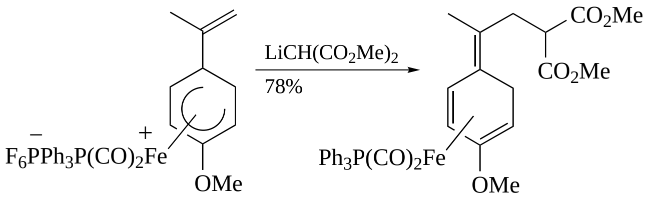
Scheme 174



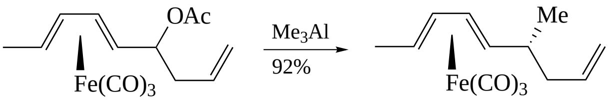
Scheme 175



Scheme 176



Scheme 177

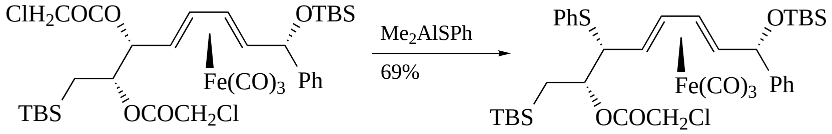


Scheme 178

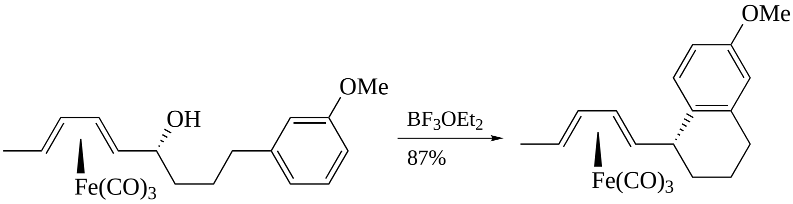
E, Z product is formed via reaction of the u-form (**123**) (Scheme 182). In contrast, more reactive nucleophiles react with the s-form (**122**) to give E, E geometry of the double bond (Scheme 183).

Cycloheptadienylcations are readily alkylated. The regioselectivity of the addition depends on the substituents on the ring. For example, the methoxy-substituted complex (**124**) is alkylated on the methoxy bearing carbon (Scheme 184). In contrast, complex (**125**) having a methyl group in place of the methoxy group affords complex (**126**).

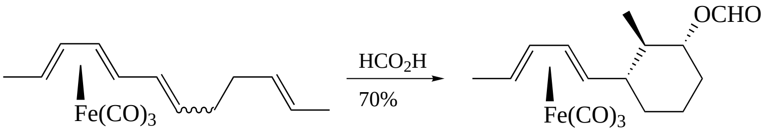
Of particular synthetic importance are the reactions of cyclohexadienyl cations with aromatic amines under oxidative conditions (Scheme 185). This type of reaction has been utilized as the key step in highly convergent synthetic relays to a variety of carbazole alkaloids. Enamines can be used



Scheme 179

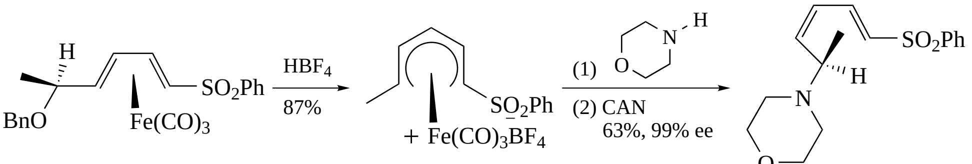


Scheme 180

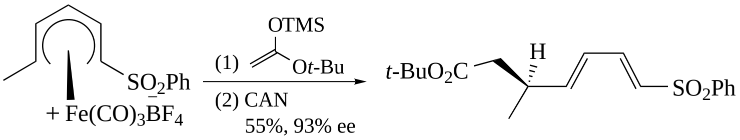


(**120**) (**121**)

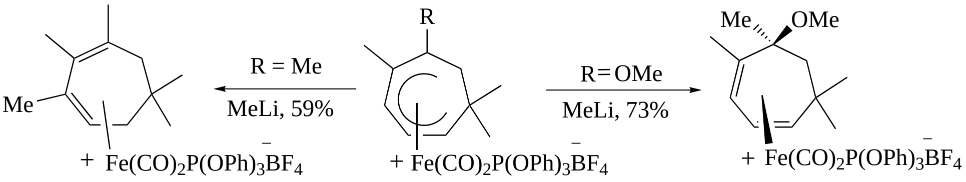
Scheme 181



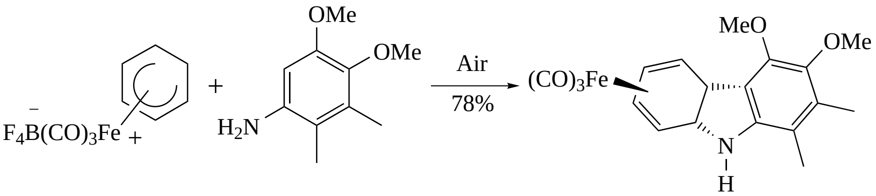
Scheme 182



Scheme 183



Scheme 184



Scheme 185

as the nucleophile affording cyclic adducts after oxidative amination (Scheme 186).

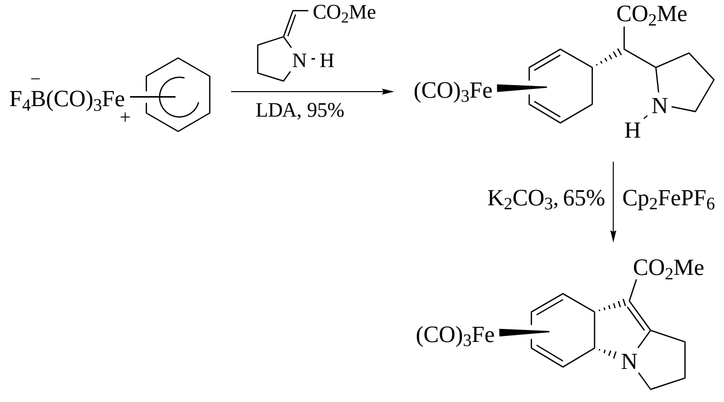
Cyclobutadiene iron tricarbonyl complexes also stabilized carbocations on an adjacent carbon. The cation reacts with silyl enol ethers to afford alkylated complexes such as (**127**) (Scheme 187). A samarium diiodide–mediated intermolecular radical cyclization of iron tricarbonyl complex (**128**) is depicted in Scheme 188. An excellent stereocontrol at three contiguous centers is observed.

5 DICOBALT HEXACARBONYL ALKYNE COMPLEXES

Alkyne complexes (*see Alkyne Complexes*) of almost all transition metals have been isolated and characterized. By far, the most studied and synthetically versatile are dicobalt hexacarbonyl alkyne complexes. The relative stability of cobalt–alkyne complexes, compared to related complexes of other transition metals, and their ability to further react with a number of reagents makes them ideal intermediates in organic synthesis. Alkyne dicobalt hexacarbonyl complexes are usually prepared by thermolysis of a solution of $Co_2(CO)_8$ in the presence of an alkyne. Alkyne cobalt complexes can also be prepared by reaction of alkynes with cobalt dibromide in the presence of zinc and carbon monoxide.

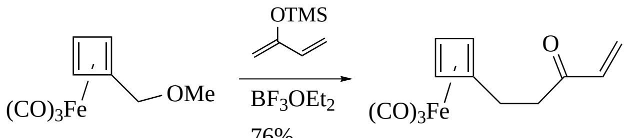
The bridged complex between two cobalt tricarbonyl units and all four π-electrons of the alkyne distorts the alkyne from being linear to being bent in a 150°C angle. For simplicity, all $Co_2(CO)_6$ complexes will be represented by a single bond from the $Co_2(CO)_6$ fragment to the alkyne (Scheme 189).

The cobalt moiety can be removed to give the free alkyne in high yields using, for example, CAN, TBAF, iron trinitrate,



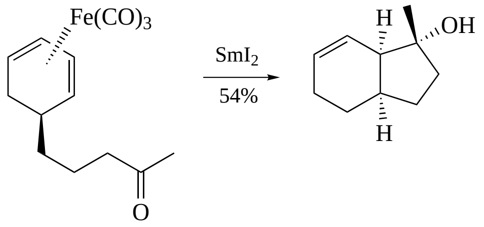
Scheme 186

iodine, or trimethylamine *N*-oxide, sodium methylthiolate, and 1,2-diaminoethane. A carbonylative decomplexation in the presence of a primary or secondary amine can be achieved. For example, reaction of phenylethyne dicobalt hexacarbonyl with *N*,*N*-dibenzylamine gave (**129**) (Scheme 190). Also of synthetic interest is the oxidative decomplexation of (**130**) furnishing an anhydride (**131**) (Scheme 191).



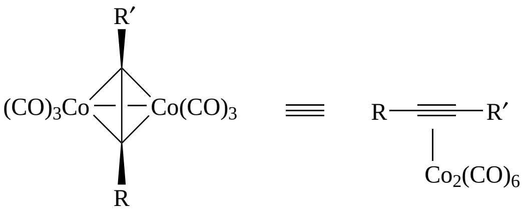
(**127**)

Scheme 187



(**128**)

Scheme 188

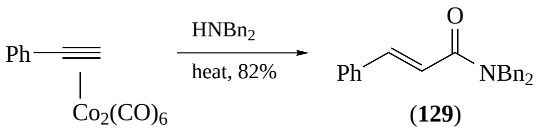


Scheme 189

A number of reductive decomplexation methods are available. A reductive removal using tributyltin hydride to give the saturated hydrocarbon has been reported (Scheme 192). Reductive decomplexation has also been observed using trifluoro acetic acid to afford a cis-alkene as the major product (Scheme 193).

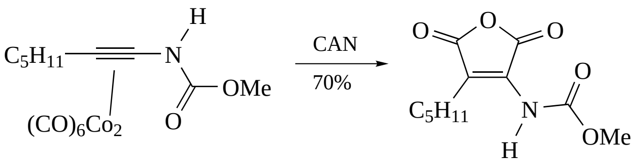
5.1 Alkyne Cobalt Complexes as a Protecting Group

Dicobalt hexacarbonyl−alkyne complexes are stable to a number of electrophilic reagents, and uncomplexed multiple



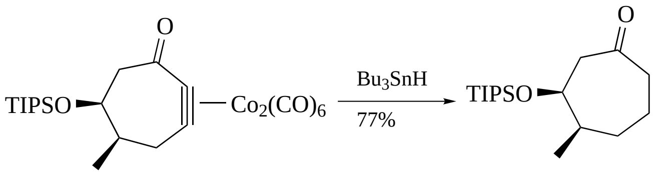
(**129**)

Scheme 190

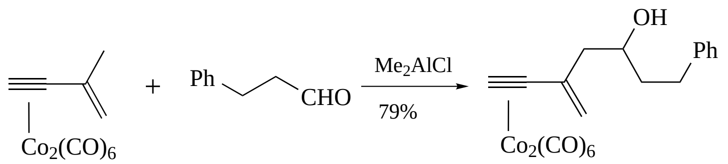


(**130**) (**131**)

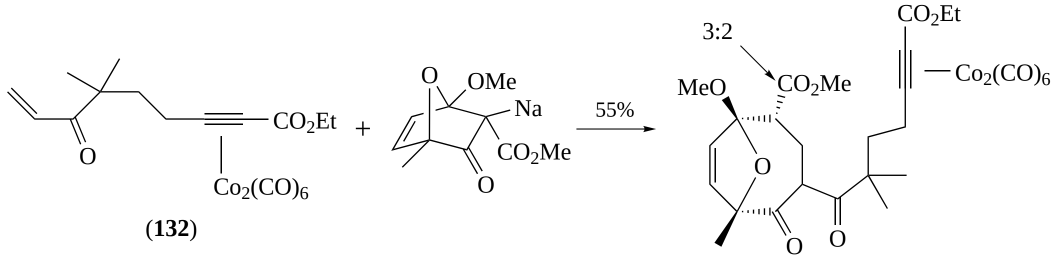
Scheme 191



Scheme 192

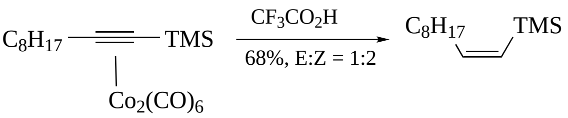


Scheme 194



(**132**)

Scheme 195

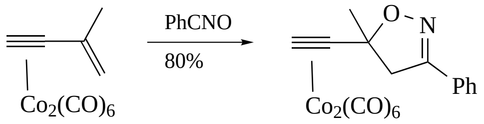


Scheme 193

bonds present within these molecules can be manipulated. For example, pendant alkenes can be reduced using hydrazine or oxidized using hydroboration-peroxide oxidation. It is noteworthy to observe that hydrogen peroxide does not result in demetallation of the complex.

Alkynols complexed to cobalt can be oxidized to alkynals without decomplexation. Propargyl aldehydes are protected from polymerization upon complexation with $Co_2(CO)_6$. These aldehydes smoothly undergo Wittig-type reactions. Carbonyl-ene reactions have been demonstrated (Scheme 194). Complexation to cobalt protected the enyne in complex (**132**) from Michael-type reactions (Scheme 195). Alkenyl-substituted complexes undergo [3 + 2]cycloadditions with nitrile *N*-oxides (Scheme 196).

Cobalt-complexed propargylic aldehydes can be alkylated using both cyclic and acyclic trimethylsilyl enol-ethers and -esters in the presence of a Lewis acid. Boron trifluoride etherate is the most frequently employed Lewis acid.



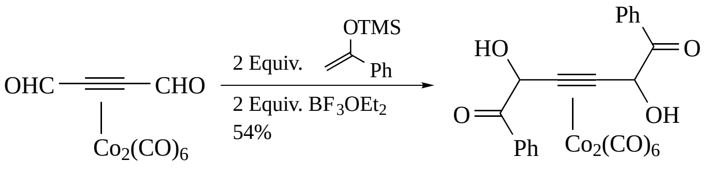
Scheme 196

Other nucleophiles include organolithiums and Grignard reagents.

Aldol-type reactions of complexed propargylic aldehydes afford mixtures of syn/anti aldol products. Double alkylation can be obtained using butynedial complex (**133**) (Scheme 197). Reaction of complexed aldehydes with diethyl zinc in the presence of a chiral ligand takes place with high enantioselectivity (Scheme 198).[81] Very high diastereoselectivities are observed upon reaction of Grignard reagents to phosphine-substituted complexes (Scheme 199). Optically active allylboranes also react with complexed propargylic aldehydes and afford propargylic alcohols in high enantiomeric excess. For example, reaction of the chiral γ-alkoxyborane (**134**) with (**135**) affords the allylation product (**136**) with an excellent degree of diastereoselectivity (Scheme 200, $R^* =$ isocampheyl).

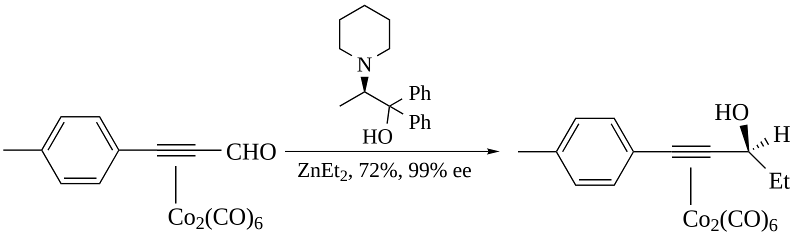
Mukaiyama-type reaction of cobalt-alkyne complexes with ketene acetals gives the *syn* product exclusively, a reaction used as a key in a relay to bengamide E (Scheme 201). Total synthesis of blastomycinone utilizing a Mukaiyama-type reaction has been reported (Scheme 202). It is interesting to note the complete reversal of selectivity compared to the uncomplexed aldehyde (Scheme 203).

Highly strained cyclic compounds containing an alkyne group can be prepared upon complexation to $Co_2(CO)_6$. The success of these reactions relies on the severely bent nature of the alkyne triple bond when complexed to cobalt. Cyclization of (**137**) to form bicyclo[7.3.0]tridecane (**138**), a calichiamycinone derivative has been reported (Scheme 204). The nine-membered enyne complex (**140**) was prepared by ring-closing metathesis of (**139**) (Scheme 205). A related reaction was used to give complex (**141**) (Scheme 206).[82] It should be noted that no cyclization occurs without prior complexation to cobalt in the latter case. A complexation-initiated

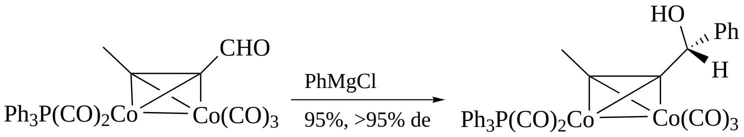


(**133**)

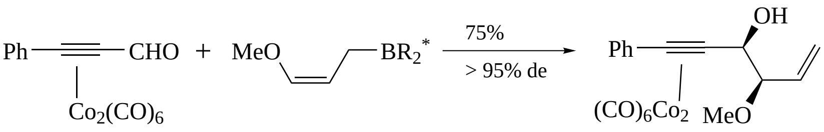
Scheme 197



Scheme 198

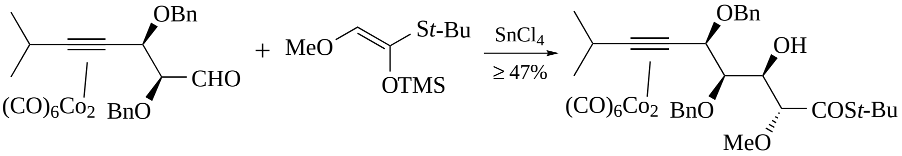


Scheme 199



(**135**) (**134**) (**136**)

Scheme 200



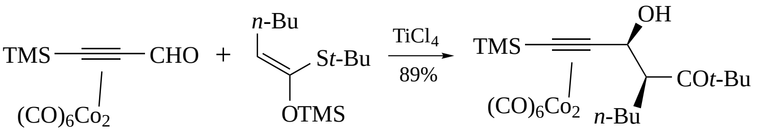
Scheme 201

Diels–Alder reaction of (**142**) was described. The equilibrium was shifted toward the product upon complexation of the alkyne (Scheme 207).[83]

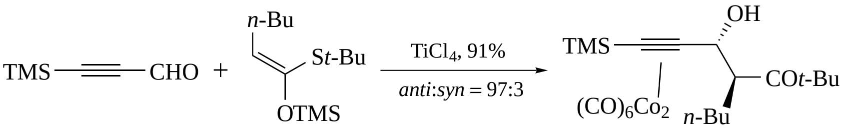
Ring expansion of complexed cycloalkynones using TMS-diazomethane is possible (Scheme 208). It should be noted that both product- and starting-material compounds are highly unstable in the absence of the cobalt carbonyl moiety.

5.2 Propargylic Activation

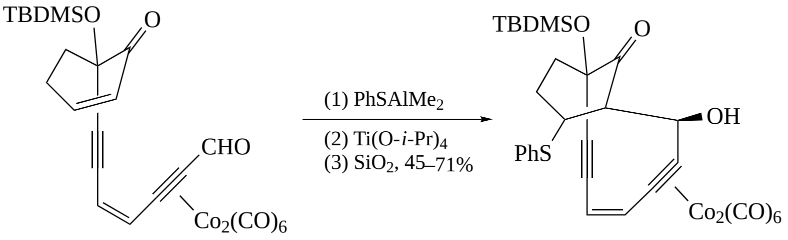
Complexation of dicobalt octacarbonyl to alkynes not only protects the triple bond against a number of reagents, but stabilization of propargylic cations, anions, and radicals is also observed. The carbocations are readily obtained as dark–red, thermally stable solids by treatment of propargylic alcohols,



Scheme 202

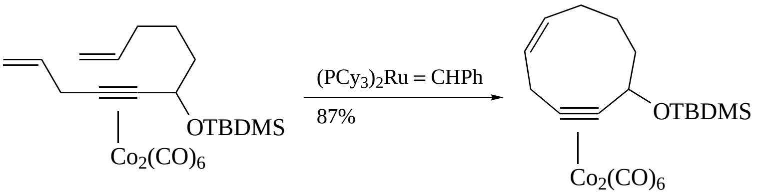


Scheme 203



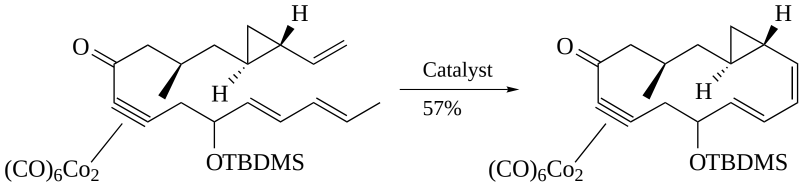
(**137**) (**138**)

Scheme 204



(**139**) (**140**)

Scheme 205

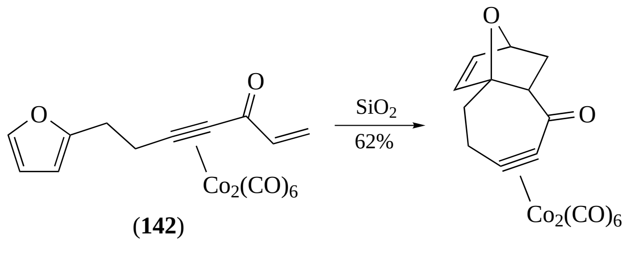


(**141**)

Scheme 206

ethers, epoxides, acetals, or acetates with Lewis acids. Stability similar to the triphenylmethyl carbenium ion is observed.

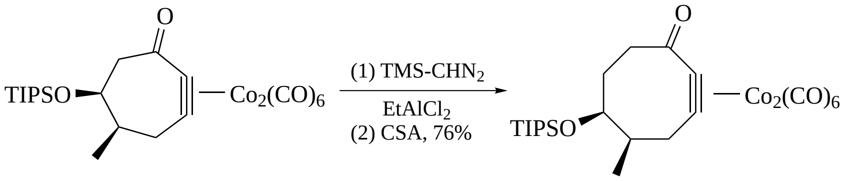
The Nicholas reaction, that is, the addition reaction of nucleophiles to cobalt-complexed propargylic cations, formed in situ, has been extensively developed.[84–87] The nucleophilic addition occurs exclusively at the α-carbon without competing formation of allenic products. Nucleophiles include amines, water, alcohols, trialkylaluminum reagents, sodium borohydride, diethylaluminum cyanide, trialkylsilyl enol ethers, enol acetates, furans, stabilized anions, and



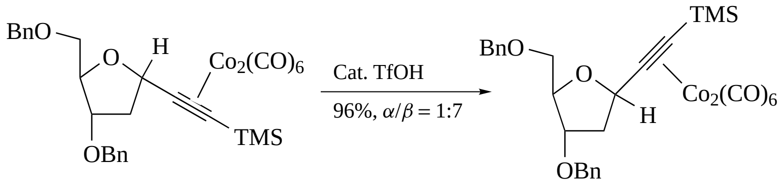
Scheme 207

allylsilanes and -boranes. Isomerization from the α-anomer to the more stable β-anomer of furanoses can be achieved in the presence of an acid (Scheme 209).

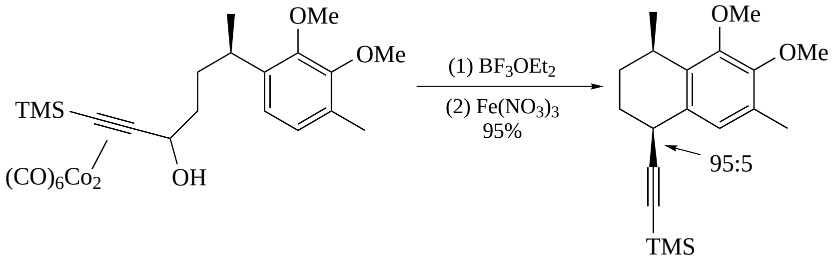
Electron-rich aromatic compounds are readily alkylated at room temperature with propargyl complexes to form, after demetallation, 2-propyne-substituted aromatic compounds. Depending on the substitution pattern of the alkyne complex and the aromatic substrate, alkylation occurs at times with very high regioselectivity. This type of annulation was used in a synthesis of pseudoipterosin



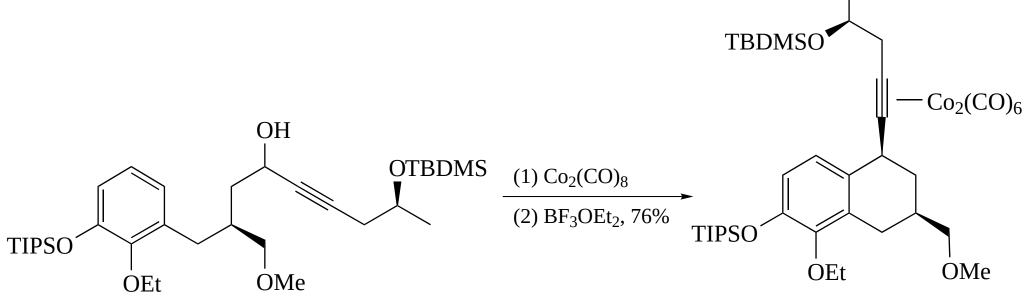
Scheme 208



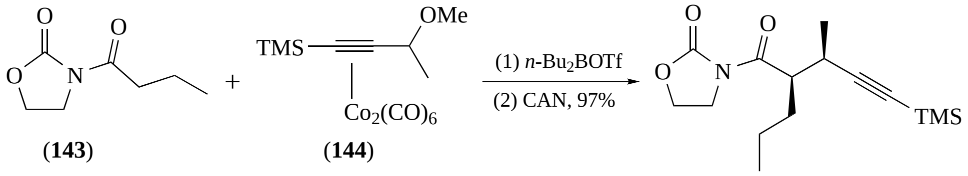
Scheme 209



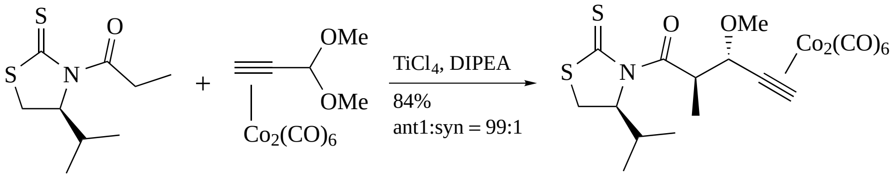
Scheme 210



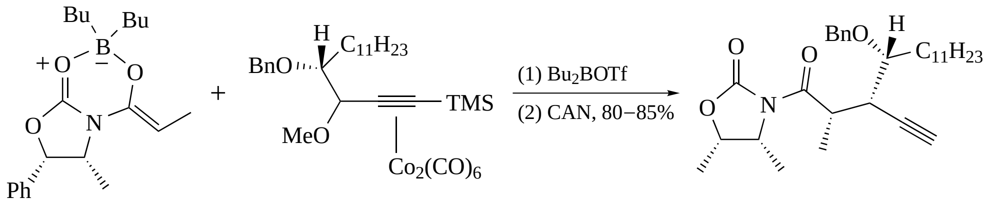
Scheme 211



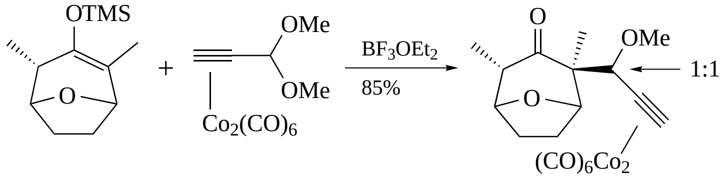
Scheme 212



Scheme 213



Scheme 214

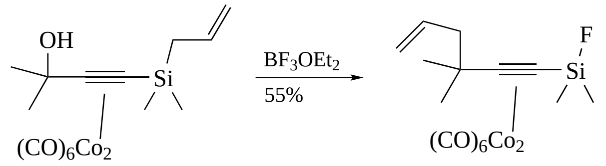


Scheme 215

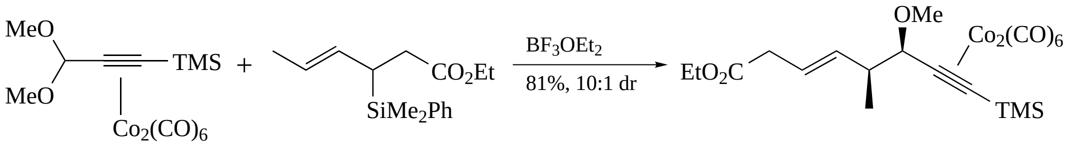
aglycones (Scheme 210)[88] and toward daphnanes and (+)-resiniferatoxine (Scheme 211).

High diastereoselectivity is observed upon reaction of the boron enolate of (**143**) with complex (**144**) (Scheme 212). This reaction was utilized in a synthesis of pyrromethenone. Chiral Evans'-type enolates can be alkylated with very high stereoselectivity. For example, reaction of the chiral 1,3-thiazolidine-2-thione (**145**) and complex (**146**) gave (**147**) with excellent selectivity (Scheme 213).[89] Enantioselective synthesis of (+)- and (−)-nephrosteranic acid has been also been reported using the chiral boron enolate (**148**) with propargylic ether (**149**) (Scheme 214).[90] A low degree of diastereoselectivity was observed at the propargylic position upon the Nicholas reaction of cyclic silyl enol ethers with propargylic acetals (Scheme 215).

Allylic transfer from a pendant allylic silane to a propargylic cation is seen in Scheme 216. Allylic silanes



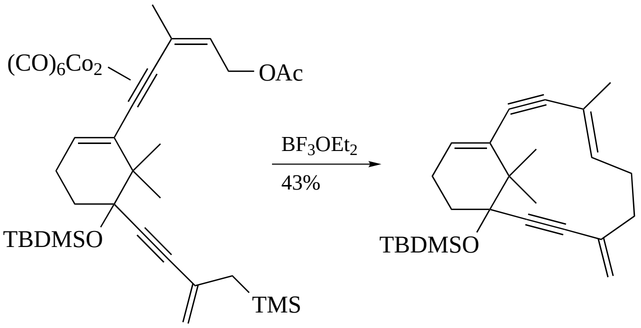
Scheme 216



Scheme 217

undergo reactions with propargylic acetals to form products with relatively high distereoselectivity (Scheme 217).

Intramolecular alkylation reactions employing allylsilanes have been developed. A taxoid bicyclo[9.3.1]pentadecane ring system was prepared via intramolecular alkylation of (**150**). It is interesting to note that the alkylation occurred in the γ-position relative to the alkyne (Scheme 218).[91] A Nicholas reaction was used in the synthesis of (+)-epoxydictymene (Scheme 219).



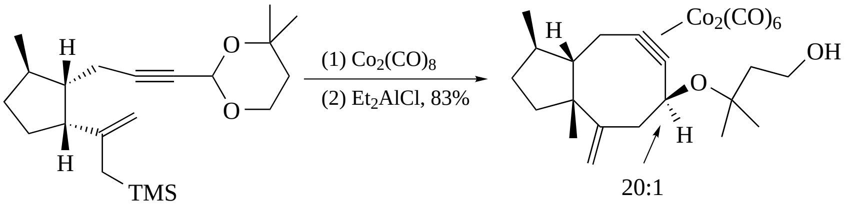
(**150**)

Scheme 218

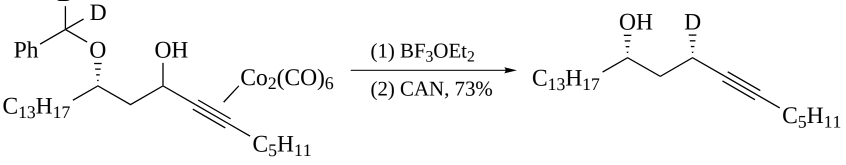
Reduction of the propargylic cation is observed upon reaction of γ-benzylprotected-α-hydroxy complexes. A hydride shift from the benzyl group to the intermediately formed carbocation is observed. For example, deuterium-labeled complex (**151**) gave alkyne (**152**) with a deuterium in the α-position (Scheme 220).[92] Benzaldehyde is observed as the side product.

Cationic cascade-type reactions of appropriately substituted complexes were used to prepare spirocyclic compounds (Scheme 221). Intramolecular variations on the carbocation theme discussed above can be employed to form macrocyclic compounds. This general strategy of propargylic activation has been used to prepare ingenol. The highly strained ring system of ingenol was obtained by intramolecular trapping of the formed propargylic cation with a pendant alkene (Scheme 222).[93] A variation of the intramolecular reaction is seen in Scheme 223, wherein an alkene reacts with the formed propargylic cation. The secondary cation undergoes nucleophilic addition reactions with the present anion. It is interesting to note that an elimination product is formed using titanium tetraiodide. Alkene-substituted complexes react with benzhydryl carbocations to form a propargylic cation that can be alkylated using an allylic silane (Scheme 224).

The complexed propargylic carbocation intermediates also react with nucleophiles to form, in some cases, a

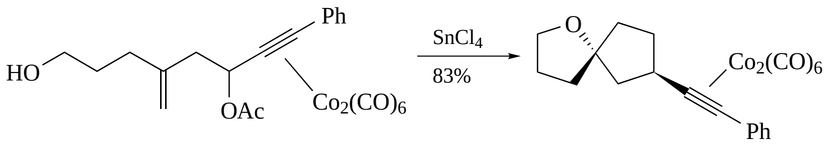


Scheme 219

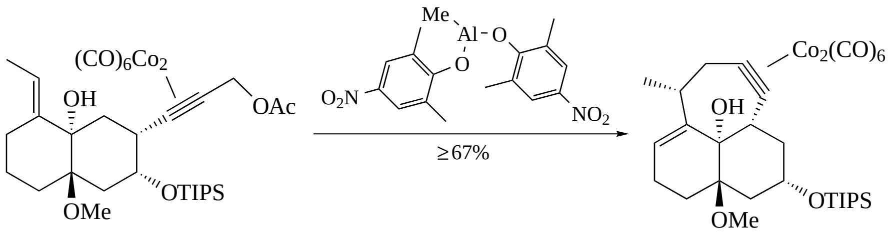


(**151**) (**152**)

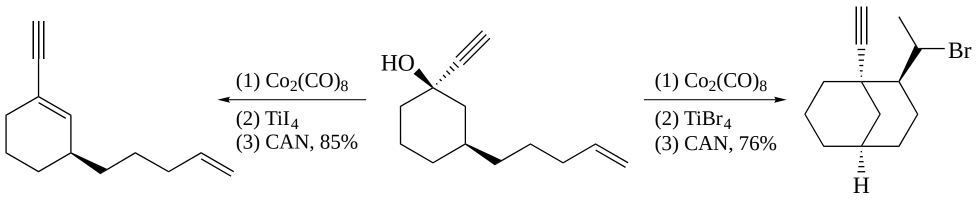
Scheme 220



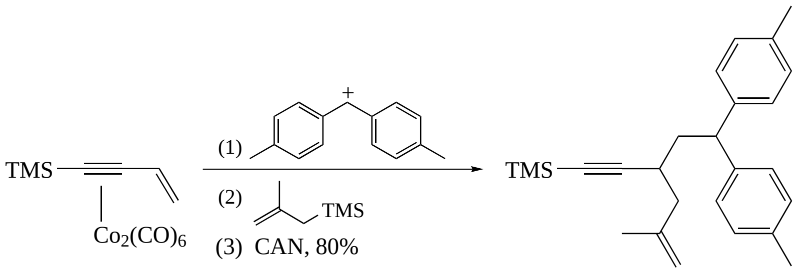
Scheme 221



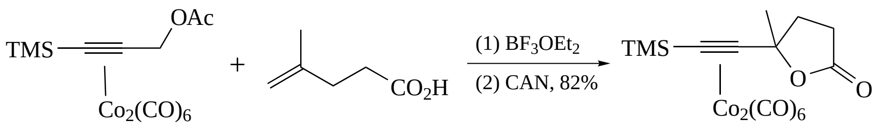
Scheme 222



Scheme 223



Scheme 224

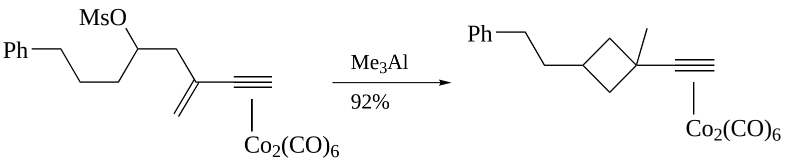


(**153**) (**154**) (**155**)

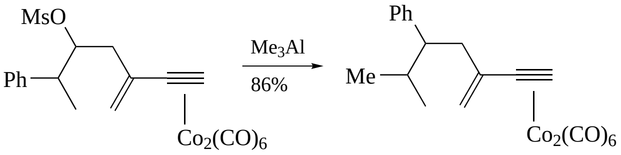
Scheme 225

new carbocation that can undergo further reaction. For example, reaction of (**153**) with the unsaturated acid (**154**) gave (**155**) after addition of the alkene and intramolecular esterification (Scheme 225). Lewis acid treatment of γ-mesylated complexes having an adjacent alkene and a remote phenyl group has been studied. Depending on the substitution pattern, cyclobutane formation or migration of a remote alkyl group is observed (Scheme 226–227).[94]

Cyclic ethers (5–10 membered) can be prepared by reaction of the formed carbocation with pendant alcohols.[95] The reaction is usually stereospecific at the propargylic carbon (Scheme 228). Intramolecular formation of ethers has been



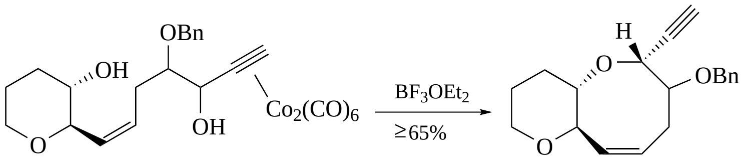
Scheme 226



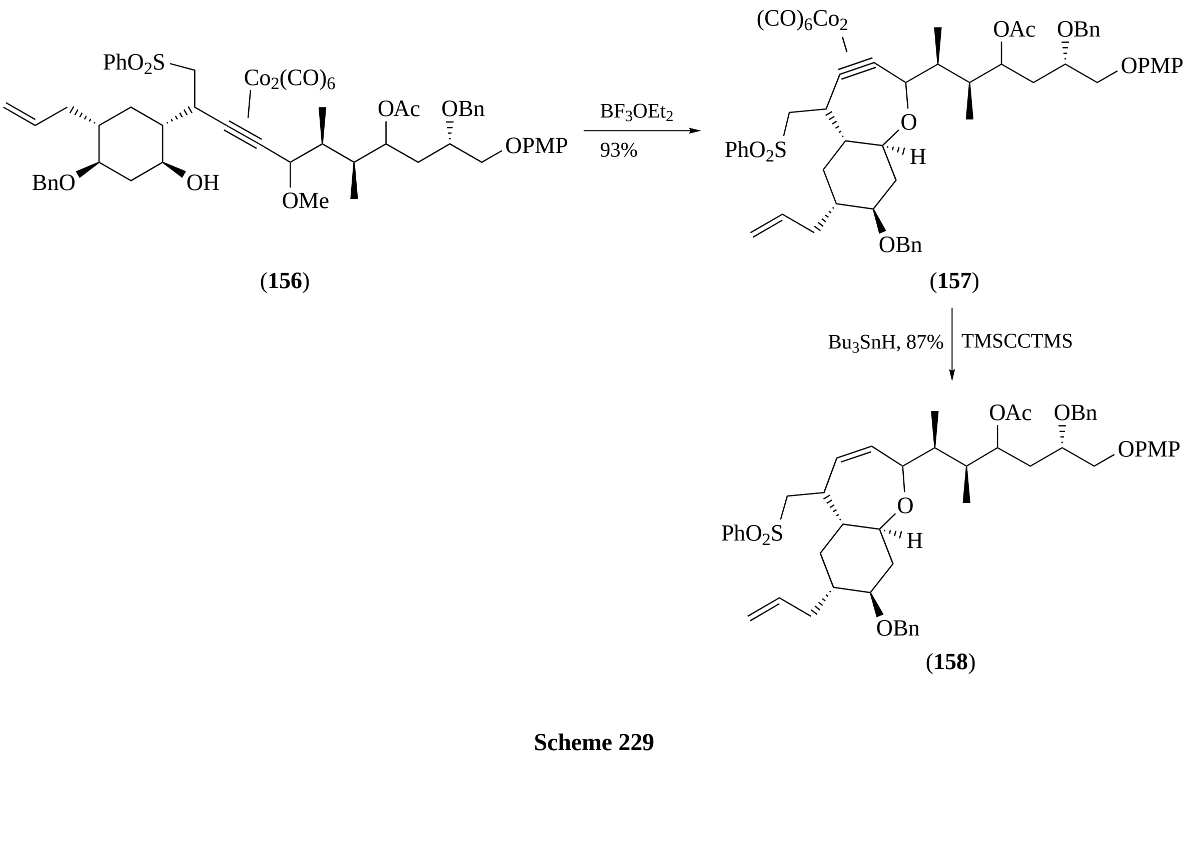
Scheme 227

utilized extensively in the total synthesis of polycyclic ethers such as ciguatoxin and gabiertoxin. For example, the seven-membered ether (**157**) was obtained upon treatment of (**156**) with a Lewis acid (Scheme 229).[96] The organic fragment was liberated using a reductive decomplexation that used tributyltin hydride and 1,2-bis-TMS-ethyne to give a cis double bond (**158**). A synthesis of (+)-secosyrins and (+)-syributins utilized the intramolecular trapping of an intermediately formed carbocation. High diastereoselectivity was observed (Scheme 230).

Propargylic epoxides can be used as precursor for the carbocations. For example, complexation of (**159**) and reaction of the complex with borontrifluoride etherate give, stereoselectively, complex (**160**) (Scheme 231). This sequence was used in a synthesis of (−)-ichthyothereol.[97]

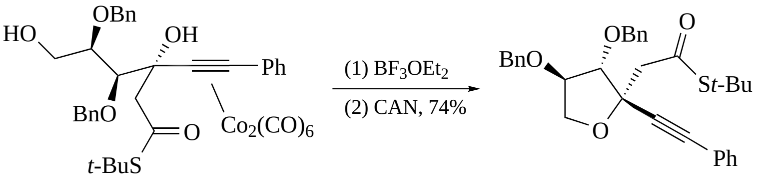


Scheme 228



(**156**) (**157**) (**158**)

Scheme 229



Scheme 230

A related ring expansion forming a seven-membered ring has been reported (Scheme 232). Ring expansion of a tetrahydrofuran-tethered alkyne complexes to give (**161**), and (**162**) can also be achieved (Scheme 233).[98]

Lewis acid–mediated rearrangement of enol ethers affords 1,2-disubstituted cycloalkanones with high stereoselectivity (Scheme 234).[99] Related reactions of dichloro-substituted enol ethers afford 2,2-dichloro-substituted cycloalkanones (Scheme 235). When titanium tetrachloride was used as the Lewis acid, a carbonyl-ene Prince-type reaction can take place (Scheme 236).

An interesting stereospecific 1,2-shift is observed upon treatment of complex (**163**) with trimethyl aluminium and a nucleophile (Scheme 237). Direct fluorination of chiral-complexed propargylic alcohols using DAST can be achieved in good diastereomeric excess (Scheme 238).

Ethyl aluminum dichloride mediates a formal [5 + 2]cycloaddition of complex (**164**) and (**166**) with enol silyl ethers to produce the highly strained seven-membered rings (**165**) and (**167**) respectively (Schemes 239–240).[100] Excellent stereoselectivity is observed in both cases. A related double alkylation affords complexed seven-membered rings via a formal [4 + 3]cycloaddition. Incorporation of fluorine is observed using boron trifluoride etherate (Scheme 241).

was used in a synthesis of climacostol. Exclusive formation of the cis-alkene is observed (Scheme 243).[101] α-Bromo-substituted alkyne complexes undergo stereoselective radical cyclizations (Scheme 244). Finally, a rearrangement of 1-(1-alkynyl)cyclopropanol derivatives to 2-cyclopentenones via the corresponding dicobalt hexacarbonyl complex has been described (Scheme 245).

5.3 The Pauson–Khand Reaction (*See Pauson–Khand Reaction*)

The cocyclization of alkyne dicobalt hexacarbonyl with alkenes is probably one of the most straightforward methods for the formation of cyclopentenones.[102–105] This formal $[2+2+1]$cycloaddition reaction was first reported by Khand

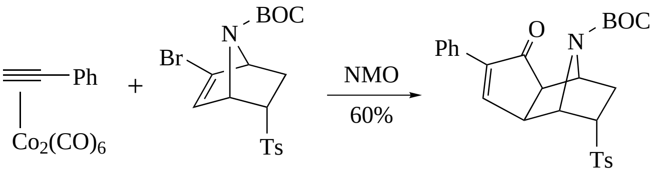
and Pauson in 1973 and has since been extensively developed. In general, $Co_2(CO)_8$ reacts with alkynes to generate thermally very stable, readily characterized metal–alkyne complexes (see Section 5.1). The complexes can subsequently be made to react, under thermal conditions, with alkenes and carbon monoxide from the cobalt ligand to form cyclopentenones. Although a number of catalytic Pauson–Khand reactions have been published, only reactions using stoichiometric amounts of cobalt are discussed herein.

The Pauson–Khand reaction is compatible with a wide variety of functionalities, such as ethers, alcohols, tertiary amines, thioethers, ketones, ketals, esters, tertiary amides, carbamates, and benzene, furan, and thiophen rings. Disubstituted alkynes, alkenes with bulky allylic substituents, and trisubstituted alkenes frequently afford reduced yields of products. Because of the reduced ability of sterically hindered alkenes to coordinate and undergo insertion, insertion of one or more molecules of alkyne occurs instead.

Water can be used as the solvent in the presence of added surfactants. Reactions in ionic liquids and supercritical fluids are also feasible. A variety of reagents promote cyclization, which can be achieved at room temperature. Examples of compounds that promote and accelerate the reaction include *N*-methylmorpholine *N*-oxide, trimethylamine *N*-oxide, phosphine oxides, dimethylsulfoxide, alkyl methyl sulfides, molecular sieves, and lithium perchlorate. A comparison of a few promoters is seen in Scheme 246. Promoters attached to a solid support and ultrasounds, microwaves, and UV irradiation can also been used to facilitate the annulation.

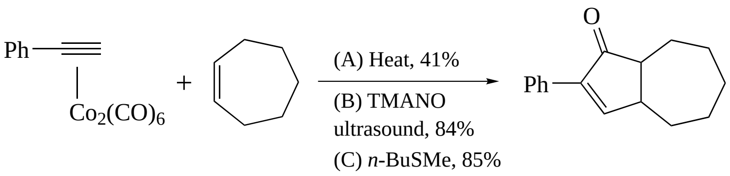
Intramolecular Pauson–Khand reactions usually afford 2-substituted 2-cyclopentenones from terminal alkynes. Mixtures of products are often seen from reactions of internal alkynes with little or no stereo- or polarity differentiation between the two sides of the alkyne. Electron-rich and hydrocarbon-substituted alkynes are usually employed but electron-deficient alkenes such as esters, sulfones, and nitriles also participate in the Pauson–Khand reaction.

Cycloaddition of 7-oxanorbornadiene derivatives has been reported (Scheme 247). 5-Bromo-7-azanorbornenes undergo regioselective Pauson–Khand reaction to give (**168**). The bromine is lost during the reaction (Scheme 248). *N*-Protected alkynylamides undergo intramolecular reactions with alkenes to give 2-amidocyclopentenones (Scheme 249).

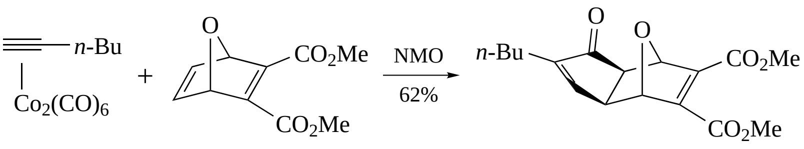


(**168**)

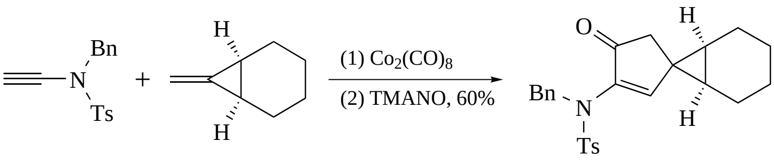
Scheme 248



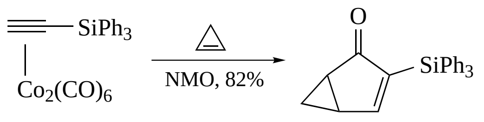
Scheme 246



Scheme 247



Scheme 249



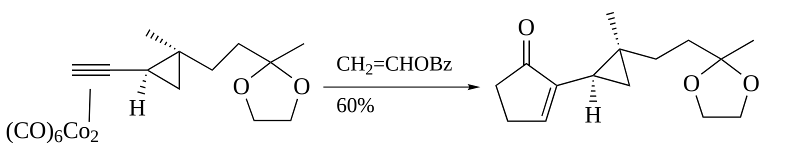
Scheme 250

Cyclopropene can also be used as the alkene component and affords bicyclo[3.1.0]hexen-2-ones upon reaction with alkyne dicobalt octacarbonyl complexes in the presence of NMO (Scheme 250). Vinyl ethers and vinyl esters serve as ethene equivalents in Pauson–Khand reactions. For example, reaction of vinyl benzoate with complex (**169**) furnished cyclopentenone (**170**) (Scheme 251). This reaction was used in a synthesis of (+)-taylorine and nortaylorine.[106] Allenes participate in intermolecular Pauson–Khand reactions affording alkylidene-substituted cyclopentenones (Scheme 252).[107]

Asymmetric intermolecular Pauson–Khand reactions have been realized using a number of chiral auxiliaries chelating to the metal and/or attached to the alkyne. One example using a camphor-derived ligand is seen in Scheme 253. Moderate asymmetric induction has been observed using chiral amine *N*-oxides as the promoter. For example, (+)-indolizino[3,4-b]quinoline *N*-oxide gave up to 53% ee.

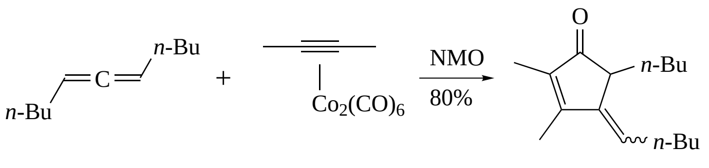
A few applications of intramolecular Pauson–Khand reactions in organic synthesis have been reported. For example, total syntheses of asteriscanolide (Scheme 254)[108] and cis-9-retinoic acid and tagretin analogs have been completed (Scheme 255).

Intramolecular Pauson–Khand reactions are synthetically more useful compared to their intermolecular counterparts. Enynes separated by either three or four atoms (1,6- or 1,7-enynes) cyclize in an intramolecular fashion upon complexation with $Co_2(CO)_8$, and subsequent heating to form bicyclic enones. Angular tricyclic ring systems have been prepared in

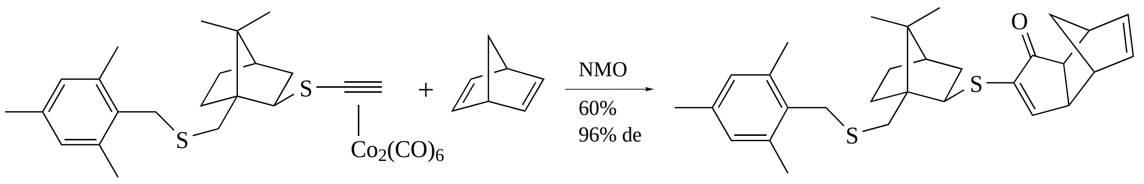


(**169**) (**170**)

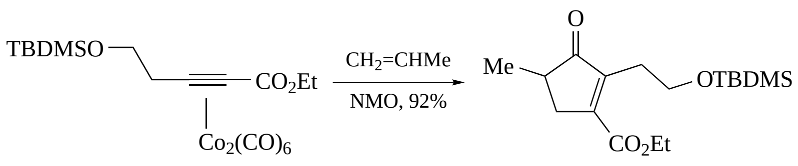
Scheme 251



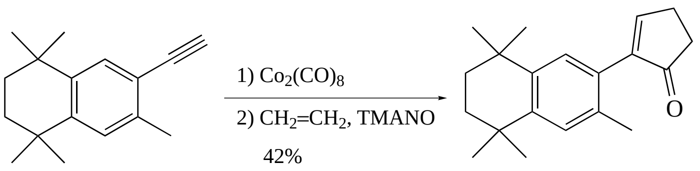
Scheme 252



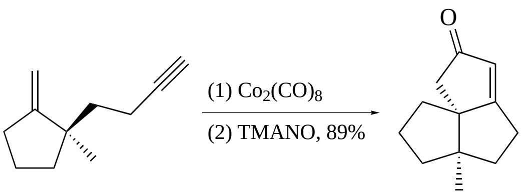
Scheme 253



Scheme 254

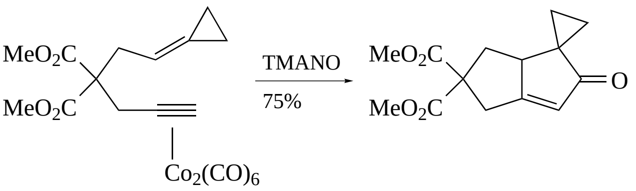


Scheme 255



(**171**) (**172**)

Scheme 256

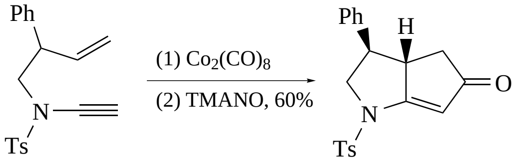


Scheme 257

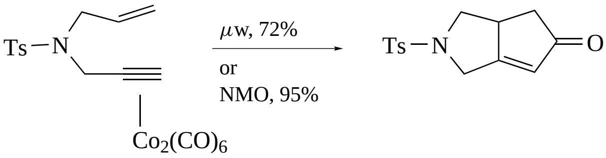
good yields (Scheme 256). For example, a single isomer of the tricyclic compound (**172**) was isolated from complexation and thermolysis of (**171**). Spirocyclopropyl-substituted bicyclic compounds can be obtained from methylenecyclopropane containing enynes (Scheme 257). *N*-Alkynylsulfonamides participate in intramolecular Pauson–Khand reactions (Scheme 258). Microwave-promoted intramolecular reactions have also been developed (Scheme 259).

Intramolecular allene–alkyne cyclizations using cobalt complexes are nonspecific and both double bonds of the allene participate in the reaction affording [4.3.0] and [3.3.0]ring systems (Scheme 260).[109] Both inter- and intramolecular Pauson – Khand-type reactions have been reported using molybdenum hexacarbonyl in place of dicobalt octacarbonyl. For example, only the bicyclo[3.3.0]ring system was observed using molybdenum hexacarbonyl (Scheme 261). In contrast, only the bicyclo[4.3.0]nonadienone was obtained using allenyne (**173**) (Scheme 262).

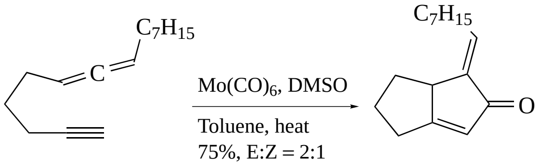
Cyclopentenones-fused indoles and quinolines can be prepared via intramolecular annulations (Scheme 263).[110]



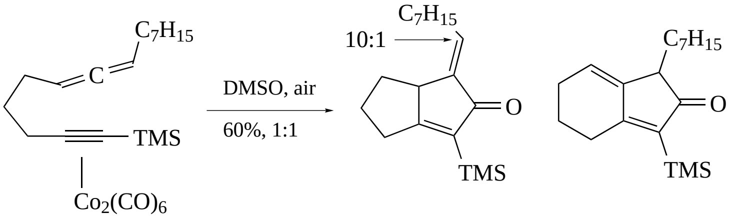
Scheme 258



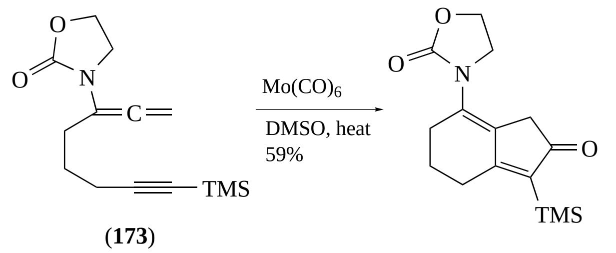
Scheme 259



Scheme 261

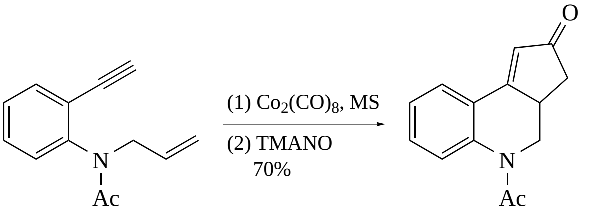


Scheme 260



(**173**)

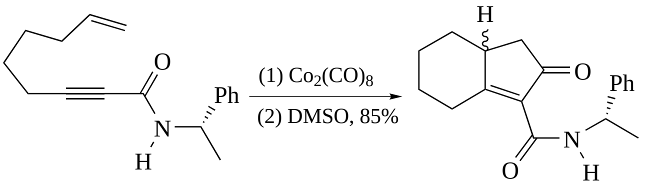
Scheme 262



Scheme 263

Seven-membered rings can be fused onto the cyclopentenone using heteroaromatic enyne-starting materials. A high stereoselectivity is observed in some cases (Scheme 264).

Steric effects are probably the main contributor to the high stereoselectivity observed in most intramolecular reactions. No chirality transfer was observed upon thermolysis of the chiral enynamide (**174**) (Scheme 265). In contrast, optically active sulfoxides are excellent chiral auxiliaries in intramolecular reactions (Scheme 266). Amino acid–derived enynes have been used with excellent enantioselectivity



(**174**)

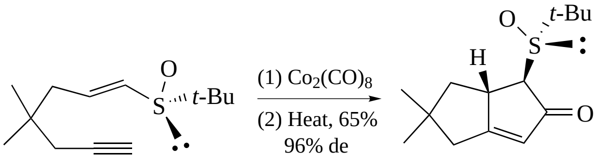
Scheme 265

(Scheme 267). A lower selectivity is observed using optically active enol ethers in place of the vinyl sulfoxide.

Combination of the propargyl activation chemistry discussed in Section 5.2 has been utilized in conjunction with the Pauson–Khand reaction. Alkylation of enol ether (**175**) with complex (**176**) followed by Pauson–Khand reaction gave the tricyclic diketone (**177**) (Scheme 268).[111]

The intramolecular Pauson–Khand reaction has been extensively used as a key step in total synthesis of fairly complex polycyclic natural products. The [2 + 2 + 1]cycloaddition was, for example, used in recent syntheses of magellanine (Scheme 269),[112] tecomanine, toward palau'amines and styloguanidines (Scheme 270), 8α-hydroxystreptazolone (Scheme 271),[113] ceratopicanol (Scheme 272), 13-deoxyserratine (Scheme 273), ABC-rings of nakadomarin and manzamine (Scheme 274), cedrone (Scheme 275), (−)-dendrobine (Scheme 276),[114] toward kalmanol (Scheme 277), and (+)-epoxydictymene (Scheme 278).

Under some reaction conditions, cycloadditions without insertion of carbon monoxide have been observed. Reaction of complex (**178**) having an electron-deficient alkene under thermal conditions furnished the expected bicyclic enone (**179**) (Scheme 279).[115] However, reaction promoted by TMANO gave cyclopentadiene (**180**). This



Scheme 266

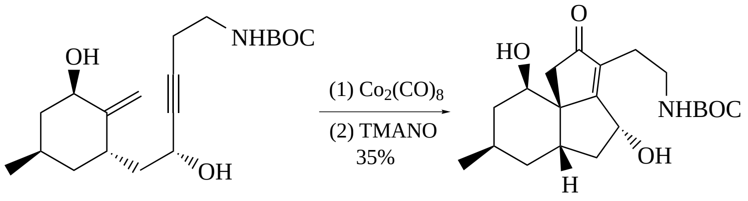
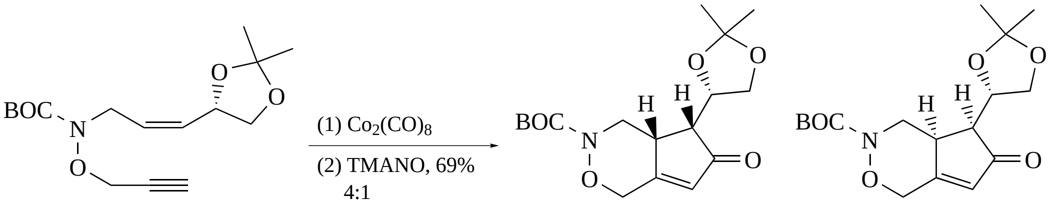
(175) (176) (177)

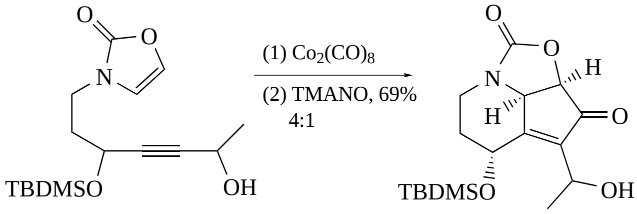
Scheme 268



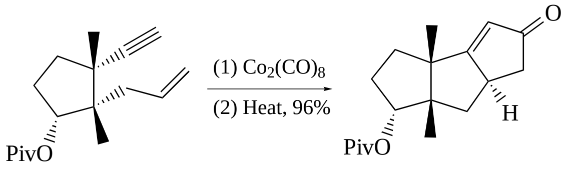
Scheme 269



Scheme 270

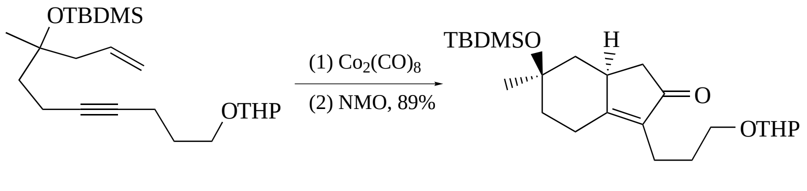


Scheme 271

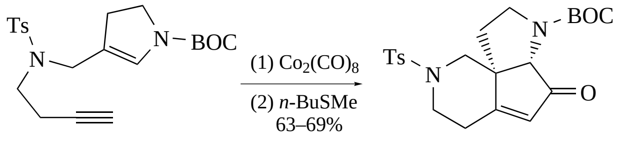


Scheme 272

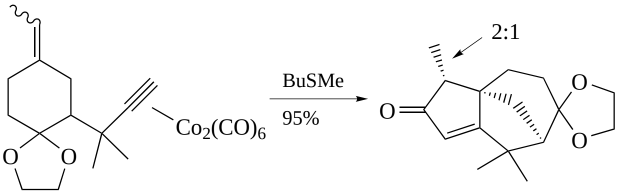
type of 'abnormal' reactivity is often observed using electron efficient alkenes. Some examples have been reported and the product formed is highly dependant on the conditions used, as can be seen in Scheme 280. Related reactions of (**181**) under thermal reactions and hydrogen gas gave the bicyclic enone (**182**); while in the presence



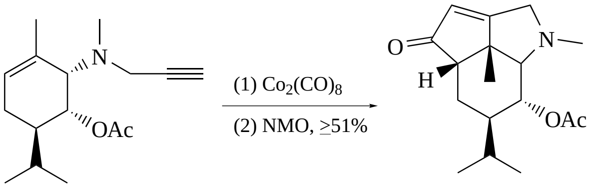
Scheme 273



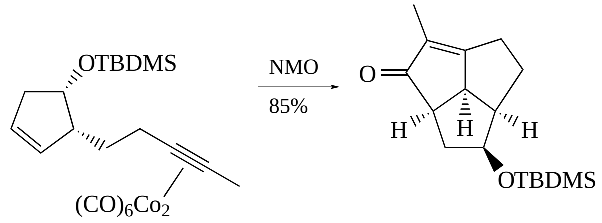
Scheme 274



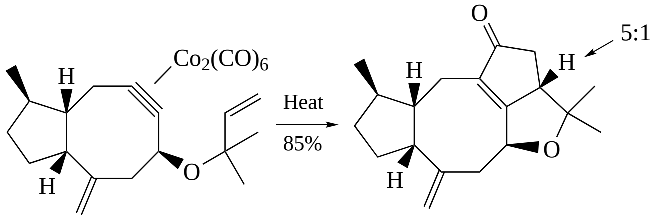
Scheme 275



Scheme 276



Scheme 277



Scheme 278

of triethylsilane, the monocyclic diene (**183**) was obtained (Scheme 281). Performing the same reaction but using $Co_4(CO)_{12}$ in 2-hydroxypropane gave a reduced bicyclic ketone (Scheme 282).

Silyloxy-tethered enones undergo a reductive process in wet nitrile solvent to give cyclopentenones. For example, complexation and thermolysis of (**183**) results both in loss of the silicon and oxygen atoms (Scheme 283).[116] As was the case for intramolecular reactions, alkoxy- and acyloxy-groups are also lost during the intramolecular Pauson–Khand reaction (Scheme 284). Carbon–oxygen bond cleavage was also observed using (**184**) (Scheme 285).[117] Performing the reaction in the presence of ammonium hydroxide gave an interesting hydroxylated product (**185**) (Scheme 285). An aminocarbonylation Pauson–Khand reaction is observed using the cobalt complex of 1-chloro-2-phenylethyne (Scheme 286).[118]

Intermolecular reductive Pauson–Khand reaction in the presence of trifluoroacetic acid is also observed (Scheme 287). Reaction in the presence of silica gel also produced reduced compounds in some cases.

Glossary

π-Bonded: coordination to a metal via π-orbitals, as with ethylene
Chemoselectivity: selectivity in reaction of one functional group in the presence of one or more other similar groups
Conjugating substituents: functional groups interacting through π-bonds with a reactive center
Electrophile: electron-deficient species that reacts by accepting a pair of electrons to form a covalent bond
Enolate anion: a carbanion obtained by deprotonation of the position adjacent to a carbonyl group
Heteroaromatics: aromatic rings with a heteroatom in the π-system
Macrolides: natural organic compounds with large lactone rings
Nucleophile: electron-rich species that reacts by donating a pair of electrons to form a covalent bond
Regioselectivity: selectivity in reaction of one site of a functional group with two or more reactive sites
Spectator ligand: ligand not involved in a relevant process around the metal center
Stereoselectivity: selectivity in generation of a stereocenter
Transmetalation: transfer of an organic unit from one metal to another
Triflate: an ester of trifluoromethanesulfonic acid, a good leaving group

1 SCOPE OF THIS ARTICLE

The focus of this article is on organic synthesis methodologies that involve transition metal complexes containing π-bonded ligands. For this discussion, π-bonded ligands are limited to those with only carbon atoms involved in the coordinating unit, such as alkenes and not, for example, imines. In addition, because some useful methods involve metal complexes with both π-bonded ligands and CO ligands, some arbitrary decisions were necessary in distributing the topics between this article and ***Organic Synthesis using Transition Metal Carbonyl Complexes***. For example, the major topics of alkyne trimerization to form arenes (Vollhardt reaction),[1] the coupling of an alkyne with CO and an alkene unit to give cyclopentenones (Pauson–Khand reaction),[2] and the coupling of alkynes and CO with vinylcarbene ligands (Doetz reaction)[3] are excluded from this discussion. Excellent coverage of related topics has appeared in compendia.[4,5] Space limitations prevent the presentation of synthesis methods that are of limited scope or not yet well developed.

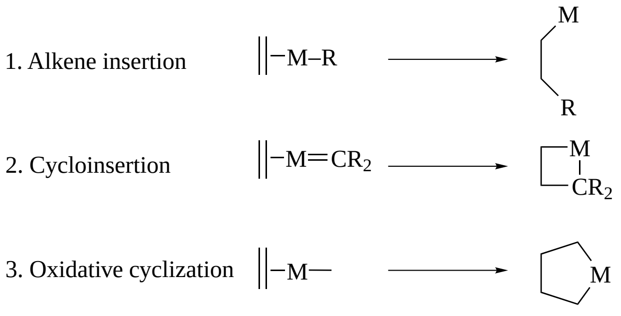
2 INTRODUCTION

π-Bonded ligands can be closed shell, $2n$ electron donors ($n = 1 - 3$) such as alkenes, allenes, alkynes, arenes, and polyenes; these have been termed ‘even’ polyene ligands.[6] They may also be open shell, ‘odd’ polyene ligands such as allyl, pentadienyl, cyclopropenyl, and cyclopentadienyl, which are formally viewed as anionic ligands, donating $2n$ electrons ($n = 1 - 3$).

2.1 Nonpolar Coupling Reactions

Even π-bonded ligands can undergo coupling reactions within the ligand sphere of the metal following the mechanistic types shown for an alkene in Scheme 1. These mechanisms are appropriately viewed as nonpolar, relatively independent of polar functional groups on the ligands, and not sensitive to polar driving forces. An analogy in traditional organic chemistry is the set of concerted electrocyclic mechanisms, the Diels–Alder reaction being a prototype.

Each of these mechanisms is the basis of a major envelope of synthetic methods. The first has appeared as the *Heck*



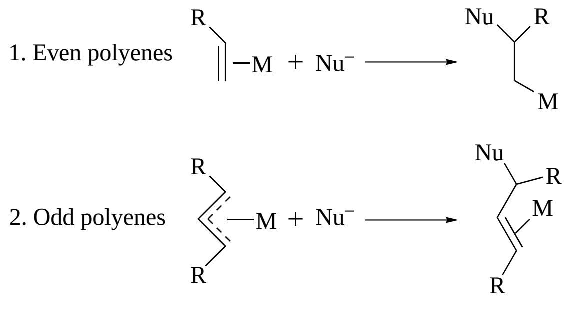
Scheme 1 Nonpolar coupling mechanisms

Reaction,[7] and will be reviewed below. The second mechanism is the first stage of the Doetz reaction,[3] while the third (operating with alkynes) is the first stage of the Vollhardt reaction[1] and of the *Pauson–Khand Reaction*.[2]

2.2 Polar Coupling Reactions

The metal and spectator ligands can influence the reactivity of a π-bonded ligand by changing the polarization or polarizibility. An increase in polarizibility is obvious for the alkene in an η^2-alkene metal complex, making it easier both to add electron density (e.g. in nucleophilic addition) and remove electron density (electrophilic addition). Depending on the oxidation state of the metal and the donor/acceptor characteristics of the spectator ligands, the coordinated alkene might be polarized and be viewed as distinctly electrophilic or nucleophilic. Key features of the activation process are: (a) the driving forces are based on polar factors and (b) the reactant (nucleophile or electrophile) need not interact with the metal, but can couple with the π-ligand directly. The metal–ligand system is a functional group, influencing the rate and selectivity of a polar addition to a π-system.

A complete survey of polar coupling reactions might include all types of organic ligands, π- and σ-bonded, and both nucleophilic and electrophilic additions. However, the only generally useful synthesis methodology based on polar activation by transition metals is nucleophile addition to coordinated alkenes and polyenes, both even and odd systems. Two prototypes are presented in Scheme 2: nucleophile addition to an alkene (even π-ligand) and nucleophile addition to an η^3-allyl ligand (odd). The first has a close analogy in the Michael reaction of traditional organic synthesis, while the second can be viewed as a special case of S_N2 reaction of allyl–X species. In both cases, the transition metal activation leads to new opportunities in control of reaction rate and selectivity, including stereo-, regio-, and chemoselectivity.

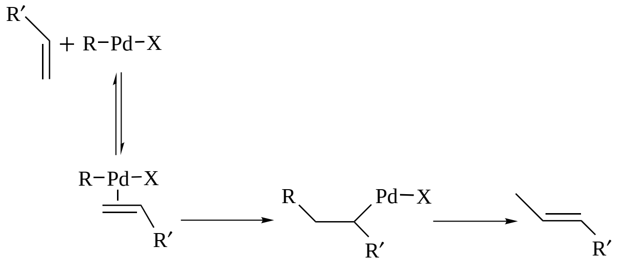


Scheme 2 Polar coupling mechanisms

3 ALKENE INSERTION/ELIMINATION: THE HECK REACTION

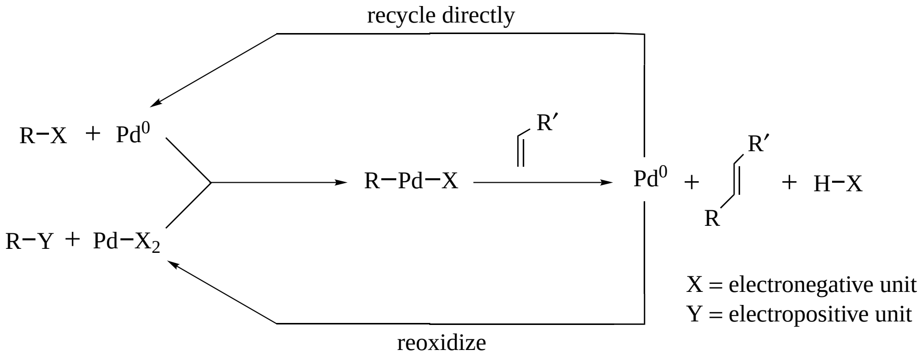
3.1 Basic Reaction

The basis for the Heck Reaction is the process shown in equation (1),[8] the coordination of an alkene to a σ-organopalladium(II) species, followed by alkene *Insertion* and then β-*Elimination*. The products are the 1,2-disubstituted alkene, HX, and Pd^0. The power of the process for organic synthesis is due to the existence of several general techniques for preparing the required R–Pd–X reactant and that the β-elimination of hydrogen can be fast. Overall substitution of a vinyl hydrogen by a carbon unit has no general analogy in traditional synthesis methodology.



(1)

For a catalytic process, the product Pd^0 must be used to regenerate the R–Pd–X reactant. Two techniques are known (Scheme 3). In the first, Pd^0 can undergo *Oxidative Addition* with R–X to give R–Pd–X directly. This requires R–X be a good substrate for oxidative addition, and many electronegative functional groups serve as effective X units. Alternatively, the Pd^0 can be reoxidized to Pd^{II}, and then direct transfer of an organic unit to the Pd^{II} can be arranged.[7] The transfer might be electrophilic aromatic substitution (aromatic palladation), giving Ar–Pd–X + HX, or *Transmetalation* from an organo-main group derivative such as R–Hg–X. Important limitations include: (a) the group R must be stabilized toward β-hydride elimination in R–Pd–X, generally meaning no β-H on an sp^3-carbon and (b) the efficiency decreases rapidly with addition of substituents to the alkene; the process is generally efficient only for monosubstituted alkenes.

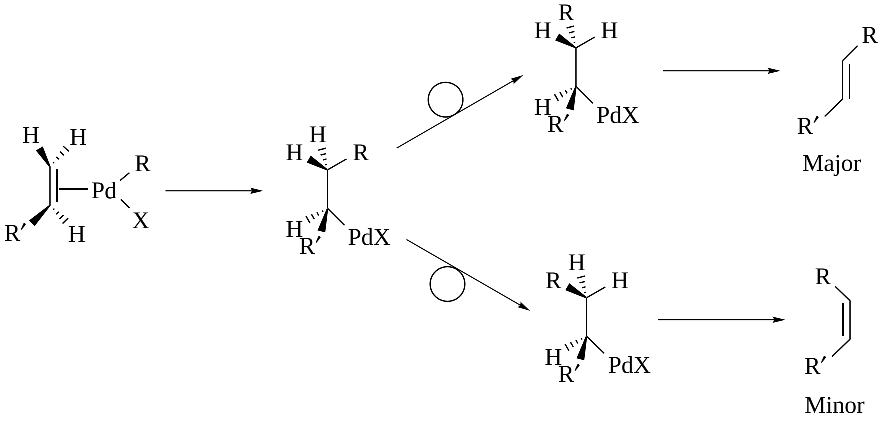


Scheme 3 Two pathways for the Heck reaction

3.2 The Alkene and Selectivity Issues

Ethylene is the most reactive alkene, and the rates of reaction can decrease with the size and number of alkene substituents.[8] However, the rate-limiting step can be the initial oxidative addition of R–X with Pd^0, making alkene structure less important in the overall rate. Successful substitution is general for monosubstituted alkenes and common even with 1,2-disubstituted alkenes. Trisubstituted alkenes are largely useless in the Heck reaction; the intermediate R–Pd–X species undergo side reactions such as homocoupling instead of vinyl substitution.

The geometry of the product 1,2-disubstituted alkene is determined to be (E) (trans) by the mechanism of β-hydrogen elimination, if two β-hydrogens are available (Scheme 4). If only one β-H is available (from 1,2-disubstituted alkene substrates), then the geometry of the product is determined by kinetic control following the syn conformation for alkene insertion and syn conformation for β-H elimination.



Scheme 4 Conformational alternatives in the β-elimination

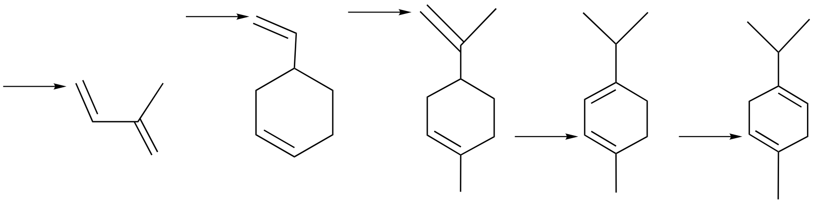


Figure 1 Regioselectivity in Heck vinylation reactions; arrows show the site of C–C bond formation

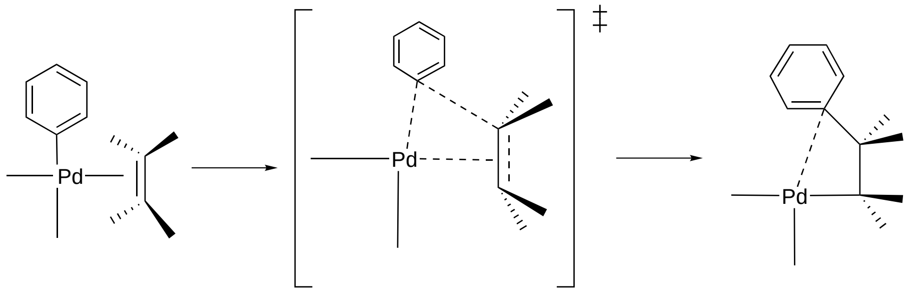

Figure 2 Transition state for alkene insertion

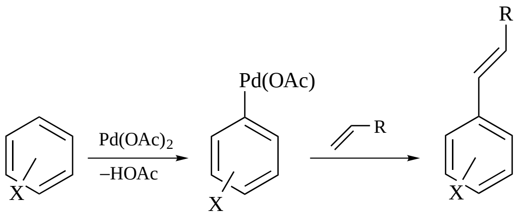
The regioselectivity of the vinyl substitution with monosubstituted alkenes shows a strong trend toward addition of the new carbon substituent at the less-substituted end, primarily attributed to a substituent steric effect, as shown in Figure 1.[3,8,9] With a simple alkyl group (propylene, 1-hexene, 3-hydroxy-1-butene), the selectivity is relatively low. Electron donors, conjugating substituents, and electron-withdrawing groups (EWG) produce the same trend, in some cases with perfect selectivity as in the case of styrene. The selectivity with enol ethers and enamines is more complex, and can favor coupling of the organic unit at the carbon-bearing oxygen. Unsymmetrical 1,2-disubstituted alkenes can give useful selectivity with substitution at a methyl-bearing carbon being strongly preferred over substitution at alkene carbon atoms bearing carboalkoxy or phenyl substituents. *Cis*-β-methylstyrene gives significantly higher selectivity compared to the trans isomer.

While there is obviously some electronic effect influencing regioselectivity, the dominant effect is steric. A simple rationale for the regioselectivity takes into account a syn transition state (Figure 2) for the alkene insertion, with a shorter distance for C–H compared to C–Pd, as the bonds develop. The shorter distance could be due to a differential degree of bond making or the intrinsically longer C–Pd bond distance. Additional examples of regioselectivity will be taken up in the appropriate section below.

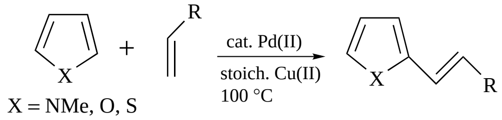
3.3 Vinyl Substitution with R–H: Direct Palladation

The primary method of direct palladation begins with Pd^{II} and proceeds by either electrophilic aromatic substitution or oxidative addition of an arene C–H bond (equation 2).[10] In both cases, loss of H–X leads to an aryl–Pd–X derivative. Simple arenes can undergo palladation, but lead to isomers in the absence of a strongly directing substituent. The process is usually done in a stepwise manner, with isolation of the aryl–Pd–X intermediate. It is not easily made catalytic; various reoxidation recipes are used for conversion of Pd^0 to Pd^{II} in other applications,[7] but none has been found satisfactory here.



(2)

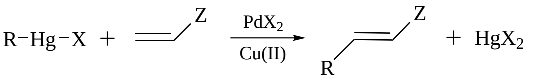
Heteroaromatics have high reactivity toward electrophilic palladation and show good regioselectivity. Reactions with pyrrole,[11] thiophene,[11] furan,[11] and indole[12] have been reported (equation 3). The use of stoichiometric copper(II) ion gives a process catalytic in Pd.



(3)

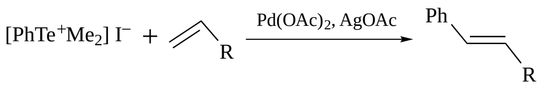
3.4 Vinyl Substitution via Transfer from a Main Group Metal

One of the earliest examples of Pd-promoted vinyl substitution involved transfer of an aryl group from Hg^{II} to Pd^{II}, followed by insertion/elimination (equation 4).[13–15] The general process requires reoxidation of the Pd for catalysis, and this is generally possible by using excess of Cu^{II}. While the method is applicable to alkyl–Hg–X reactants, it is limited to those alkyl groups that cannot undergo β-hydride elimination after transfer to Pd, such as Me and alkoxycarbonyl.



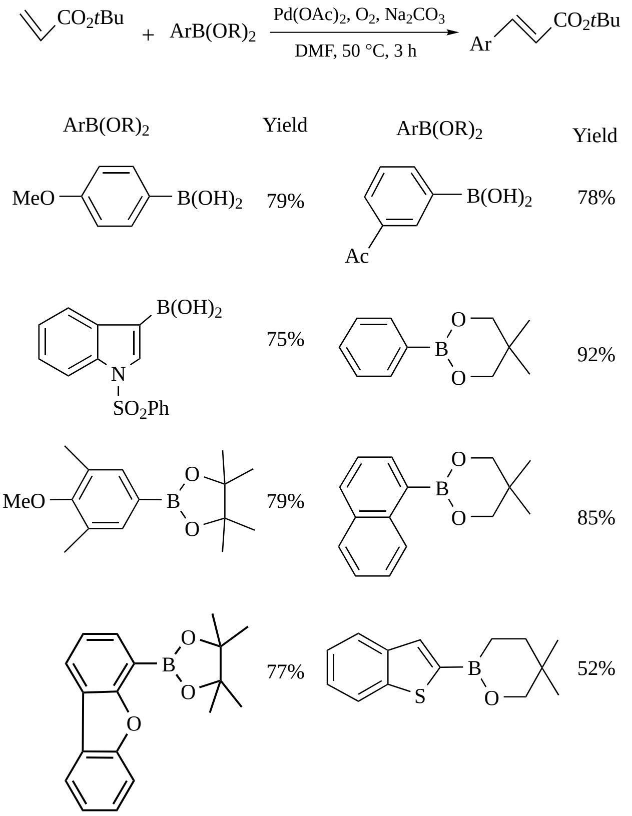
(4)

For organic synthesis applications, C–C bond formation between the R group and an alkene carbon atom is of paramount importance and Pd-catalyzed R–R coupling is to be avoided. Equation (5) displays a palladium-catalyzed Mizorki-Heck-type (MH) reaction using tellurium salts.[16]



(5)

One general approach takes advantage of the *Hydroboration* of alkynes to give vinylboron compounds.[17] As shown in equation (6), Heck vinylation occurs using a variety of aryl-boron reagents.[18–20]



(6)

Recently, it was found that organometallic compounds, such as silicon (equation 7),[21,22] tin (equation 8),[23] antimony (equation 9),[24] and lead (equation 10),[25] instead of organic halides, react with olefins to produce the same products as obtained by the MH reaction.

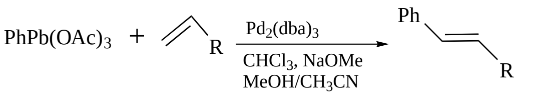
Ar = Ph; 4-MeC_6H_4; 3-MeC_6H_4; 2-MeC_6H_4; 2,4,6-$Me_3C_6H_2$; 4-$MeOC_6H_4$

(9)



(10)

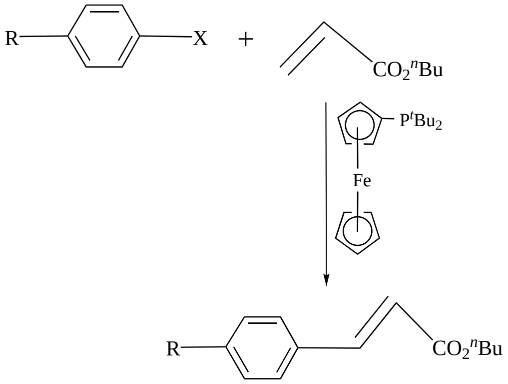
R = Ph (75%), CO_2Me (71%), $CH(OH)CH(OH)CH_2OBn$ (54%)

Other main group metals (or nonmetals) also serve as the agents for transfer of organic units to Pd for the Heck reaction; these include lead,[13] lithium,[26] magnesium,[13,26,27] sodium,[28] and boronic acids.[29]

3.5 Vinyl Substitution via Oxidative Addition of an Organic Halide or Equivalent

The second general mechanism of the Heck reaction involves oxidative addition of an organic species to Pd^0 to give the key organo-Pd^{II} intermediate, and then the usual final stage with an alkene to produce vinyl substitution and generate Pd^0.[7] This mechanism allows for spontaneous recycling of the Pd; no reoxidation is necessary. A base is present as buffer since strong acid is generated from the leaving group on the organic substrate.

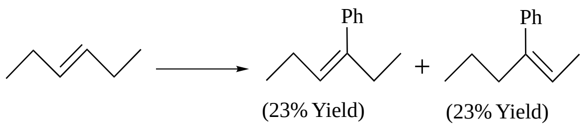
Aryl and vinyl bromides and iodides have been employed most commonly, with 1–5 mol% Pd^0, and reaction temperatures ranging from ambient to 125 °C (equation 11). The Pd catalyst can be $Pd(Ph_3P)_4$ or the Pd^0 species produced by in situ reduction of Pd^{II}. The alkene itself can serve as the reducing agent for Pd^{II}, but the catalyst can also be produced by deliberate addition of a reducing agent, such as sodium borohydride, formic acid, or hydrazine.[30]



(11)

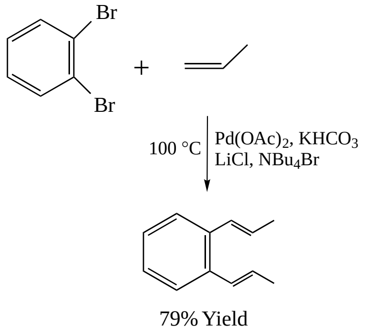
R	X	Time (h)	Temp (°C)	Yield
CO_2Me	Br	2	75	92%
MeO	Br	2	75	91%
CO_2Me	Cl	4	110	97%

As before, the reaction is best with monosubstituted alkenes; regioselectivity is not high with 1,2-disubstituted alkenes, and the yields are less impressive (equation 12).[31]



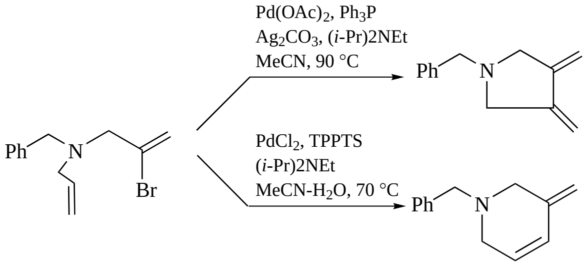
(12)

In another stoichiometric process, 1,2-dibromobenzene combines directly with propene to give a divinyl substitution product in 79% yield (equation 13).[32]



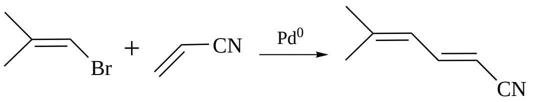
(13)

Intramolecular versions are generally successful. The position of the newly formed π-bond in the product can be the result of equilibration, especially in cases where a particularly stable position is available, as for indole in equation (14).[33]



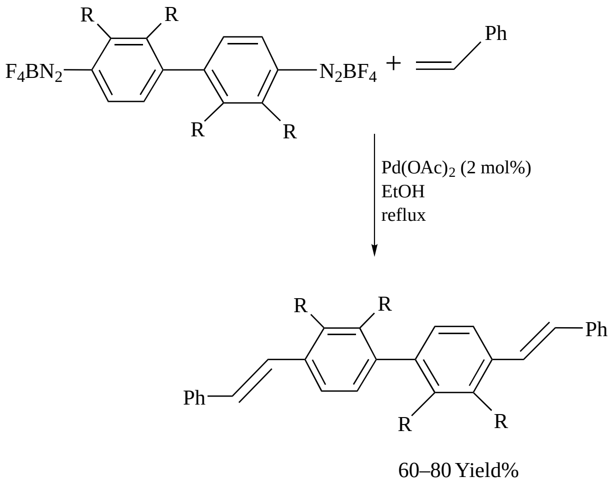
(14)

Vinyl substitution has been developed and applied in many examples. A simple intermolecular example summarizes the power of this technique in the formation of unsymmetrical (or symmetrical) 1,3-dienes (equation 15).[34]



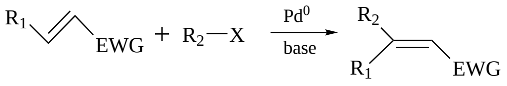
(15)

Aryl diazonium salts are effective aryl transfer agents, as shown in equation (16).[35] Divinylation of a biphenyl nucleus is achieved.



(16)

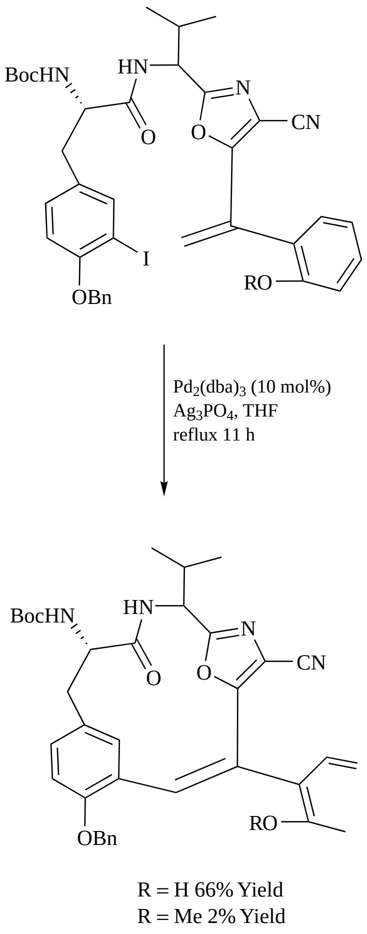
Electron withdrawing group (EWG) have been found to serve as leaving groups for C–C coupling as seen in equation (17).[36]



(17)

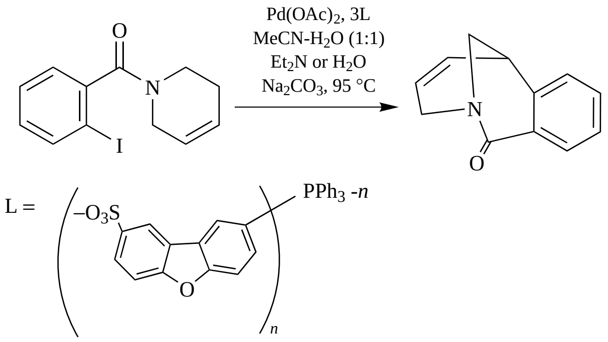
EWG = CO_2R, COR, CN, SOAr
R_1 = Alkyl, Aryl
R_2 = Aryl, Alkenyl

The intramolecular version of vinyl–vinyl coupling has been less often applied, but the potential should be clear from one example of macrolide formation. This example also demonstrates the use of formic acid as an in situ reducing agent and the high reactivity of vinyl iodides; 25 °C is an unusually low temperature for the Heck reaction (equation 18).[37]



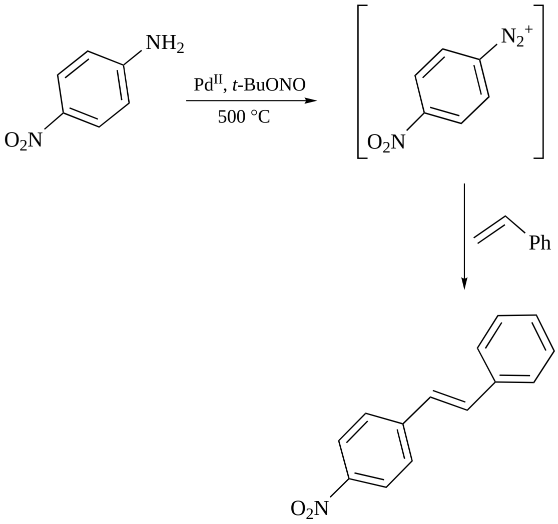
(18)

The use of alkyl halides is much more restricted. Only those alkyl groups that cannot allow β-hydride elimination are useful for intermolecular examples, but the restrictions on intramolecular examples are fewer. Both five- and six-membered rings are formed in good yield (equation 19).[38]



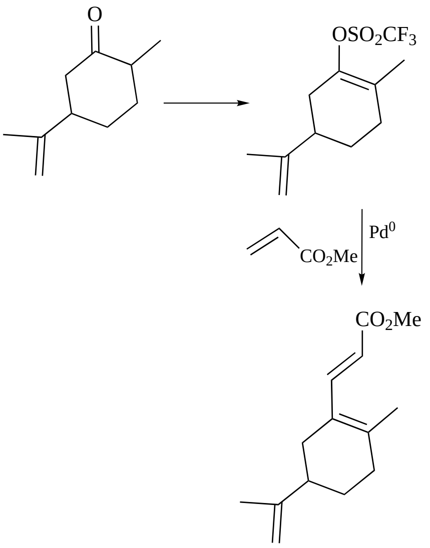
(19)

Other leaving groups are effective in the oxidative addition with Pd^0, and can lead to efficient Heck reactions. An attractive possibility is an aniline as starting material, with in situ generation of a diazonium salt. While the oxidation of the amino group can occur with Pd^{II} alone at elevated temperatures, deliberate addition of t-butyl nitrite leads to higher yields (equation 20).[39]



(20)

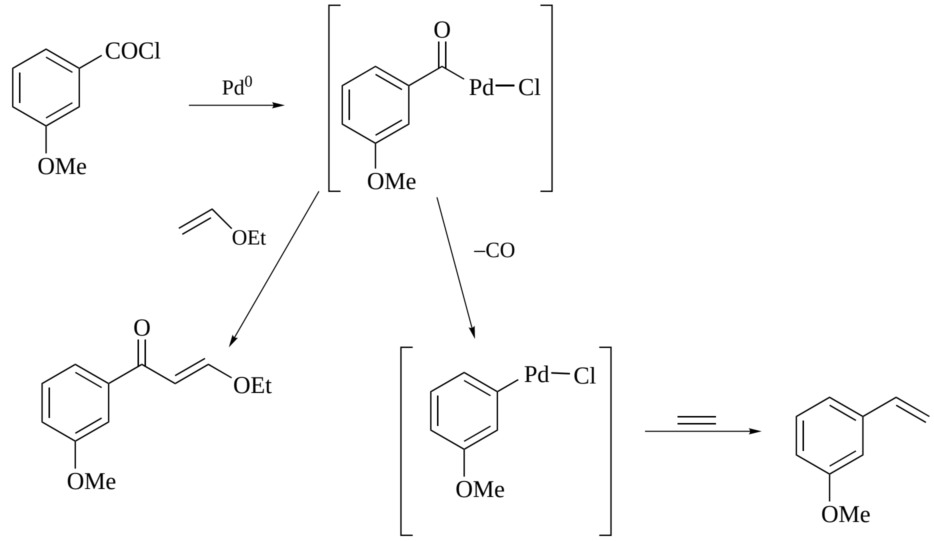
Aryl and vinyl sulfonate esters are reactive toward oxidative addition, and the perfluoroalkyl versions are useful substrates in the Heck reaction. Conditions can be mild, comparable to those for vinyl iodide reactions. The enol (vinyl) triflates are particularly attractive, since they are prepared directly from the corresponding ketone (equation 21).[40–42]



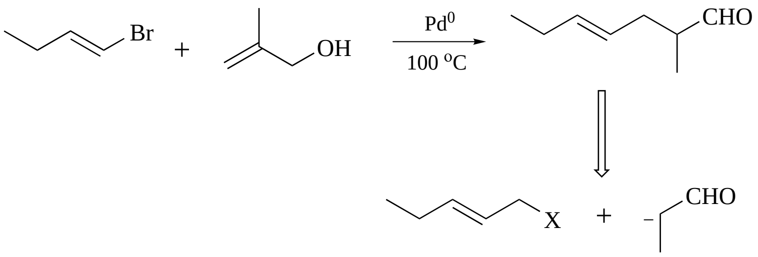
(21)

Conversion of phenols to triflate esters followed by vinylation constitutes one of the few general methods for the direct substitution of a carbon unit for a phenolic hydroxyl. Relatively few examples are known,[43] but high generality is easy to predict.

Carboxylic acid halides present interesting alternative processes (Scheme 5). Oxidative addition of acid chlorides to Pd^0 occurs under mild conditions, and the resulting acyl–Pd^0 complex will undergo decarbonylation upon heating. The decarbonylated product, an organo-Pd^0 species, can undergo



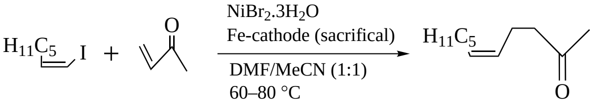
Scheme 5 Heck coupling with and without CO incorporation



Scheme 6 Synthetic equivalency of Heck coupling with allylic alcohols and enolate alkylation

vinylation in the usual way. However, with very reactive vinyl derivatives, the vinylation can occur with the acyl unit intact. The two possibilities are illustrated with *m*-methoxybenzoyl chloride.[44,45]

Heck reactions without Pd or Pt (equation 22).[46]

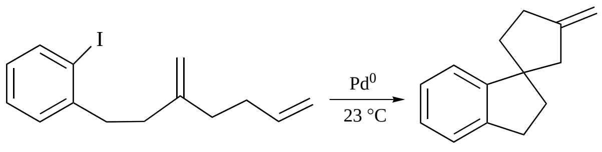


(22)

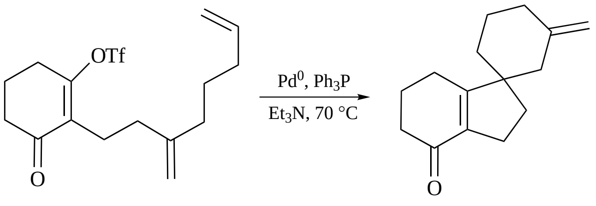
3.6 Special Applications

Two transformations require special note because of their very high potential in organic synthesis. First, the use of allylic alcohols as substrates has been shown to result in *β*-hydride elimination toward the OH group, and the resulting enol tautomerizes to the aldehyde. This overall conversion, illustrated for 2-methallyl alcohol and 1-bromobutene, opens a new strategy for the synthesis of carbonyl-containing compounds, and is equivalent (with very different selectivities) to the allylation of an enolate anion by traditional techniques (Scheme 6).[47–49]

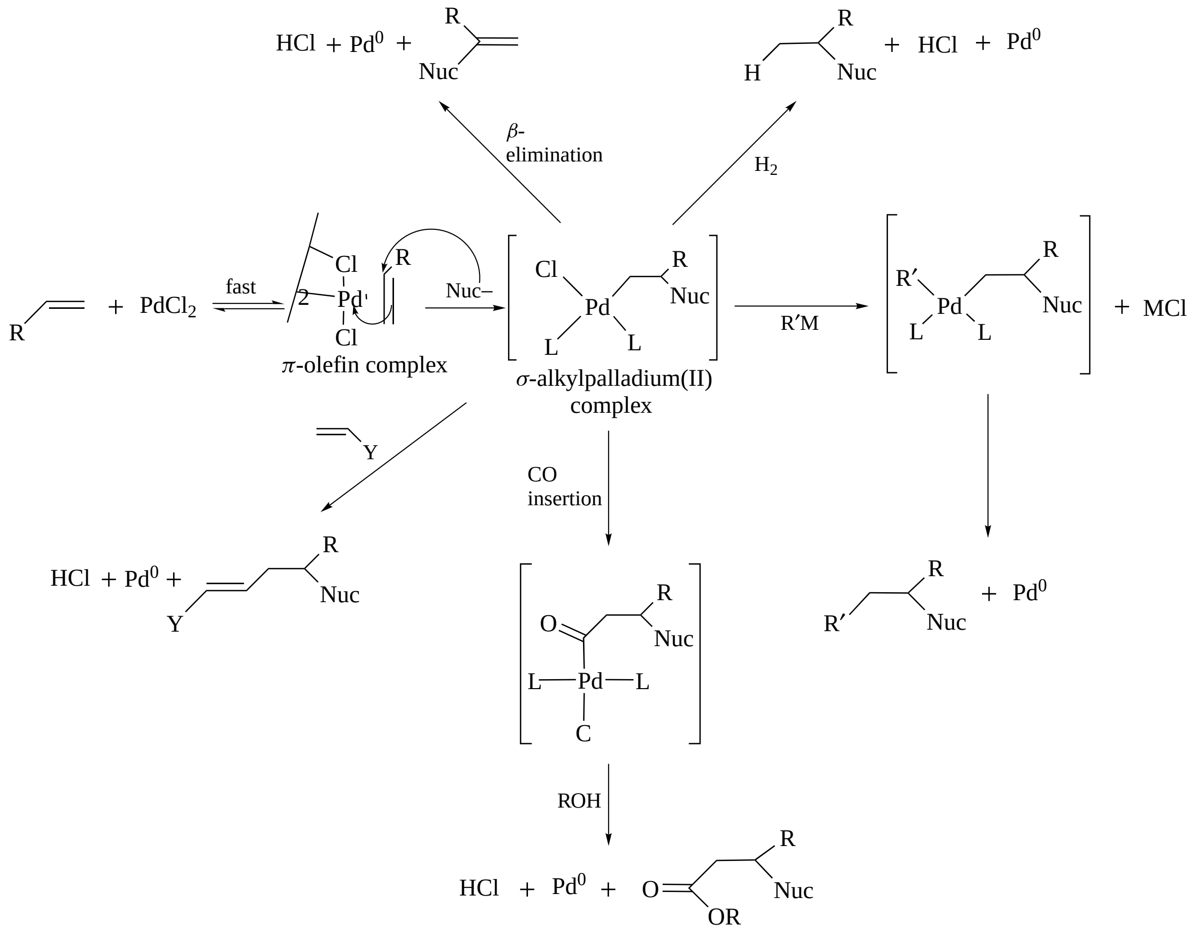
The second general transformation is the intramolecular version with multiple vinyl substitution steps (equations 23 and 24). There is high potential for synthesis of complex rings in a very efficient manner.[50,51]



(23)



(24)



Scheme 7

3.7 Summary

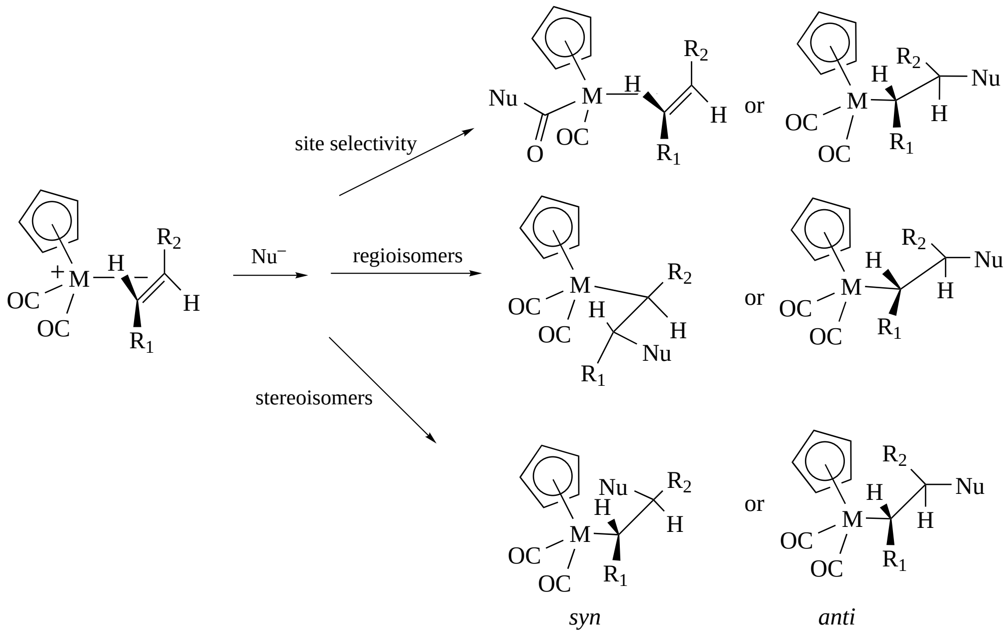
The Heck reaction is a powerful process for vinyl substitution by a carbon unit, with no direct analogy with traditional organic synthesis methodology. While it has not seen many applications in complex synthesis, it has been adapted to the preparation of a variety of 'value added' organic intermediates.

4 NUCLEOPHILIC ADDITION TO METAL-ACTIVATED ALKENES

4.1 Basic Reaction

The addition of EWG to alkenes promotes nucleophilic addition to the alkene, an activation that is the basis of powerful general methodology in organic synthesis (e.g. the Michael reaction).[52] Coordination of a metal–ligand unit to an alkene via the π-orbitals can also enhance nucleophile addition, leading to a σ-organometal species without a change in the oxidation state of the metal.[53–60] The organometal bond can then be led into characteristic processes, such as *Carbonylation*, β-hydride elimination, or others, as illustrated by several examples in Scheme 7. Overall, the process leads to addition of a nucleophilic species to one end of an alkene and one further elaboration at the other end. The fundamental difference between the traditional addition to electron-deficient alkenes (conjugate addition) and the metal-promoted process is that the metal activation does not dominate the regioselectivity. To a first approximation, the activation influence is independent of the orientating influence. In the traditional addition to electron-deficient alkenes, the activating group also dominates the regioselectivity factors.

Two systems have been developed to the level of useful organic synthesis methodology: spontaneous coordination of the alkene to Pd^{II} and the preparation of discrete $Cp(CO)_2Fe$–alkene cationic complexes. With the Pd system, efficient catalytic processes have been developed for the addition of heteroatom nucleophiles, while the coupling with carbon nucleophiles is mainly relegated to stoichiometric reactions: these two topics will be presented separately. In the iron series, the reactions involve stable intermediates and are invariably not amenable to catalysis.



Scheme 8 Three selectivity issues in nucleophilic addition to alkene–metal complexes

There are three primary issues of selectivity. (1) Site selectivity: which of several electrophilic ligands will add to the nucleophile? In Scheme 8, the alkene, the CO, and the Cp ligands are all candidates. (2) In an unsymmetrical polyene, which end or position of the π-system will be more reactive? In Scheme 8, either end of the alkene might be attacked, giving rise to two regioisomers. (3) The metal is coordinated to one face of the polyene. Which face will be attacked by the nucleophile? Addition from the face opposite the metal is anti addition, while attack from the same face as the metal is syn addition. Syn addition is generally thought to involve initial coordination of the nucleophile to the metal and then conventional alkene insertion, as for the Heck reaction. A coordinatively unsaturated metal is required for syn addition, and the configurations of the new sp^3 centers in the product would be opposite to that for anti addition.

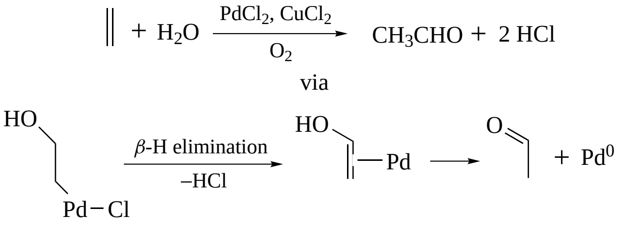
The issue of site selectivity has been considered,[6] and a simple pattern was identified and analyzed. The guidelines are useful, but typically the activation energies for addition to the various electrophilic ligands depend on a number of parameters, such as the type of nucleophile. It is not possible to predict from a set of rules whether, in a new complex, an alkene ligand will be more or less reactive toward nucleophiles compared to a CO ligand. However, the higher reactivity of noncyclic polyenes (alkene, η^3-allyl) compared to pseudoaromatic ligands (cyclopentadienyl, cyclobutadiene, arene) is quite general; in the example of Scheme 8 the Cp ring is unlikely to be the preferred site of addition.

Regioselectivity is quite predictable, and consistent in a simple way with typical electrophilic activation of an alkene (Markovnikov's rule). Just as in bromination of an unsymmetrical alkene, initial coordination of an electrophile (M^+, Br^+) activates the alkene toward nucleophilic addition of a nucleophile, the addition is preferred at the end of the alkene that best stabilizes a cation. Electronic effects dominate over steric effects. An molecular orbital (MO) analysis has been put forward ('the slip mechanism') to rationalize the activating effect of the metal and, in a secondary way, the regioselectivity.[61] It focuses on the reactants and products, and notes that the metal moves during the reaction from the approximate midpoint of the alkene to one end. As that 'slip' occurs toward one end of the alkene, the lowest unoccupied molecular orbital (LUMO) for the complex changes and a large coefficient develops at the other end.

Stereoselectivity is largely predictable, as most examples involve coordinatively saturated reactants and initial coordination of the nucleophile with the metal is inhibited. Anti addition is prevalent, addition from the face opposite the metal. Especially with Pd^{II}, as summarized below, the preference for syn or anti addition depends on the nucleophile, and an MO analysis has been advanced.[62]

4.2 Activation with Pd^{II}

Nucleophilic addition to metal-activated alkenes as a synthetic method can be traced to the *Wacker Process*, the oxidation of ethylene to acetaldehyde with Pd^{II} and

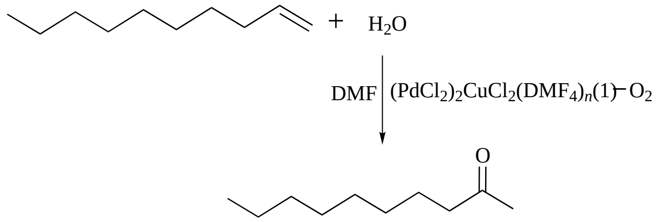


Scheme 9 The Wacker process

oxygen (Scheme 9).[7,63] This process includes all of the basic features of the Pd^{II} activation and has now been greatly extended with regard to substrate type and generality. The alkene spontaneously coordinates with the Pd^{II} species, even at low temperature, but in a rapidly reversible process. Initial addition of the water nucleophile has been shown to occur by anti addition, although stereoselectivity is not an issue in this case.[63,64] The resulting β-hydroxyethyl–PdCl intermediate is unstable with respect to β-elimination of a vinyl hydrogen, and produces the new alkene complex (an enol complex in this case). Ligand dissociation after successive β-hydride rearrangements leads to acetaldehyde and Pd^0. Typical of reactions in this series, a stoichiometric reoxidant for the Pd^0 is necessary in order to be able to use catalytic amounts of Pd^{II}. Copper offers the possibility of reoxidation using catalytic Cu^{II} and stoichiometric oxygen. There are numerous other techniques for reoxidation, as given in the examples below.[63] The problem of reoxidation of the Pd in order to have an efficient catalytic process has no general solution.

A direct extension of the Wacker process is the general conversion of α-alkenes into methyl ketones (equations 25 and 26).[65] The regioselectivity shown in many examples (strong preference for the methyl ketone over the aldehyde) is consistent with the regioselectivity rule of attack at the more substituted carbon of the alkene (Markovnikov's rule). Functional group compatibility is high. The method is very general and efficient for monosubstituted alkenes, but gives lower yields (lower rates) and mixtures of regioisomers with more substituted substrates.

(25)



(26)

Selective oxidation of styrene to acetophenone by a Pd(II) catalyst in the presence of ionic liquids has been achieved (equation 27). Electronic effects on the site of Pd(II) oxidation of substituted styrenes are indicated in equation (28).[66,67] Strong pi-donation from the phenyl substituent favors oxidation at the alkene carbon alpha to the aromatic ring.

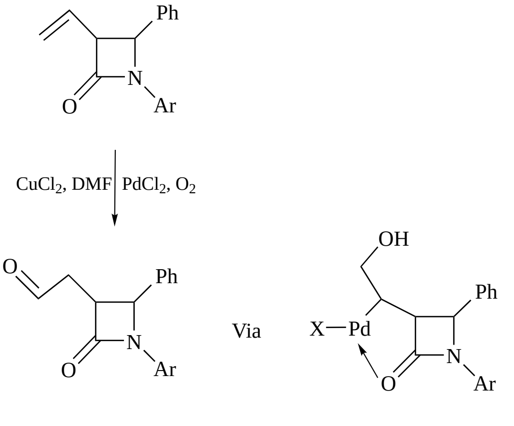
2,4,6-OCH_3	Dominant	

An interesting case in the β-lactam series gave selective anti-Markovnikov addition, attributed to the directing effect of the lactam carbonyl group (equation 29).[68]



(29)

Other oxygen nucleophiles are also effective, from alcohols to carboxylic acids. The conversion of ethylene to vinyl acetate and vinyl ethers is well documented, but applications in synthesis with more complex alkenes are few.

The intermolecular addition of nitrogen nucleophiles has been shown to lead to interesting products, with remarkable control based on the reaction conditions (Scheme 10).[68,69] Carbonylation of the organo-Pd intermediate can also be efficient, leading to β-amino esters.[69] Unfortunately, these processes require stoichiometric Pd^{II}; no reoxidation scheme has been developed.

Much more general and efficient is the intramolecular version, the formation of tetrahydrofuran and tetrahydropyran rings from oxygen nucleophiles, and pyrrolidine and indole rings from amine nucleophiles. The general reaction in Scheme 11 summarizes the questions: regioselectivity now includes a question of ring size preference, and the relative configuration of existing stereocenters might be expected more strongly to influence the newly formed sp^3 carbons. Several recent examples of these and related cyclizations are shown in equations (30–44).[70–86]

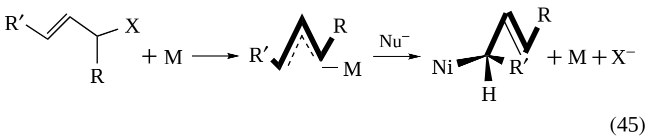
4.3 Summary

The activating effect of Pd^{II} and Fe^{II} toward nucleophilic addition to alkenes is powerful and allows addition of stabilized anions to simple alkenes at low temperatures. However, the only efficient catalytic processes are based on the addition of oxygen nucleophiles to alkenes activated by spontaneous coordination with Pd^{II}, extensions of the Wacker process.

5 NUCLEOPHILIC ADDITION TO ALLYL LIGANDS: ALLYLIC ALKYLATION

5.1 Introduction

Oxidative addition of an allylic σ-bond can lead to η^3-allyl ligands. The allyl ligand can behave as a nucleophile (M = Ni, X = halide) or as an electrophile, depending on the metal–ligand system. The electrophilic allyl ligand can couple with a nucleophile to produce an alkene (equation 45). There are several issues of selectivity as well as reactivity. The addition can be syn or anti, resulting in opposite configurations of the newly formed chiral center. There are three potentially reactive sites in the typical allyl ligand; either terminus and the central carbon (C-2). The useful methodology has been developed around addition at a terminal position. Finally, the alkene unit in the product can be (E) or (Z), depending on the configuration of the terminus not undergoing coupling.

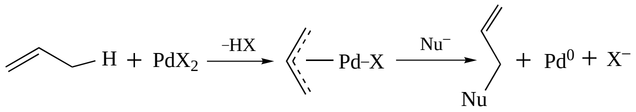


(45)

There are a number of metal–ligand systems that will provide the proper activation for nucleophile coupling, but the Pd^{II} system is by far the most well developed and useful. In recent years, asymmetric allylic alkylation reactions have received the most interest for organic synthesis applications (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***). Metals other than Pd have also received some additional attention.

5.2 Allylic Alkylation with Allyl–Pd^{II} Complexes

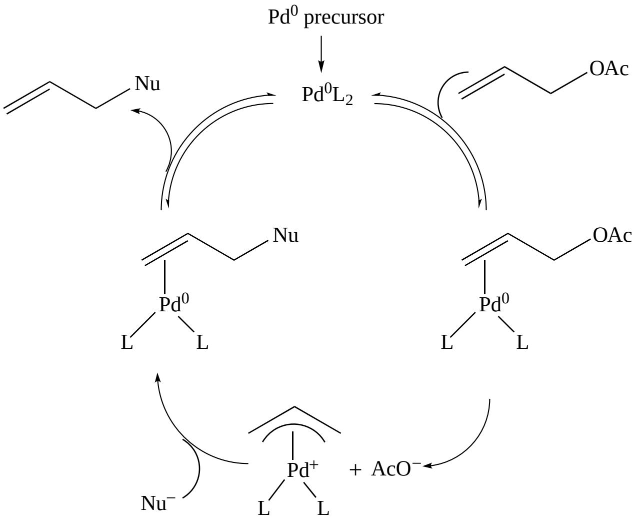
What should be the nature of the group X undergoing oxidative addition in equation (46) In the initial formulation of the possibilities, there was a focus on X = H, relying on spontaneous insertion of Pd^{II} into a C–H bond (equation 46). The overall process would be very powerful, analogous to the synthetic methods depending on the reactive site adjacent to a C=O π-bond.[87]



(46)

While good procedures are available for the initial oxidative addition to give allyl–PdX complexes, and the nucleophile addition has been fully developed, this process has not been amenable to catalysis. The Pd^{II} is reduced to Pd^0 during the basic pathway, and no compatible reoxidation system has been defined.

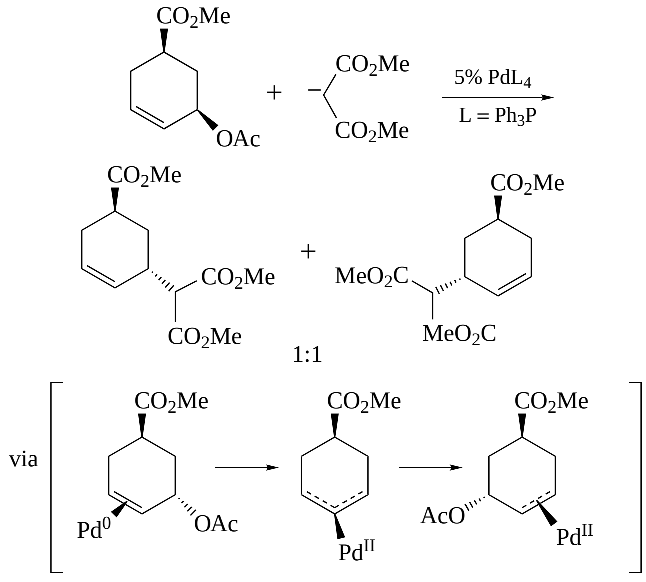
The useful procedures began to be developed with the recognition that by initial activation of the allylic position with an electronegative atom, direct oxidative addition with Pd^0 can give the key η^3-allyl intermediate.[87] Spontaneous recycling then leads to an efficient catalytic process (equation 47).



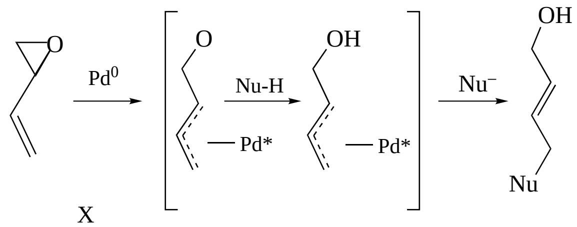
(47)

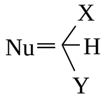
The overall process is illustrated by the reaction of a homochiral allylic acetate (Scheme 12). With 'soft' anions, derived from carbon acids of pK_a 8–15, the addition is very efficient, exclusively anti, and can occur at either end of the allyl system (1:1 in the symmetrical case). In contrast to the addition to alkene ligands, the primary influence on regioselectivity is steric and not electronic. The less-substituted end of the allyl ligand is preferentially attacked.

The acetate unit is particularly convenient, since it is obtained from the corresponding alcohol and is relatively stable toward solvolysis, S_N2 reactions, and so on. Many other electronegative units are also effective, including halide and tosylate. Less obvious is the high reactivity of allylic sulfones and allylic nitro compounds toward the oxidative addition. Three special cases are outlined here. First, an allylic epoxide can undergo rapid oxidative addition of the allylic C–O bond under mild conditions, leading to the zwitterion or equivalent (Scheme 13).[87,88] Proton abstraction can lead to the anion form of the nucleophile, and then nucleophilic addition gives the final product. The process requires no base. For example, a mixture of the allylic epoxide with dimethyl malonate can react with a small amount of Pd^0 in the absence of solvent or base to give rapid and efficient conversion to the nucleophile adduct.



Scheme 12

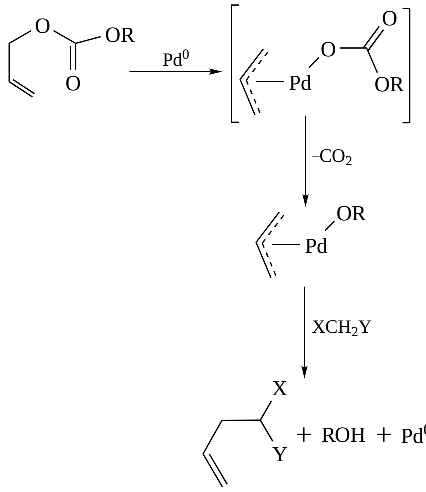




X, Y = CO_2R, COR, SR, SOR, SO_2R, NO_2, and ethamine

Scheme 13

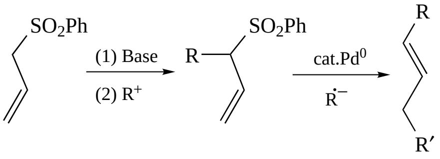
Allylic carbonates also undergo oxidative addition, cleavage of the allyl–O bond, and loss of CO_2 can occur to give a species formulated as the allyl–Pd–alkoxide (equation 48). In the presence of a suitably acidic carbon acid (pK_a15 or lower), the carbanion is generated and nucleophile addition can occur. The overall process requires only a catalytic amount of Pd^0; no base or other stoichiometric reagents is necessary.[87]



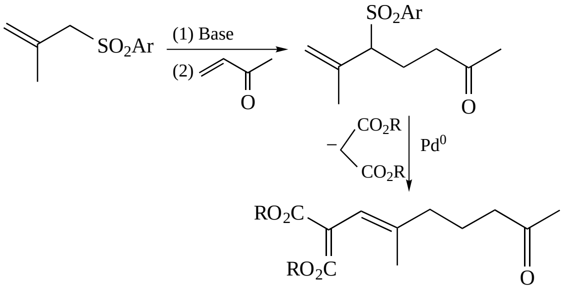
(48)

The oxidative addition of allylic esters is also gaining popularity as a means of deprotecting a carboxylic acid or alcohol (concomitant loss of CO_2 from a carbonate).[89]

Allylic sulfones show a reactivity toward oxidative addition that seemed remarkable when first defined, being much higher than other conditions for breaking the carbon–sulfur bond (e.g. an S_N2 process). This reactivity, together with the well known stabilizing effect of the SO_2 group on an adjacent carbanion, allows a strategy for double functionalization of the allyl unit with opposite polarization for each operation. For example, proton abstraction followed by α-electrophile trapping gives monosubstitution; then treatment with catalytic Pd^0 and a soft nucleophile gives γ-substitution by allylic alkylation (equation 49). The electrophile can be a simple alkyl group (S_N2) or conjugated carbonyl compound (1,4-addition) (equation 50).[87,90]

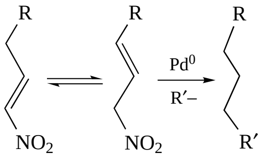


(49)



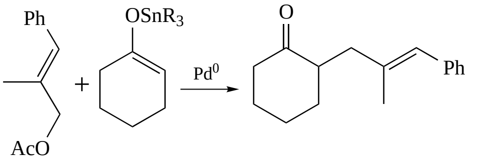
(50)

A similar strategy is available with allylic nitro compounds, but the applications are less well developed. It is interesting to note that both alkene isomers of the nitro species react smoothly by oxidative addition of the carbon–nitro bond, presumably by rapid equilibration of the alkene isomers under the allylic alkylation conditions (equation 51).



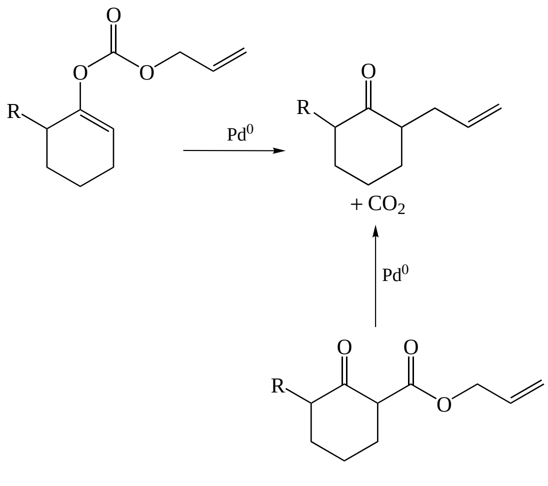
(51)

More reactive anions, such as the very well studied enolate anions from ketones and esters, do not undergo allylic alkylation except in special cases. Tin enolate derivatives are generally effective (equation 52).

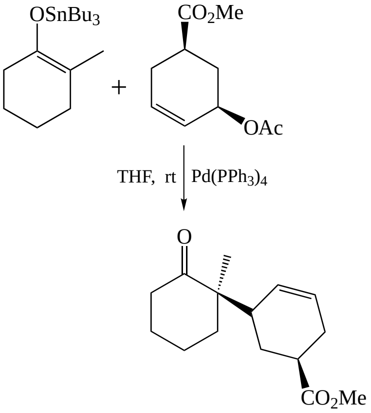


(52)

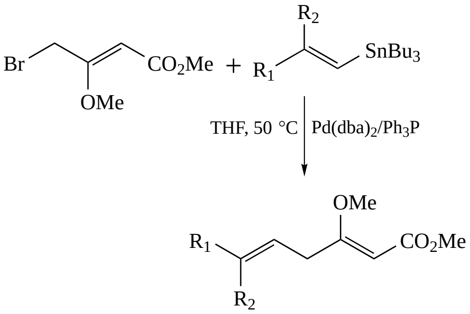
The enolate can be 'built-in' in the allyl esters of β-keto esters (equation 53).[87] The chemoselectivity is excellent, as shown by selective reaction of an allylic acetate in the presence of a simple ketone, using a tin enolate anion (equation 54).[87] Even mildly nucleophilic species, such as allylic–tin^{IV} derivatives, react at room temperature, the method of choice for cross coupling of allylic units (equation 55).



(53)

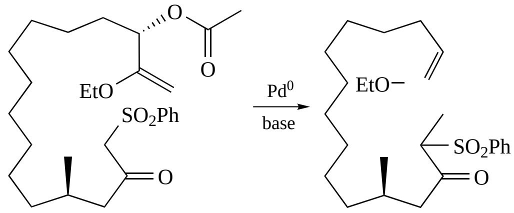


(54)



(55)

Intramolecular couplings have been among the more impressive applications, with macroring structures prepared in good yield without using high dilution conditions (equations 56 and 57). In the case of the allylic epoxide example (equation 57), the Pd^0 catalyst is attached to polystyrene beads, apparently important in producing the high yields at normal concentrations.



(56)

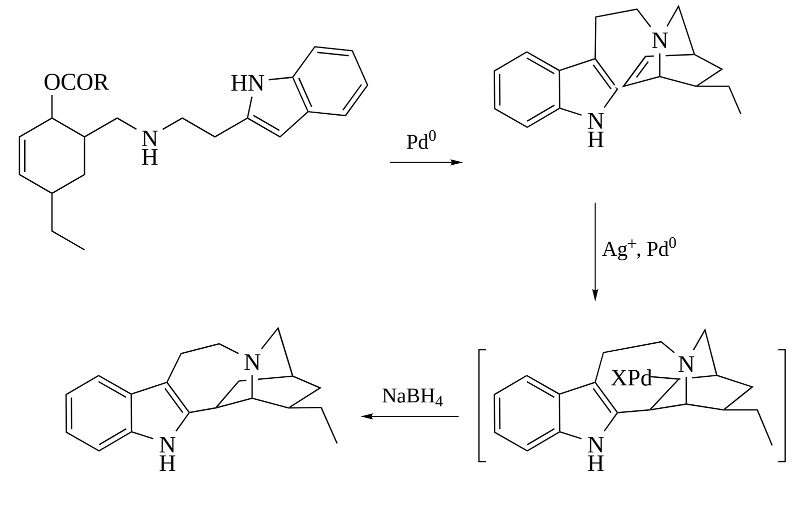
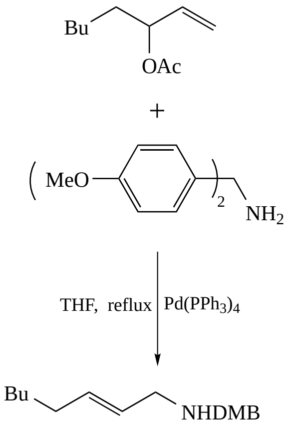
Heteroatom nucleophiles have not been developed extensively. Amine nucleophiles behave well if derivatized



Scheme 14

as a benzylamine or sulfonamide (equation 58).[87] The intramolecular version with indole nitrogen as nucleophile was used in a simple and elegant construction of the ibogamine alkaloid skeleton (Scheme 14).

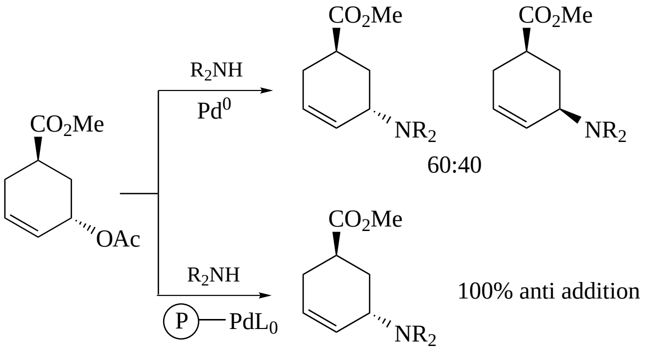


(58)

The direction of addition (syn or anti) with amine nucleophiles has been tested and found to be dependent on the reaction conditions. The situation is clearest with the homochiral cyclohexane derivative (Scheme 15). In this example, a simple Pd^0 catalyst gives a mixture of isomers owing to competitive syn and anti addition, while the polymer-supported catalyst produces only the (usual) anti addition.[87]

The transfer of main group metal derivatives can be achieved efficiently using aluminum derivatives, but the stereoselectivity is now *syn*, suggesting initial transfer of the metalloid to the Pd (Scheme 16).

A particularly clear example of syn versus anti addition was carried out in stoichiometric fashion using vinyl–zirconium reagents, in direct comparison with the stereochemical outcome of the catalytic allylic alkylation with soft anions (Scheme 17). The zirconium reagent gives the natural steroid configuration, while the malonate anion gives the opposite epimer.[91]



Scheme 15

Regioselectivity is primarily driven by steric factors. A systematic comparison is available with Me and other alkyl groups (equation 59). The sensitivity is obviously high, with a change from 77:23 to >99 by a change from primary alkyl to secondary alkyl.

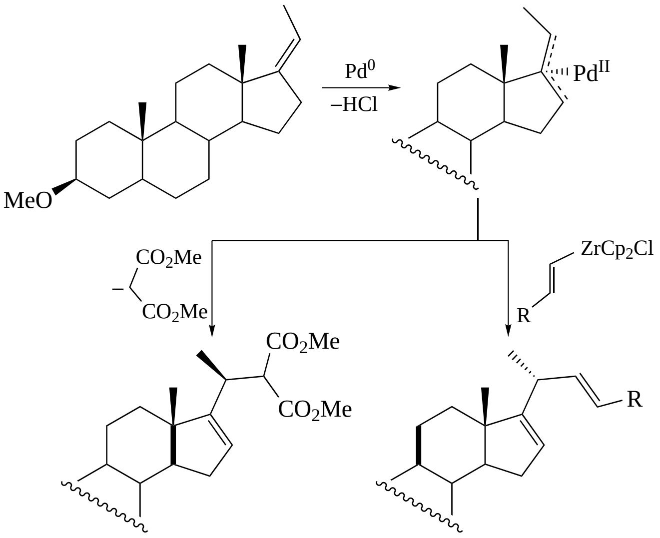
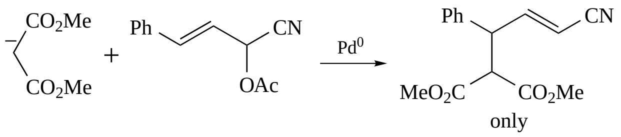
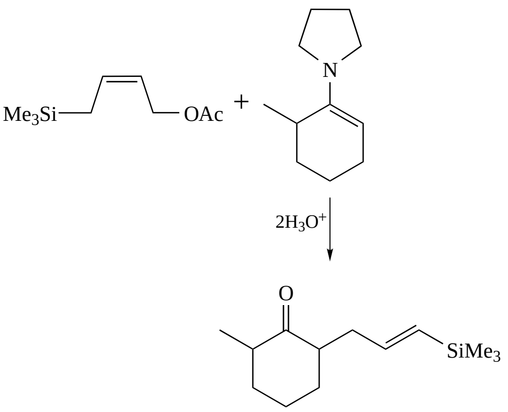


Scheme 17



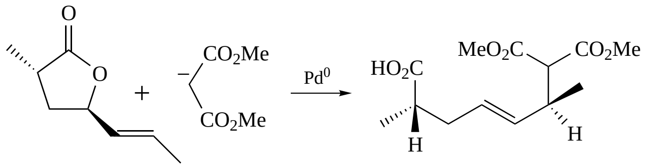
(60)

Allylsilanes lead to vinylsilanes by the usual allylic rearrangement mechanism, and the example in equation (61) nicely demonstrates the equilibration of the alkene unit to the more stable (E) version.



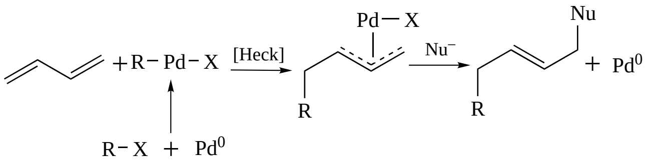
(61)

The vitamin E side chain can be prepared stereoselectively by addition to an homochiral vinyl lactone (equation 62). The product is the result of selective anti addition.



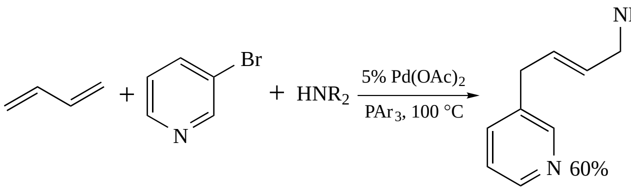
(62)

The Heck reaction with 1,3-dienes can lead to in situ generation of allyl–Pd complexes, with nucleophile coupling in a second step (equation 63).



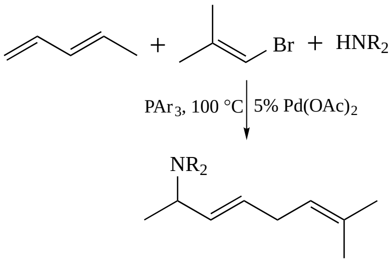
(63)

An example of the overall strategy is the coupling of bromopyridine and a secondary amine across 1,3-butadiene (equation 64). The conditions employ Pd^{II} and rely on in situ reduction to the effective catalyst, a version of Pd^{0}.

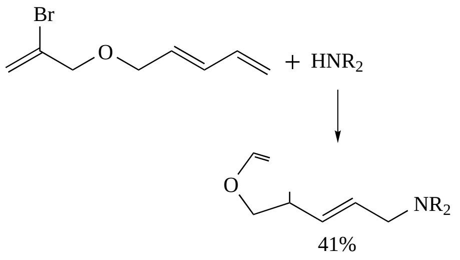


(64)

The selectivity of the Heck reaction shows up with unsymmetrical dienes, leading to initial coupling at the less-substituted alkene and then nucleophile addition at the other end (equation 65). The intramolecular Heck reaction also is efficient, leading in equation (66) to dihydrofurans.



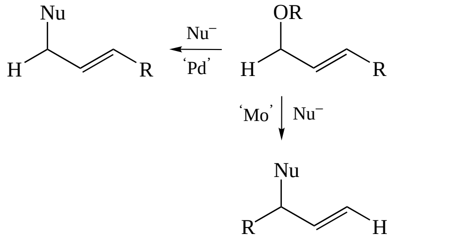
(65)



(66)

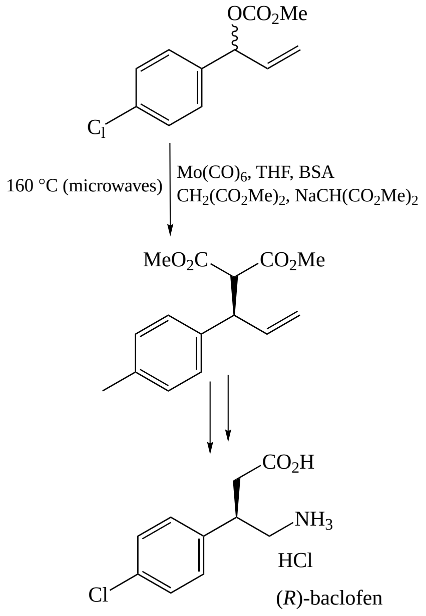
5.3 Variations: Other Metals

The simple metal hexacarbonyls of molybdenum and tungsten will catalyze allylic alkylation, with dramatic effects on the regioselectivity.[92] The comparison of $Mo(CO)_6$ with Pd^0 shows a remarkable contrast in regioselectivity (equation 67).[92] The basis for the selectivities is somewhat mysterious, especially considering another dramatic reversal of selectivity with change in anion, from malonate, using $Mo(CO)_6$ and the same conditions. This regioselectivity of Mo carbonyl catalysts has been used to synthesize (*R*)-baclofen, as shown in equation (68).



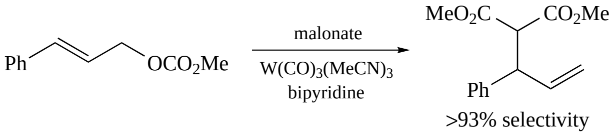
(67)

Parent Ligand: bis(pyridylamide)

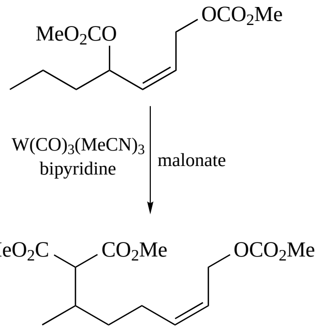


(68)

Tungsten carbonyl complexes are also effective catalysts, showing some preference for nucleophile addition at the more hindered position of an unsymmetrical allyl ligand (equations 69 and 70).[93] Other allylic alkylation reactions have been reported.[94]

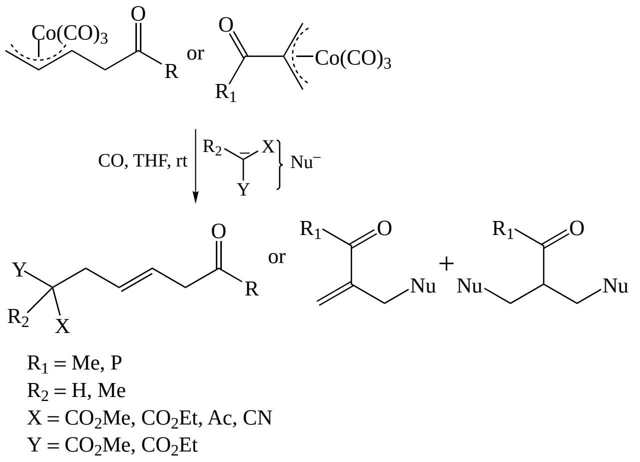


(69)



(70)

A number of π-allylmetal complexes react with nucleophiles resulting in transfer of the allyl group from the metal to the nucleophile.[95–100] As previously shown the most developed are the π-allylpalladium complexes. However, π-allyltricarbonylcoblat(I) complexes also react with carbanions to produce allylic alkylation products in good yield. Acylated π-allylcobalt complexes when reacted with a nucleophile result in an overall acylation/alkylation of 1,3-dienes, (equation 71).

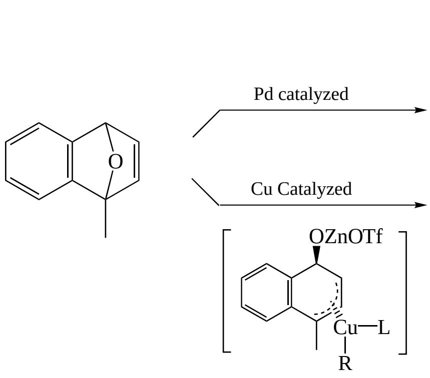


(71)

Unsubstituted malonate esters and ethyl acetonate give highest yields, while methyl substituted analogs are less effective. Esters and ketones enolates are do not undergo allylic alkylation, and instead induce proton abstraction, generating acyldienes. There seems to be competition between nucleophilic attack and proton abstraction when utilizing unstable carbanions.[95]

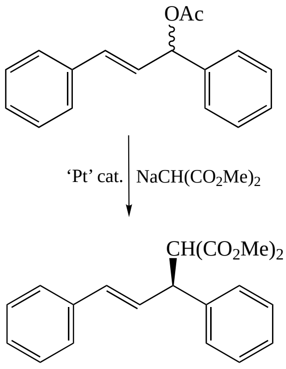
Copper-catalyzed asymmetric allylic alkylations with organometallic reagents used for small-ring openings, such as epoxides and aziridines, have gained interest. Illustrating

the differences between palladium and copper is the ring opening of oxabicycles alkenes, (equation 72), where the regioselectivity found with the unsymmetrical palladium-catalyzed product rules out the formation of π-allyl palladium intermediate. In contrast the copper-catalyzed products configuration points to a π-allyl pathway followed by reductive elimination at the less-hindered secondary terminus with retention of overall structure.[96]



(72)

An in-depth study of platinum allylic alkylation and subsequent comparison to ligand-identical palladium catalysts was done by Blacker *et al.* The allylic alkylation of diphenyl-2-enyl acetate with dimethyl malonate, (equation 73), reveals activity for a variety of complexes with activity restricted by the source of zerovalent platinum (Table 1). Nonactive complexes are thought to be less prone to dissociation into coordinatively unsaturated catalytical active species.



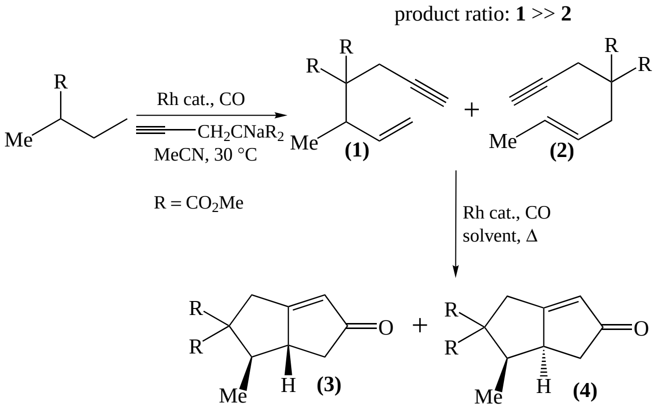
(73)

Table 1 Types of platinum complexes that catalyze allylic alkylation at room temperature

	Catalyst	Conversion	Isolated yield
1	$[(Ph_3P)_4Pt]$	100	82
2	$[(Ph_3P)_2Pt\text{-ethylene}]$	100	88
3	$[(dppe)_2Pt]$	0	0
4	$[(Ph_3P)_2Pt\text{-stilbene}]$	100	N/A
5	$[\{(PhO)_3P\}_4Pt]$	0	0
6	$[(dppe)PtC_3H_5]BF_4$	100	78
7	$[(Ph_3P)_2PtCl_2]$ and $NaBH(OMe)_3$	100	85

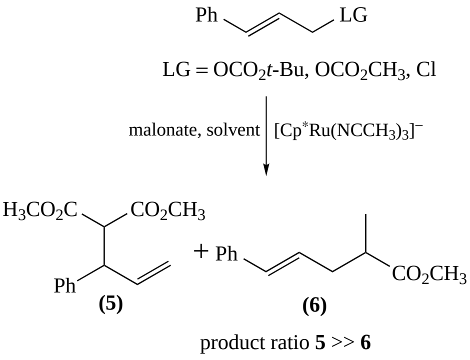
A phosphinooxazoline ligand has been utilized to control enantioselectivity with success. It is determined that overall platinum catalyst generally give better regioselectivity than palladium towards products containing more electron-deficient double bonds.[97]

Rhodium-catalyzed allylic alkylation demonstrates excellent regioselectivity provided there is a strong π-acidic ligand present on the metal center (equation 74). In a unique approach, Evans *et al.* demonstrated a tandem allylic alkylation and Pauson–Khand annulation reaction using the same Rh catalysis with high regio- and diastereoselectivity. Initially product (**1**) is produced in excess (37:1, **1:2**) and the following annulation is highly enantioselective (7:1, **3:4**) resulting in one major product (**3**).[98]



(74)

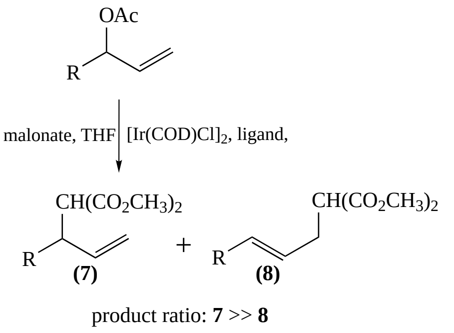
Ruthenium-catalyzed allylic alkylation falls between known catalysis with respect to regioselectivity and chirality of products. Like Pd, Mo, and W – but unlike Rh – regioselectivity is not highly dependent on the nature of the starting carbonate. However, unlike Pd and Mo, but similar to Rh and W, substitution of the chiral substrate occurs with high retention of configuration, (equation 75). Hence the Ru system compliments other metal-catalyzed allylic systems well.[99]



(75)

Though largely unstudied, it has recently been shown that Ir-catalyzed allylic substitution reactions where a strong π-acceptor ligand, for example, triphenylphosphite, is present

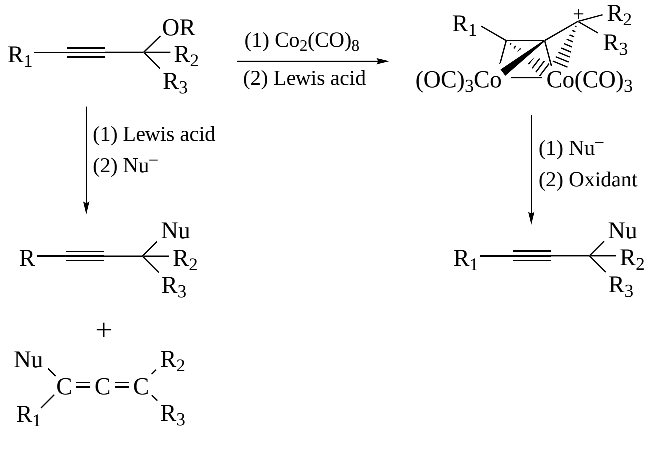
in situ will give rise to excellent regioselectivity in favor of the branch product (equation 76) for both aryl and alkyl-substituted substrates. When a chiral π-acceptor ligand, for example, phosphinooxazoline, is used, high enantioselectivity can be achieved as well.[100]



(76)

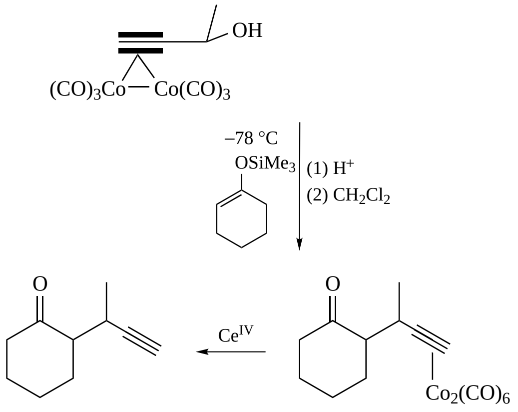
5.4 Variations: Propargyl–Metal Complexes

While little is known about the reactivity of simple propargyl–metal complexes toward nucleophiles, the special case of alkyne coordination with $Co_2(CO)_6$ leads to stable propargyl cations that can react smoothly with nucleophiles. The overall process begins with spontaneous coordination of the cobalt unit, added as $Co_2(CO)_8$, with the alkyne in a pseudotetrahedral arrangement. If there is an electronegative atom in the propargyl position, ionization is strongly enhanced; the metal-coordinated propargyl cation can be directly observed and is comparable in stability to the trityl cation. Nucleophile addition produces a coordinated alkyne with the nucleophile in the propargylic position; oxidative cleavage releases the newly substituted alkyne – sometimes referred to as the Nicholas reaction (Scheme 18). The process is stoichiometric, primarily because of the stability of the alkyne–cobalt complexes; simple ligand exchange to release



Scheme 18

the alkyne unit has not been demonstrated. The overall result, replacement of an electronegative atom from an activated position by nucleophile displacement, does not appear to justify the elaborate intermediates compared to easy direct displacement. However, the direct displacement is often complicated by appearance of allene substitution products, while the metal-promoted process gives 100% selectivity for the alkyne derivative. The reactivity is high, as illustrated by direct reaction with an enol silyl ether (equation 77). After cation generation by acid treatment and nucleophile coupling, the intermediate substituted alkyne complex can be isolated, purified by chromatography, and the cobalt detached by oxidation.[101]



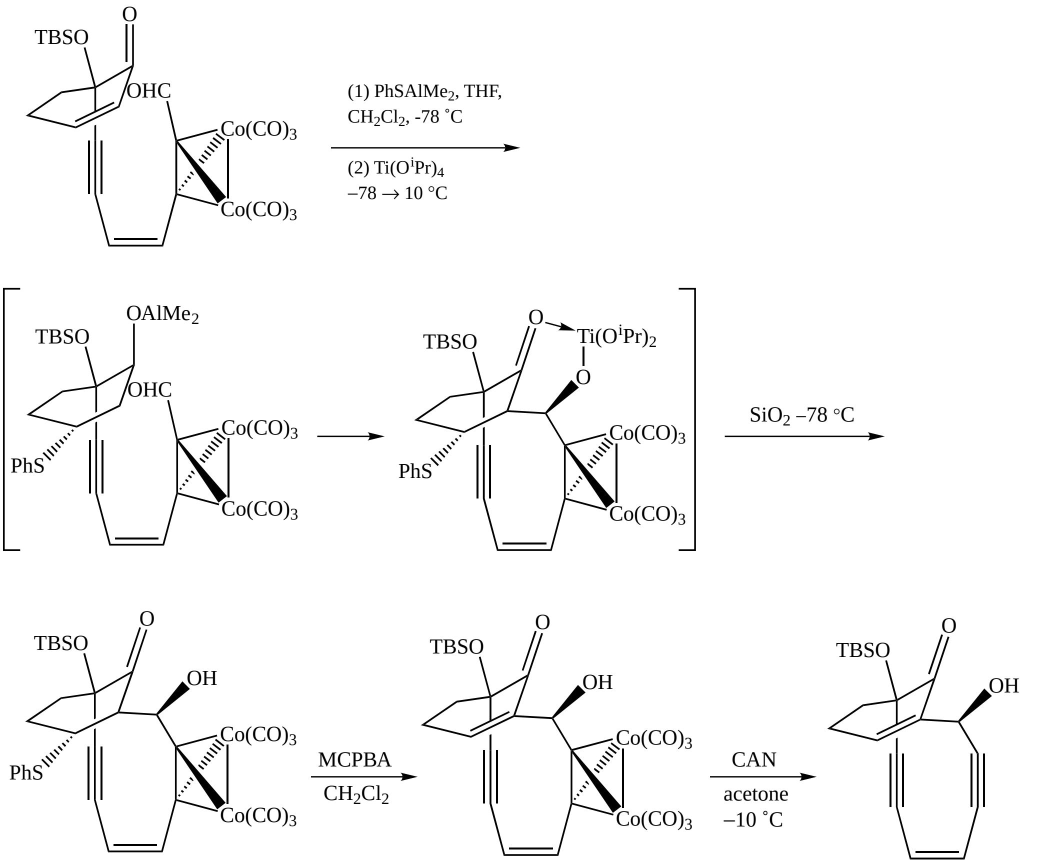
(77)

The method is limited because of the requirement for stoichiometric reagents, but impressive applications in the preparation of complex molecules have appeared. For example, a model system for ene–diyne antibiotics has been prepared by an intramolecular route (Scheme 19).[102] Added versatility arises from the electophilic coupling of vinyl–propargyl complexes, such as in Friedel–Crafts acylation conditions.

Coupling of silyl enol ethers or boron enolates with $Co_2(CO)_6$-stabilized carbocations, generated via Lewis acid treatment of the appropriate propargyl ethers or aldehydes (aldol reaction), via the Nicholas reaction has been used to obtain large, highly strained, ring ketones.

5.5 Summary

Catalytic allylic alkylation with Pd^0 is one of the most powerful techniques to come out of the development of organotransition metal reagents for organic synthesis. Especially powerful is the versatility in the reactants; a wide range of allyl species with electronegative allylic substituents and essentially every type of nucleophile. Allylic alkylation using metals other than Pd are known but have been less commonly applied to organic synthesis.

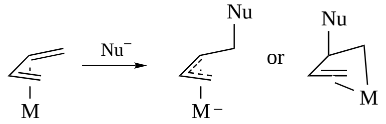


Scheme 19

6 NUCLEOPHILIC ADDITION TO 1,3-DIENE LIGANDS

6.1 Introduction

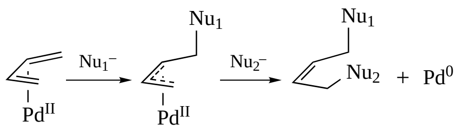
Complexes of 1,3-dienes in the η^4-arrangement with metals can be formed by direct ligand displacement, and are known for many metals. The η^2-arrangement is also possible, and is probably the preferred mode of coordination with Pd^{II} in the examples below. Even with the simplest diene ligand, from 1,3-butadiene, questions of regioselectivity arise. Addition at the terminal position leads to an allyl–metal complex, while internal addition produces a homoallyl complex (equation 78). The early correlation of regioselectivity in all types of nucleophile addition to ligands in metal complexes suggested that terminal addition would be preferred for cationic complexes.[6] The general rule of anti addition again applies. Two systems have been studied more: the complexes formed in situ from Pd^{II} and a 1,3-diene, and the stable diene complexes of $Fe(CO)_3$.



(78)

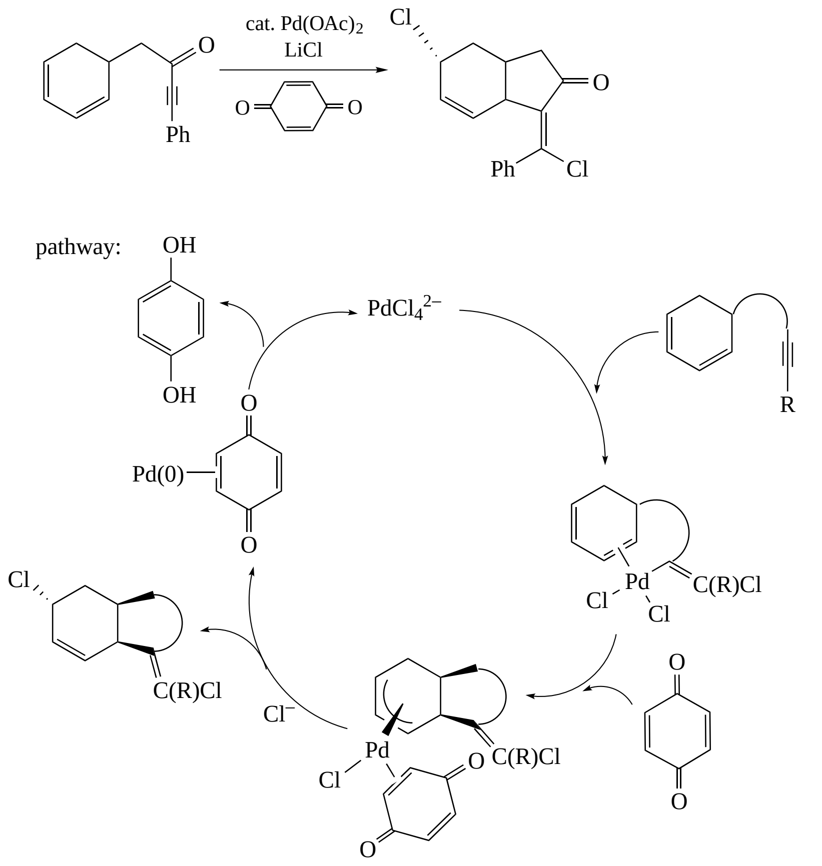
6.2 Oxidation of 1,3-Dienes with Palladium(II) Catalysis[103]

This process takes advantage of the fact that coordination of a 1,3-diene with Pd^{II}, presumably in the η^2-mode, can activate the diene toward nucleophile addition. The product is an allyl–Pd^{II} complex, which, as described in the previous section, is also reactive toward nucleophiles, also at the less-substituted position, and eventually leads to a 1,4-disubstituted 2-alkene. The Pd ends up as Pd^0 and must be reoxidized in order to operate a smooth catalytic cycle (equation 79). The optimum conditions for the process have been worked out in fine detail.[103]

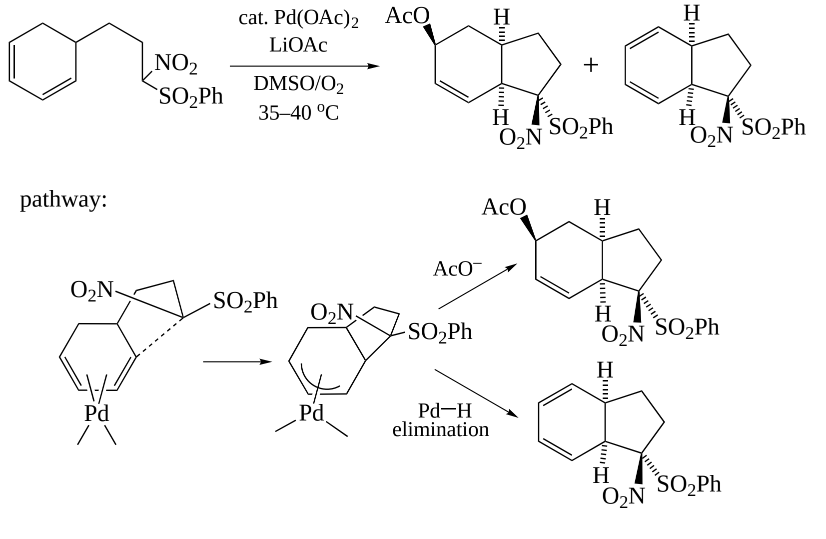


(79)

An interesting example of Pd-catalyzed oxidation of a 1,3-conjugated diene is shown in Scheme 20. This reaction type produces stero-defined 1,4-functionalized dienes, which are useful synthetic building blocks and reaction intermediates. Benzoquinone oxidation of an η^3-allyl–Pd intermediate is a key step in releasing the organic product.[104]



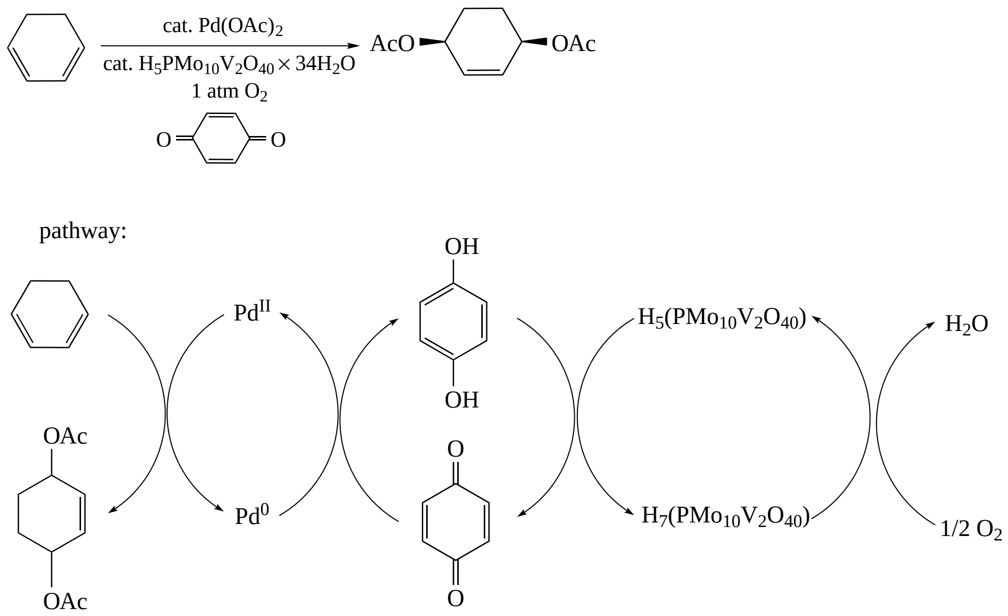
Scheme 20 Pd(II) catalyzed intramolecular 1,4-oxidation of 1,3-conjugated diene



Scheme 21

An example of cis-addition of two nucleophiles to a 1,3-diene catalyzed by Pd(II) is shown in Scheme 21.[105] Pd–H elimination is competitive with addition of the second nucleophile affording either mono or di-unsaturated bicyclic products.

With a limited amount of chloride anion (0.2 mol. equiv.; twice the amount of Pd^{II}), the coordination of acetate is inhibited, and the key intermediate is presumably an allyl–Pd^{II} with chloride attached to the Pd (Scheme 22).[106] Then *syn* addition of an acetate is unlikely,

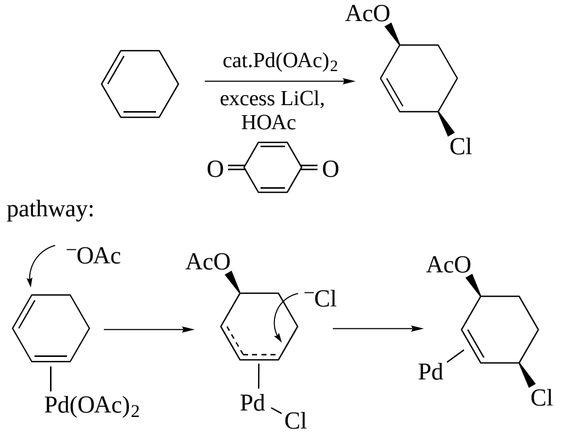


Scheme 22 Pd(II) catalyzed 1,4-diacetoxylation of 1,3-dienes

and the product results from anti (external) addition of acetate.

With excess chloride anion, not only is the syn acetate addition mechanism blocked, but the chloride competes effectively with external acetate as the primary nucleophile in anti addition (Scheme 23).[107]

The versatility of the 1,4-disubstituted cyclohexene derivatives as synthesis intermediates, with emphasis on stereo control, was demonstrated by substitution procedures. Direct S_N2 with malonate anion proceeds selectively for Cl with inversion, and Pd^0-catalyzed substitution also proceeds selectively at Cl, but with retention. A second substitution, Pd^0-catalyzed, using dimethylamine in this case, leads to replacement of the acetate with retention (Scheme 24).[103]



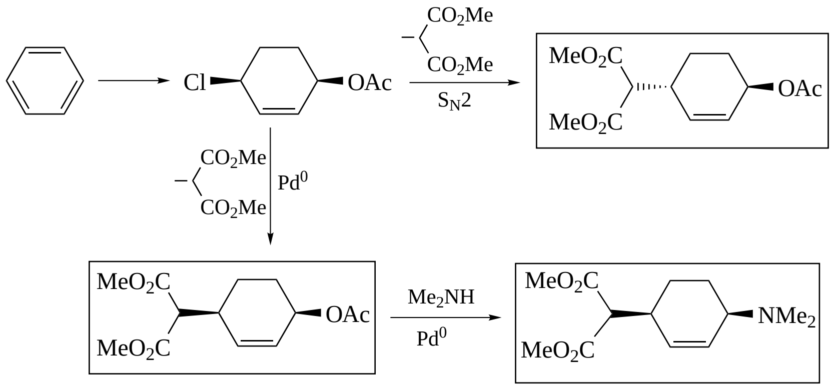
Scheme 23 Formation of *cis*-1-acetoxy-4-chlorocyclohex-2-ene

6.3 Nucleophilic Addition to 1,3-Diene–Fe(CO)$_3$ Complexes

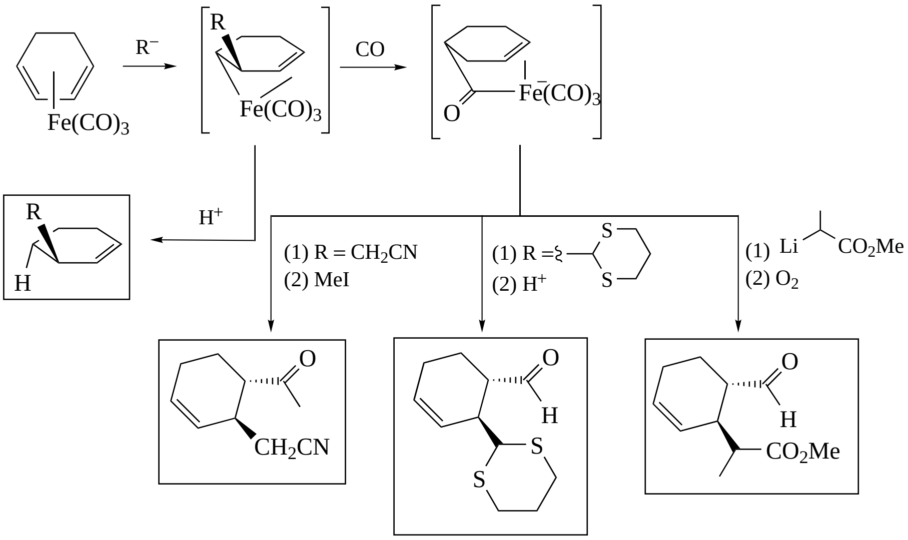
Iron tricarbonyl forms exceptionally stable complexes with 1,3-dienes. The complexes are uncharged, readily soluble species, chromatographable and, for the simpler versions, distillable. They are formed by direct reaction of the 1,3-diene with $Fe(CO)_5$, $Fe_2(CO)_9$, or $Fe_3(CO)_{12}$. These iron–diene complexes are known to be reactive toward electrophiles, undergoing the analogous reaction to electrophilic aromatic substitution under Friedel–Crafts conditions. However, it is clear that the metal–ligand unit increases the polarizibility of the diene unit, and, with a sufficiently reactive nucleophile, can provide a sink for electron density. How reactive does the nucleophile need to be? The other important selectivity question for 1,3-dienes concerns the regioselectivity.

It was determined that carbon nucleophiles derived from carbon acids with $pK_a > 22$ or so are sufficiently reactive to combine with the diene ligand rapidly at $-78\,°C$ to produce an anionic intermediate (Scheme 25).[108–110] With a few exceptions, the regioselectivity favors formation of the homoallyl anionic complex from addition at C-2, by kinetic control. This intermediate can be quenched with protons to give the terminal alkene, or can react with excess CO to produce an acyl iron intermediate. Following the recipes of Collman's reaction, the acyl iron intermediate can lead to methyl ketones, aldehydes, or carboxylic acids. The processes are illustrated with the 1,3-cyclohexadiene complex (Scheme 25).[111]

The carbon nucleophiles which will add to 1,3-diene-$Fe(CO)_3$ complexes include $LiCH_2$–X (where X = CO_2Me, CN, SPh) as well as the cyanohydrin acetal carbanions and



Scheme 24 Substitution procedures to elaborate the 1,4-disubstituted-2-cyclohexenes

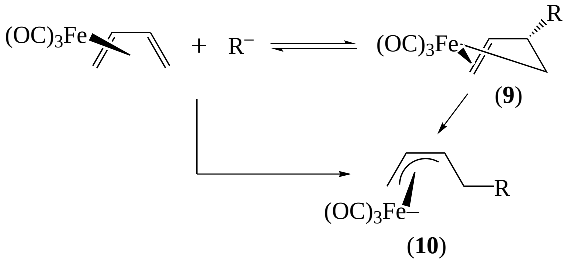


Scheme 25 Pattern of reactions of 1,3-cyclohexadiene–$Fe(CO)_3$

2-lithio-1,3-dithiane. Simple ketone enolate anions are of borderline reactivity; with activation, such as the use of a potassium counterion and a crown ether additive, 50% yields or better are observed. With more reactive anions, such as PhLi, alkyl–Li, and alkyl–MgX, addition is preferred at a CO ligand.

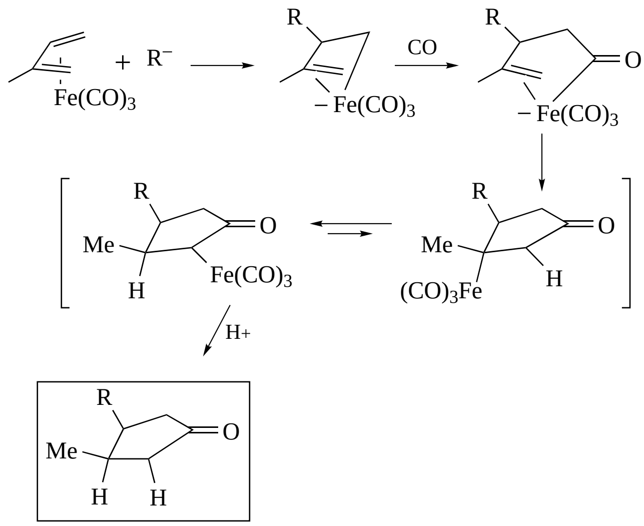
Addition of carbon nucleophiles to an internal carbon atom of a diene ligand, even with highly reactive nucleophiles such as diphenylmethyllithium, is reversible at higher temperatures, around 0 °C.[112] Equilibration allows slower but more favorable addition at a terminal position, to give (irreversibly) the allyl–$Fe(CO)_3$ anionic complex. The process is illustrated in Scheme 26. Intermediate (**9**) can be trapped with electrophiles at – 78 °C and undergoes transformation to the thermodynamically stable η^3-allyl structure, (**10**), at elevated temperatures.

The example shown in Scheme 25 of 1,3-cyclohexadiene undergoing nucleophile addition and then CO insertion and



Scheme 26 Reversible addition at an internal carbon of (1,3-diene)$Fe(CO)_3$ complexes

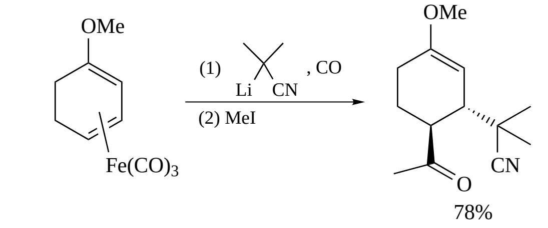
trapping is not, in fact, the general case. With most open-chain 1,3-dienes, the intermediate acyl–Fe anionic complex undergoes CO insertion and then intramolecular rearrangement by alkene insertion (Scheme 27).[113] The resulting cyclopentanone undergoes a set of β-H eliminations/readditions to



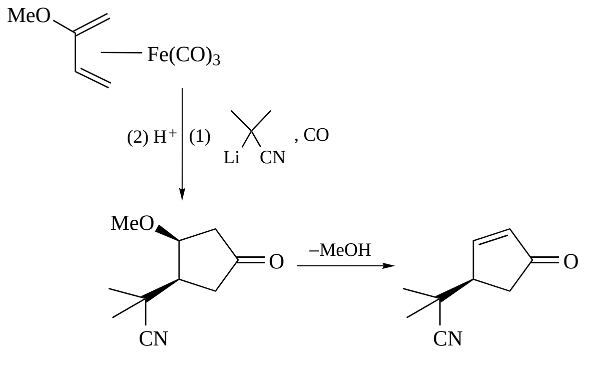
Scheme 27 Mechanism of cyclopentanone formation

give a stable iron enolate. This species is resistant to further CO insertion and is simply protonated during the isolation procedure to produce a cyclopentanone. The overall anti stereoselectivity is revealed with isoprene as the substrate, giving a 3,4-*cis* disubstituted cyclopentanone.

There is no exception to the regioselectivity rule that nucleophile addition proceeds by kinetic control at the unsubstituted internal position of the diene ligand. With 1-methoxy-1,3-cyclohexadiene, the addition/CO insertion/MeI quenching leads to a latent 1,4-dicarbonyl derivative (equation 80). With 2-methoxy-1,3-butadiene, the same conditions (but with protons instead of MeI) lead to a 3-methoxycyclopentanone that is very sensitive to acid, and can be readily converted to the corresponding cyclopentenone (equation 81).



(80)



(81)

The selectivity demonstrated by these examples is potentially very attractive in synthesis problems; the stoichiometric use of iron carbonyl should not be a serious limitation. The reactivity of the nucleophile is required to be quite high, and perhaps this lends a significant limitation.

6.4 Nucleophilic Addition to Cationic 1,3-Dienyl–Mo(CO)$_2$Cp Complexes

Cationic complexes of Mo^{II} have an intrinsically higher reactivity compared to the Fe^0 analogs. For example, the complex of 1,3-cycloheptadiene reacts with nucleophiles ranging from simple enamines to organomagnesium reagents.[114] The stereoselectivity verifies the expected anti addition. The product is an allyl–Mo^{II} complex, which can be converted back into a 1,3-diene cationic complex by abstraction of an anti-hydride using, for example, trityl cation. A second addition leads to overall 1,4-substitution with complete control over the two new stereocenters (cis). However, detachment of the ligand from the Mo requires further reaction, such as oxidative decomplexation.

Related chemistry of a cationic η^4-α-pyran Mo(II) complex is shown in Scheme 28. Hydride addition to the cationic reactant complex gives a neutral allyl–Mo that is oxidized by pyridinum dichromate (PDC) to a cation. Nucleophilic addition of water and oxidative decomplexation of the Mo fragment gives an enone. Substituted α-pyran ligands follow one of two paths depending on the electronic and steric effects of the substituent, as shown.

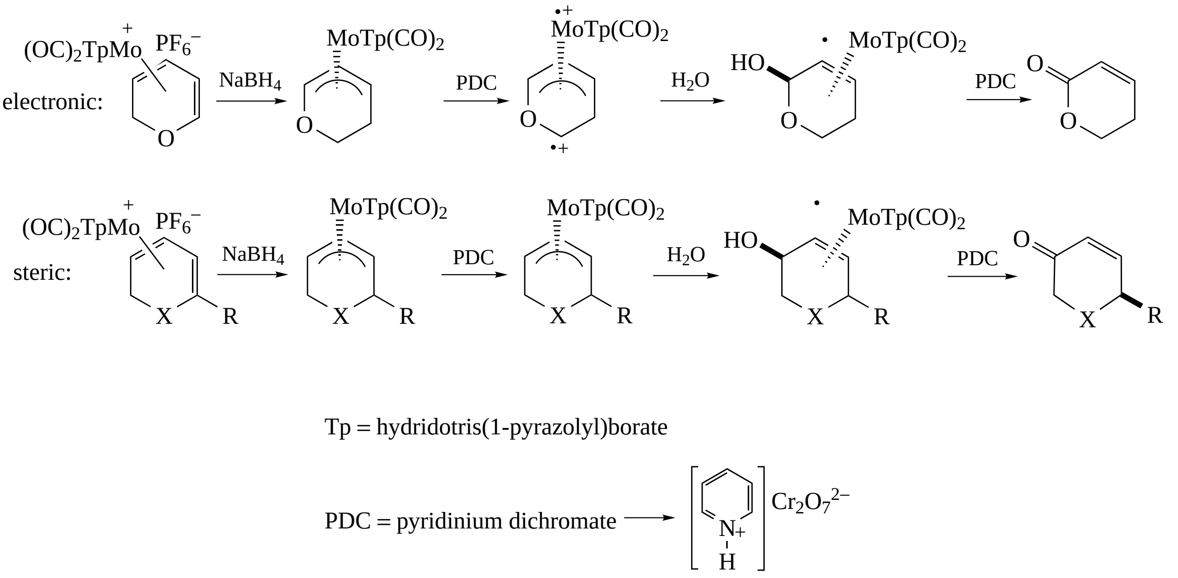
6.5 Summary

The addition of oxygen and chloride nucleophiles to dienes transiently activated by catalytic Pd^{II} is a practical process for production of 1,4-disubstituted 2-alkenes from 1,3-dienes; however, it is not useful with carbon nucleophiles. Examples of carbon nucleophile addition to Fe^0 and Mo^{II} complexes show useful selectivity, but only in stoichiometric processes, and few applications have appeared.

7 NUCLEOPHILE ADDITION TO η^5-CYCLOHEXADIENYL LIGANDS

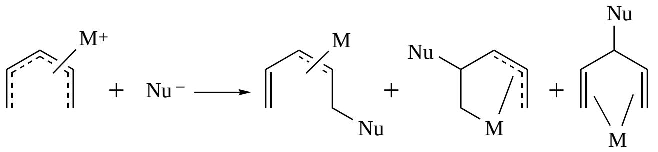
7.1 Introduction

As the complexity of the ligand increases and as additional carbon atoms are included, the restrictions on starting material availability and potential applications increase rapidly. The

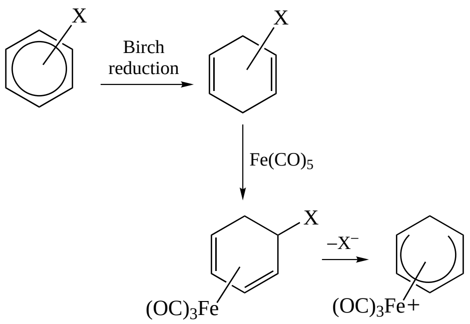


Scheme 28

selectivity questions also increase, as suggested by the general process (equation 82). There are relatively few different types of η^5-pentadienyl ligands.



(82)



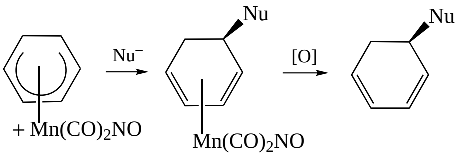
(83)

7.2 Cyclohexadienyl–M(CO)$_3$ Cation Complexes[115–119]

7.2.1 Basic Process

One type of η^5-pentadienyl ligand is easily available, and many substituted variations are simple to arrange. This is the η^5-cyclohexadienyl-Fe(CO)$_3$ set of cationic complexes, which are obtained from Birch reduction products of arenes in a thermal reaction, followed by loss of a substituent with a pair of electrons. Equation (83) oversimplifies the process for the preparation of η^5-cyclohexadienyl-Fe(CO)$_3$ cation, typically, the leaving group is a hydride, pulled off with agents such as trityl cation. In special cases, the leaving group is a heteroatom such as methoxy; key questions include how to position the X group in the proper position (adjacent to the 1,3-diene system) to leave smoothly. Similar synthetic strategies have been employed to prepare the corresponding η^5-cyclohexadienyl cation complexes of the following metals, Cr,[120–123] Mo,[120] W,[120] and Mn.[120,124]

The cationic complex is highly electrophilic, reacting even with simple electron-rich arenes as nucleophiles. The range of successful nucleophiles extends across the complete range of nucleophile reactivity, up to n-BuLi, under the proper reaction conditions (see below). The addition is from the anti direction, without exception, and at a terminal position. The product 1,3-diene–metal complex is very stable, and the ligand can be obtained only by deliberate oxidation; trimethylamine N-oxide is a gentle oxidants, but I$_2$ is often used. The stability of the reactants and products, together with the oxidative detachment methods means that the process is not a reasonable candidate for catalysis (equation 84).[124] At the same time, the metal system is convenient, inexpensive, and has minimal toxicity problems, so that a large-scale batch process is not unreasonable.



(84)

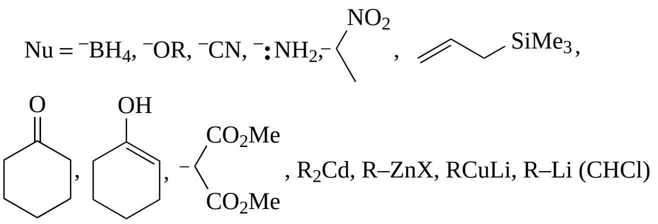
7.2.2 Range of Effective Nucleophiles

In the initial development of the methodology, using standard conditions in tetrahydrofuran (THF), for example, a wide range of carbon and heteroatom nucleophiles was successful (Scheme 29).[119]

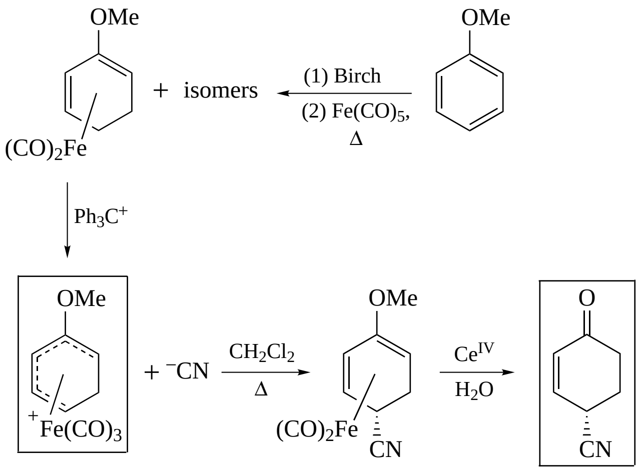
A special case is the use of dichloromethane with organolithium reagents. This solvent is not the obvious choice for RLi reactions, but it has a strong effect in minimizing electron-transfer side reactions and/or promoting the simple nucleophile addition. Similarly, the reaction of the cyclohexadienyl cationic complexes with Grignard reagents leads to homocoupling of the cyclohexadienyl ligand (Scheme 30). There is obviously a delicate balance between the pathway for two-electron transfer, with bond formation of the nucleophile with the cyclohexadienyl ligand, and one-electron transfer to give the 19-electron cyclohexadienyl–$Fe(CO)_3$ complex, which then dimerizes. Replacing a CO ligand with the more electron-donating phosphine ligand should clearly slow both processes, but it turns out that the one-electron transfer reduction is more strongly inhibited and good yields of coupling with Grignard reagents is the general rule for the monophosphine complexes.

7.2.3 Regioselectivity

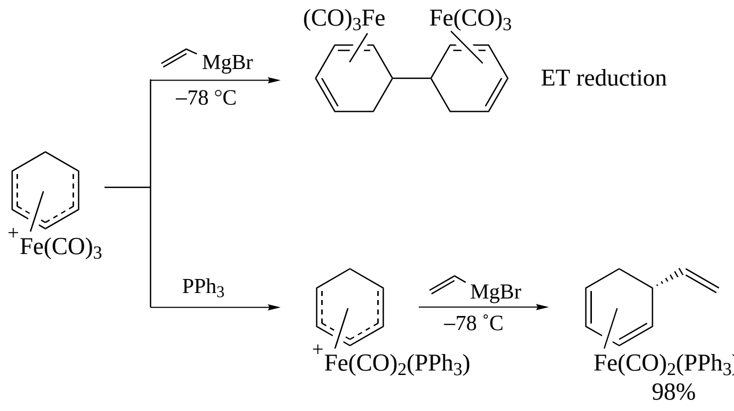
There are three nonequivalent positions on the simplest η^5-pentadienyl ligand. In the parent case (η^5-cyclohexadienyl) and in every other case that has been studied, the addition is at a terminal position to give a 1,3-diene–$Fe(CO)_3$ complex. Questions immediately arise regarding the effect of substituents on the reactivity of the cyclohexadienyl ligand: how does an original arene substituent influence the regioselectivity in the nucleophile addition? From examples with strong perturbations, such as alkoxy and carbomethoxy substituents, rules for regioselectivity have been formulated: addition is at the terminal position away from the more electron-donating substituent (such as methoxy). This is true even when the predicted position is already substituted with an alkyl group. The 2-methoxycyclohexadienyl complex is readily available, since it is the preferred isomer from hydride abstraction from the complex of the Birch reduction product of anisole (Scheme 31). In this example, cyanide anion adds under mild conditions, and the iron is decomplexed oxidatively while the enol ether spontaneously hydrolyzes to the ketone. The overall transformation is equivalent to nucleophilic aromatic substitution with the



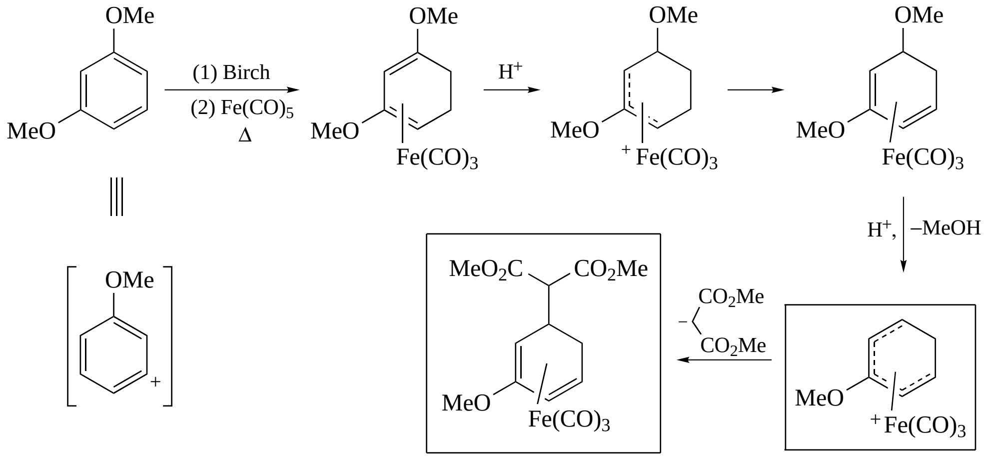
Scheme 29 Range of nucleophiles that add successfully



Scheme 31 Application of anisole



Scheme 30 Electron transfer versus nucleophile addition

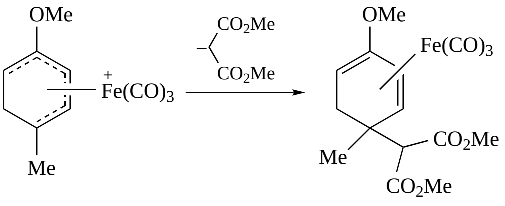


Scheme 32 Generation of the 3-methoxycyclohexadienyl complex

methoxy group serving as a para-directing group. This same regioselectivity can be seen in the application of anisole using the corresponding η^5-cyclohexadienyl $Cr(CO)_3$ complex.[121–123]

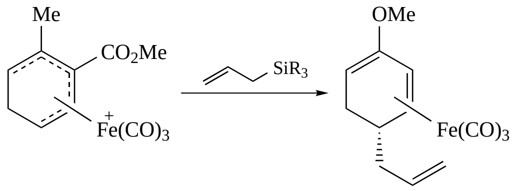
At the same time, the 3-methoxycyclohexadienyl complex (Scheme 32) can also be prepared, presumably under kinetic conditions that do not allow isomerization of the double bonds. The key technique is acid-induced elimination of an alkoxy group, and the starting material is *m*-dimethoxybenzene. The addition of the malonate anion is at one of the two equivalent terminal positions, and from a direction anti to the iron. The product is a stable complex that may be purified by chromatography or may be decomposed oxidatively to free the organic ligand.

The strong directing effect of a 2-methoxy group is evident in the nucleophilic addition to the 2-methoxy-5-methylcyclohexadienyl ligand. Addition is strongly selective for the position pseudopara to the methoxy group, even in the presence of the steric hindrance provided by the Me group (equation 85). As the steric hindrance grows, addition can shift to the other terminal position.



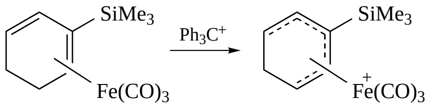
(85)

The more stable position for a electron-withdrawing group, such as carbomethoxy, is at C-3 of the starting cyclohexadienyl complexes, and terminal addition is again observed. Even the weak nucleophile, allylsilane, reacts at room temperature at the less-hindered terminal position (equation 86).



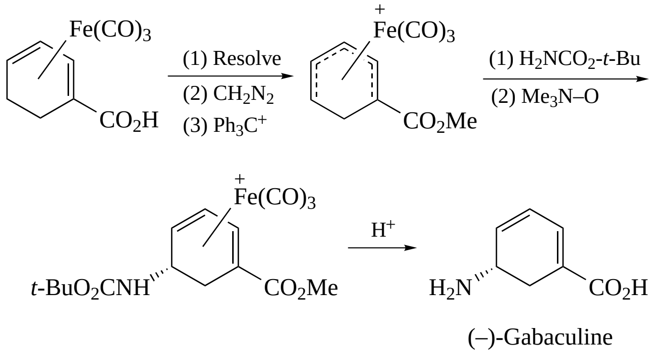
(86)

Silicon acts as an electron acceptor and stabilizes the 3-silylcyclohexadienyl ligand during hydride abstraction (equation 87).



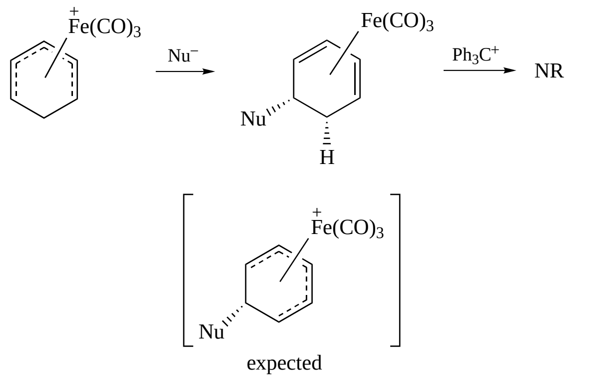
(87)

A particularly attractive starting material is the homochiral carboxylic acid derivative, obtained by conventional resolution. Esterification and then simple amine addition and oxidative decomplexation produces a precursor of (−)-gabaculine (Scheme 33).



Scheme 33 Homochiral complexes

There is an opportunity for multiple substitution, via regeneration of the cyclohexadienyl cationic complex, after the initial nucleophile addition. Unfortunately, the required *exo* hydride abstraction is severely retarded by the exo substituent (nucleophile unit) (equation 88).



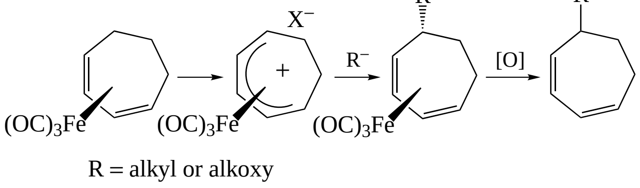
(88)

7.3 Cycloheptatrienyl–Fe(CO)$_3$ Cationic Complexes[125–127]

Cycloheptadiene complexes are useful synthetic building blocks in the preparation of complex organic and natural products. A variety of substituted cycloheptadiene complexes can be prepared via catalytic hydrogenation of the respective cycloheptatriene–Fe(CO)$_3$ complex. Subsequent oxidation liberates the iron carbonyl moiety affording the uncomplexed substituted cycloheptadiene complex (Scheme 34).

7.4 Summary

A number of substituted cyclohexadienyl–Fe(CO)$_3$ cationic complexes are readily available and will add nucleophiles with a wide range of reactivity. The addition can be highly regioselective and always stereospecific (exo addition). This methodology leads to useful and complex intermediates, but is limited by the need for stoichiometric application of the metal and deliberate synthesis of the starting iron complexes.



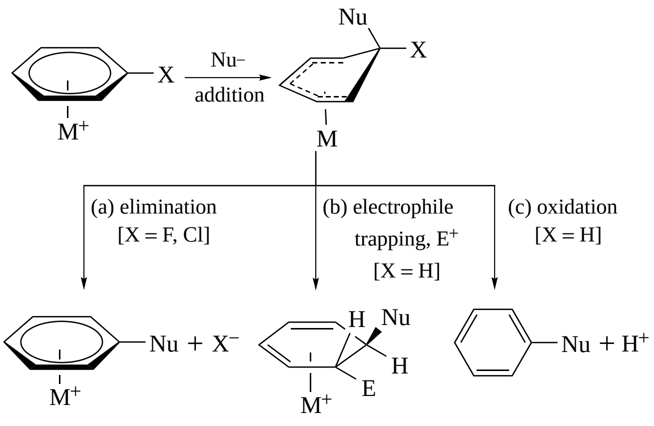
Scheme 34 Synthesis of substituted cycloheptadiene complexes

8 NUCLEOPHILIC ADDITION TO ARENE–METAL COMPLEXES

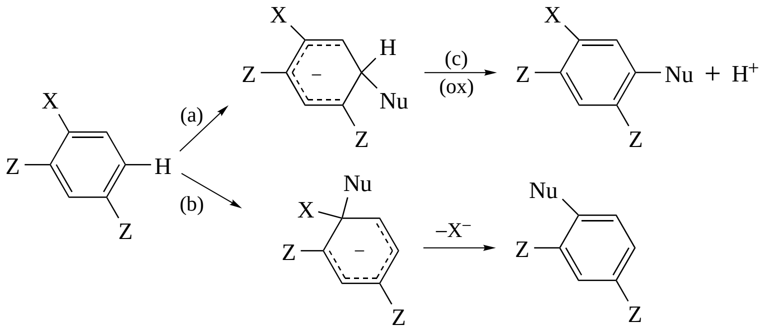
8.1 Introduction

The coordination of the metal to the π-orbital system of an arene ring makes the system much more polarizable and can generate a large permanent dipole moment, with the ring being electron poor. The arene ring can then be reactive toward nucleophiles, and provide ‘umpolung’ of the usual reactivity of arenes.[128] Most of the transition metals have been observed to form such π-complexes,[129] and the reactivity depends on the formal charge, oxidation state, and the spectator ligands. The initial addition produces a cyclohexadienyl complex, and three processes have been worked out from this intermediate (Scheme 35).[130] First, if there can be an electronegative atom at the ipso position, elimination of that atom can occur, usually slowly, to give a substituted arene. Alternatively, an electrophile can add to the electron-rich dienyl intermediate and produce a disubstituted 1,3-cyclohexadiene. Finally, and uniquely, oxidation leads to removal of an ipso hydrogen and detachment of the metal.

The reactions are related mechanistically to traditional nucleophilic aromatic substitutions (S$_N$Ar),[131] but offer several unique features. With suitable electron-withdrawing substituents attached to the arene via σ-bonds, nucleophiles may add to produce the corresponding anionic intermediate, a cyclohexadienyl anion, stabilized by interaction with the substituents (Scheme 36). Attack is kinetically favored at a position bearing a hydrogen (path a), but the intermediate thus formed cannot proceed directly to substitution (by loss of a hydride ion). In the general version of the S$_N$Ar reaction, an electronegative atom (usually halide) is attached to the arene ortho or para to an activating group, and the addition of the nucleophile is reversible. A slower addition occurs at the carbon bearing the electronegative atom, to produce an anionic intermediate that can lose the electronegative atom in an irreversible step and give the product from nucleophilic



Scheme 35 General reactions of arene metal complexes after initial nucleophilic addition

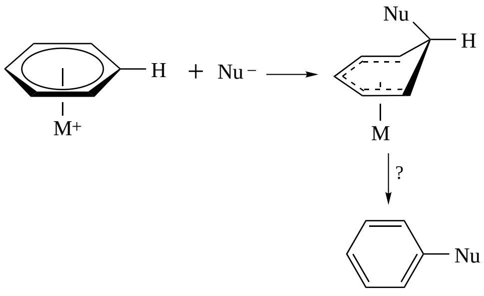


Z = electron-withdrawing group
X = electronnegative atom (group)

Scheme 36 Comparison with traditional nucleophilic aromatic substitution

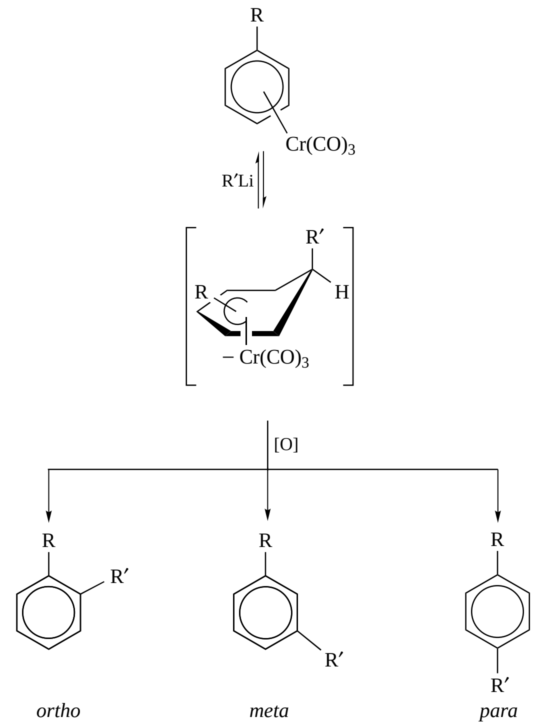
substitution for halide (path b). In a few cases, loss of hydrogen from the cyclohexadienyl anionic intermediates has been induced by oxidation, which presumably allows departure of a proton, as shown in step c.[12] The overall addition/oxidation pathway of nucleophilic aromatic substitution for hydrogen is too limited to be considered synthesis methodology.

The first arene–transition metal complexes were prepared in the 1950s,[129,132] and it was immediately recognized that the added polarizibility or electron deficiency would promote addition of nucleophiles to the arene ligand. A number of cyclohexadienyl complexes were characterized following nucleophilic addition, but the question of inducing the ipso hydrogen to depart was not answered (equation 89).



(89)

The isolation of the first halobenzene complex, (η^6-chlorobenzene)tricarbonyl Cr^0, allowed a test for a direct analog of classical S_NAr reactivity.[133] The activating effect of the $Cr(CO)_3$ unit was found to be comparable to a single *p*-nitro substituent in reaction with methoxide in methanol, and the substituted arene ligand was detached with mild oxidation. The regiochemistry of nucleophilic addition to substituted arenas can be controlled by electronic factors, as shown in equation (90).[134] Resonance donor R groups attack at the meta position, while bulky R groups and resonance acceptor R groups attack at the para position. R groups that can coordinate to the incoming organolithium reagent direct attack to an ortho position.



(90)

Three types of arene π-complexes have seen significant development in synthesis methodology: neutral η^6-arene–$Cr(CO)_3$,[135–138] the isoelectronic cationic η^6-arene–$Mn(CO)_3$,[139] and the cationic (η^6-arene)(η^5-cyclopentadienyl)iron(II) complexes (Figure 3).[140,141] The arene–$Cr(CO)_3$ species are formed by simple displacement of neutral ligands (L) from $Cr(CO)_3L_3$ by the arene, and a large number of variously substituted arene–$Cr(CO)_3$ complexes

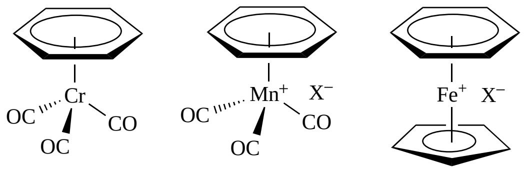


Figure 3 Examples of electrophilic arene–metal complexes

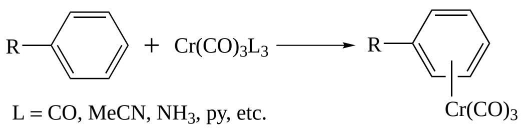
are available.[129] Gentle and general syntheses of the cationic complexes are only recently available, and the development of these complexes as synthesis intermediates is far less advanced.

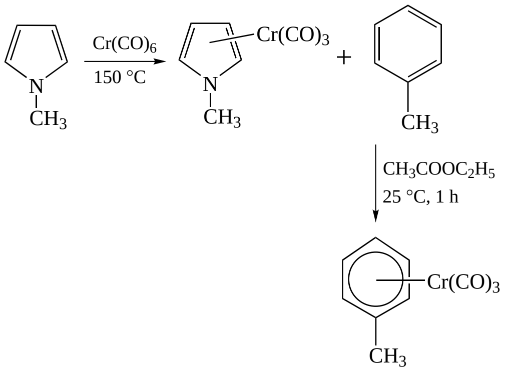
8.2 Preparation of Arene–$Cr(CO)_3$ Complexes

The general process begins with $Cr(CO)_3L_3$, in which the L unit can be CO (most common),[142] MeCN,[143] *o*-alkylpyridine,[144] ammonia,[145] and other donor ligands (equation 91). The rate (reaction temperature) is related to the nature of L; the most reactive readily available source of $Cr(CO)_3$ is (η^6-naphthalene)$Cr(CO)_3$, which undergoes favorable arene exchange under mild conditions with many substituted arenes.[146] The most general and convenient procedure employs a mixture of THF and di-*n*-butyl ether at reflux.[147] A variety of polar and nonpolar aprotic solvents has been used; and, for some purposes such as complexation of α-amino acids with aromatic side chains, water–THF mixtures are effective.[142]



(91)

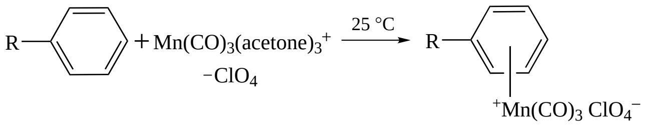
After complexation, the yellow to red arene–$Cr(CO)_3$ complex can be purified by crystallization from nonpolar organic solvents or chromatographed on silica gel. Most common synthesis operations, such as acid and base hydrolysis, hydride reduction, and carbanion addition to ketones, can be carried out on side-chain functional groups without disturbing the arene–Cr bond.[128,148] However, even very mild oxidation conditions will detach the arene by oxidizing the metal. An important aspect of the complexation procedure is diastereoselectivity. Complexes of disubstituted (and more highly substituted) arenes can have molecular asymmetry; a stereogenic center in a side chain leads to diastereoisomers. Under favorable conditions, especially with low-temperature conditions for complexation, significant diastereoselectivity is observed in the complexation step. Arene–$Cr(CO)_3$ complexes can also be formed under very mild thermal conditions by the ligand displacement reaction shown in equation (92).[149]



(92)

8.3 Preparation of Arene–$Mn(CO)_3$ Complexes

A gentle procedure has made these complexes available with a variety of substituted arenes.[150] Direct displacement of CO from the perchlorate salts of $^+Mn(CO)_5$ or $^+Mn(CO)_3(acetone)_3$ with the arene in dichloromethane at reflux leads to precipitation of the arene–$Mn(CO)_3$ salt. The conditions are milder than the $AlCl_3$-promoted procedure employed earlier.[151] Only a handful of substituted arenes have been attached to $Mn(CO)_3{}^+$, but the general synthesis method suggests few limitations (equation 93).

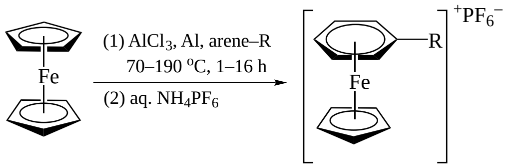


(93)

The complexes are air stable; indeed, a limitation is the need for powerful oxidizing agents, such as Jones reagent [Cr^{IV}], to detach the arene ligand.[152] They are highly reactive toward nucleophiles, which limits the number of compatible synthesis manipulations that can be carried out in the presence of the arene–$Mn(CO)_3$ unit, but broadens the scope of effective nucleophiles.

8.4 Preparation of Arene–$FeCp^+$ Complexes

One of the few useful reactions of ferrocene is the $AlCl_3$-catalyzed exchange of one Cp group for an arene ligand (equation 94).[153] The requirement for $AlCl_3$ adds some obvious limitations, but a modest number of substituted arenes have been successfully coordinated to the $FeCp^+$ unit. The charged complexes are not purified by conventional organic techniques such as chromatography, but recrystallization is possible. The complexes are very air and heat stable; again, methods of removal of the arene from the Fe are few. The simplest is pyrolysis at $>200\,°C$.[154]



(94)

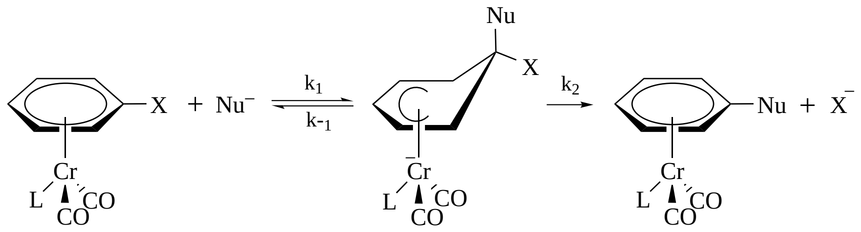
8.5 Nucleophilic Substitution for Heteroatoms on Arene Ligands: S_NAr Reaction

8.5.1 The Basic Process

The smooth replacement of a heteroatom (usually halide) from arene ligands requires reversible addition of the nucleophile, since the kinetic site of addition



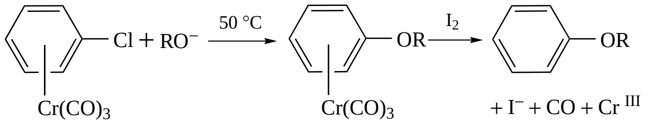
Scheme 37 Pathway for substitution of halides

is usually at a position bearing a hydrogen substituent (path k_1) (Scheme 37).[155] The relative rates of each step depend critically on the nature of M and of the nucleophile. More reactive nucleophiles and more reactive complexes disfavor equilibration ($k_1 \gg k_{-1}$), and the process can stop with formation of the first cyclohexadienyl intermediate. Equilibration leads through to the substitution product. The overall order of reactivity for electron-deficient arenes is (arene)$(CO)_3Mn^+$ > 2,4-$(NO_2)_2C_6H_3Cl$ > (arene)$CpFe^+$ $\gg$ 4-$(NO_2)_2C_6H_4Cl$ > (arene)$(CO)_3Cr$.[128,155]

8.5.2 Halobenzene–$Cr(CO)_3$ Complexes

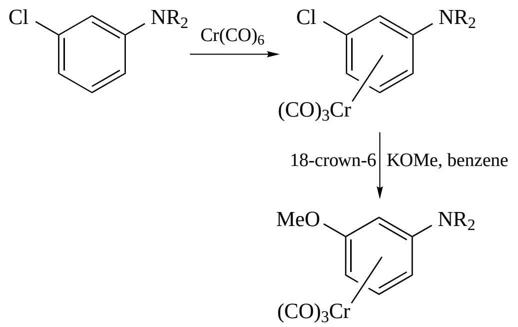
Intermolecular Nucleophilic Substitution with Heteroatom Nucleophiles. A patent issued in 1965 claims substitution for fluoride on fluorobenzene–$Cr(CO)_3$ in dimethyl sulfoxide (DMSO) by a long list of nucleophiles including alkoxides (from simple alcohols, cholesterol, ethylene glycol, pinacol, and dihydroxyacetone), carboxylates, amines, and carbanions (from triphenylmethane, indene, cyclohexanone, acetone, cyclopentadiene, phenylacetylene, acetic acid, and propiolic acid).[156] In the reaction of methoxide with halobenzene–$Cr(CO)_3$, the fluorobenzene complex is ca. 2000 times more reactive than the chlorobenzene complex.[155] The difference is taken as evidence for a rate-limiting attack on the arene ligand followed by fast loss of halide; the concentration of the cyclohexadienyl anion complex does not build up. In the reaction of fluorobenzene–$Cr(CO)_3$ with amine nucleophiles, the coordinated aniline product appears rapidly at 25 °C, and a careful mechanistic study suggests that the loss of halide is now rate limiting.[157]

Hydroxide, alkoxide, and phenoxide nucleophiles react with chlorobenzene–$Cr(CO)_3$ at 25–50 °C in polar aprotic media to give high yields of the phenol or aryl ether chromium complexes; oxidation with excess iodine at 25 °C for a few hours releases the free arene, CO, chromium(III), and iodide anion.[133,158] Only the arene remains in the organic layer after a conventional aqueous extraction (equation 95). An alternative general procedure for detaching the arene ligand from the $Cr(CO)_3$ unit is to expose a solution of the complex to air in the presence of normal room light or sunlight.

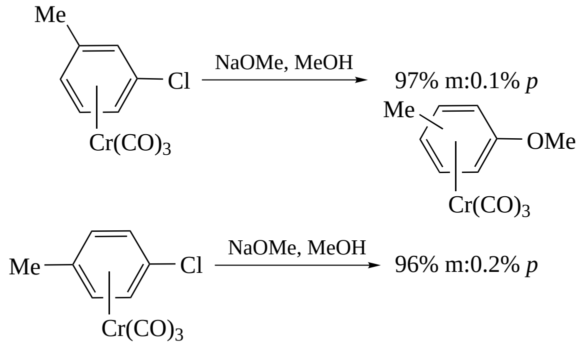


(95)

The reaction proceeds almost exclusively by direct substitution (ipso), as shown by reactions of isomeric chlorotoluene complexes (Scheme 38). While polar protic solvents, such as MeOH, strongly retard reaction,[159] phase transfer catalysis (*see Phase Transfer Catalyst*) using benzene[158] or addition of *Crown Ethers* to potassium alkoxides in benzene[160] allows reaction at 25 °C. Even with strong electron donors such as alkyl, methoxy, or dialkylamino in the ortho, meta, or para positions, substitution for chloride by potassium methoxide proceeds smoothly using the crown ether activation in benzene (equation 96).[160]



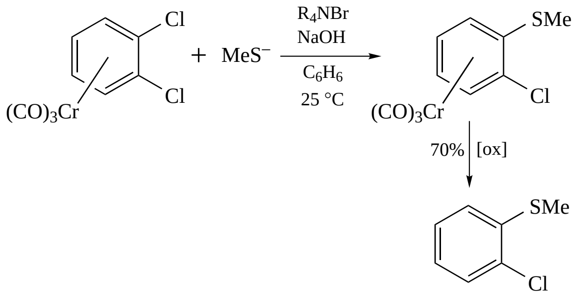
(96)



Scheme 38 Selective reactions of chlorotoluenes

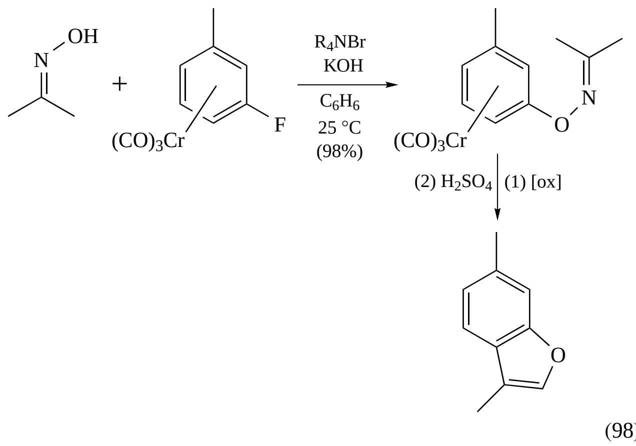
In general, replacement of fluoride occurs under milder conditions and in higher yield than chloride; however, compared to chloride, a fluoride substituent slows the complexation of arenes and often leads to lower yields in the formation of the starting arene–Cr complexes. An excellent procedure for formation of the parent fluorobenzene–$Cr(CO)_3$ complex has been reported.[161] The bromo- and iodoarene complexes are known, but generally are not effective in the S_NAr reaction.[162] Direct replacement of oxygen leaving groups, such as tosylate, is not effective, perhaps owing to steric retardation of the departure of the endo leaving group.

Thiolate anions[163] and oxime alkoxides[163] react under phase transfer conditions to give aryl thio ethers and *O*-aryl oximes, respectively; the *o*-dichlorobenzene complex can be converted selectively to the monosubstitution product (equation 97).



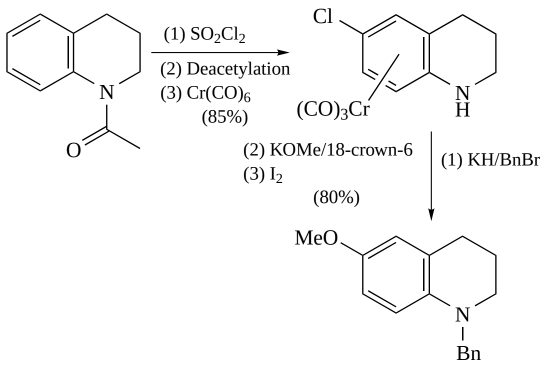
(97)

The arylation of oximes leads to a simple process for benzofuran formation. Simple primary and secondary amine nucleophiles react smoothly in the absence of added base, in a very general and efficient process for aniline derivatives (equation 98).[157]



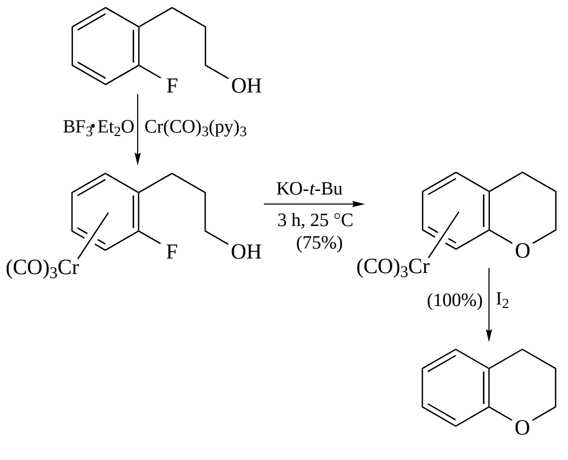
(98)

Chromium activation allows a strategy for aryl ether synthesis in four stages: (a) electrophilic chlorination, (b) chromium coordination, (c) alkoxide substitution for chloride, and (d) oxidative decomplexation.[159] The process is effective for the synthesis of 6-methoxytetrahydroquinoline and 5-methoxydihydroindole derivatives, for example. Chlorination of *N*-acetyltetrahydroquinoline with SO_2Cl_2 followed by deacetylation provides 6-chlorotetrahydroisoquinoline in 77% yield.[159] The complexed amine is moderately acidic and must be protected (in situ) as the benzyl ether before methoxide treatment (equation 99). The overall yield for protection, substitution, and oxidative decomplexation is 80%.



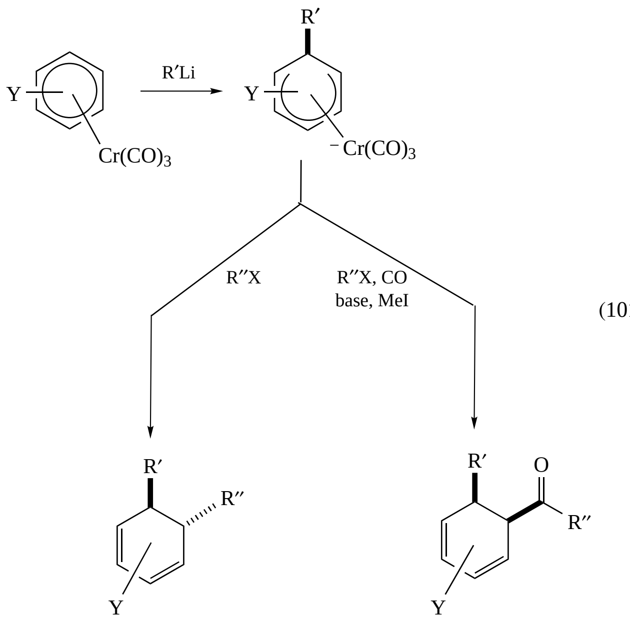
(99)

Intramolecular Heteroatom Substitution for Halide. Intramolecular substitution for chloride or fluoride is particularly effective. Oxygen heterocycles with fused benzo rings are obtained from $Cr(CO)_3$ complexes of fluorobenzene with an *o*-(hydroxyalkyl) side chain (equation 100). Efforts to produce the dihydrobenzofuran under the same conditions failed; only intermolecular substitution products were obtained.[164]



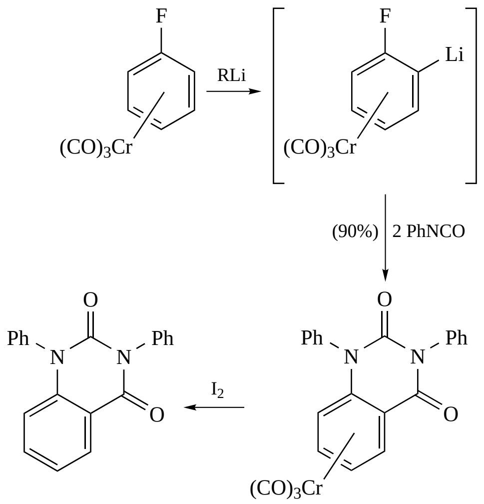
(100)

Coordination of arenes with $Cr(CO)_3$ also activates the ring hydrogens toward abstraction with strong base (metalation).[164,165] Simple arene ligands can be metalated with alkyllithium reagents; alkoxy, amino, and halo substituents on the arene direct the metalation to the ortho position with rates and regioselectivity higher than with the corresponding free arene (see equation 101).[134,161,166,167] This allows a strategy for annulating aromatic rings via ortho-lithiation, trapping with a bifunctional electrophile, and finally nucleophilic substitution for the electronegative substituent.



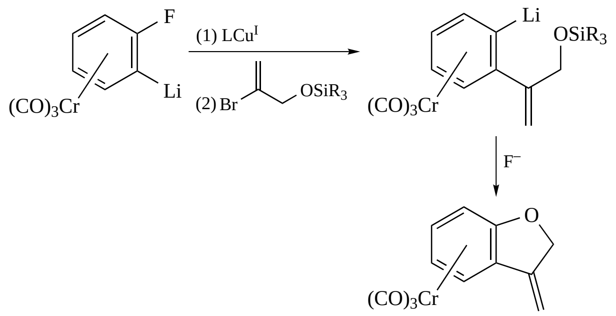
(101)

Although chlorobenzene–Cr(CO)$_3$ undergoes lithiation to give a moderately stable species that can be trapped with electrophiles to produce *ortho*-substituted chloroarene–Cr(CO)$_3$ complexes,[168] the fluoro analog appears to be more efficient, in the same way. The *ortho*-lithio haloarene complexes are highly basic, and the electrophilic trapping species is restricted to those with low kinetic acidity and high electrophilicity. Good results are obtained with isocyanates, ketenes, and acyl derivatives with α-protons of low acidity.[161,166] Examples include phenyl isocyanate, which reacts twice to give a six-membered heterocycle, while the dimethyl-N-carboxyanhydride proceeds directly to the five-membered ring after spontaneous decarboxylation (equation 102).



(102)

A variation involves an aryl cuprate coupled with a vinyl halide, leading eventually to the β-methylenedihydrobenzofuran complex (equation 103). Cyclization occurs spontaneously upon fluoride-induced removal of the silyl protecting group.[166] The complex is much more stable than the free ligand, and can be used to advantage as a synthesis equivalent of 3-methylenedihydrobenzofuran.



(103)

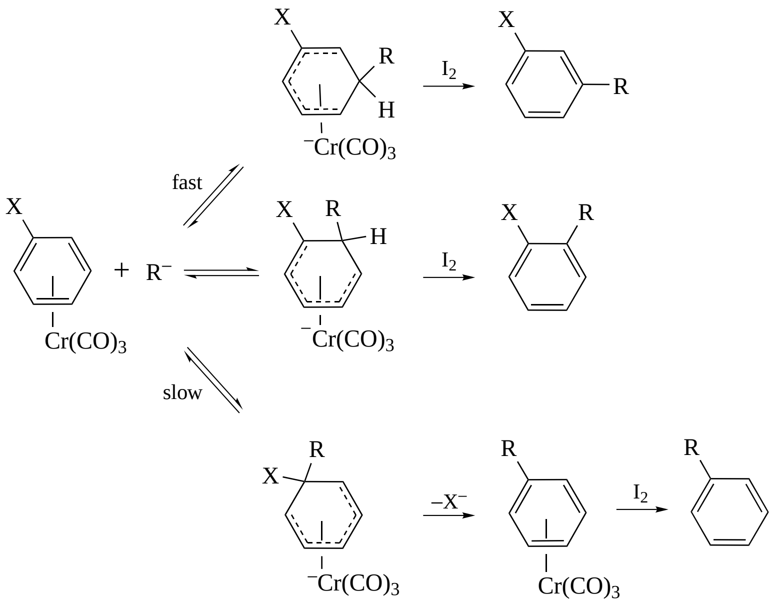
8.5.3 *Substitution with Carbon Nucleophiles*

While carbon nucleophiles were suggested to be efficient in substitution for fluoride in the 1966 patent,[156] the first examples in the primary literature appeared in 1974.[162,169] It is now clear that there are three reactivity classes of carbon nucleophiles (Scheme 39): (a) stabilized carbanions (from carbon acids with pK_a < ca. 18); (b) more reactive carbanions (pK_a > 20), which give complete conversion to cyclohexadienyl addition products prior to slow equilibration via reversible anion addition; and (c) more reactive carbanions (pK_a > 20), which give irreversible addition to the arene ligand.[170]

Diethyl sodiomalonate is an example of type (a). Reaction with fluorobenzene–Cr(CO)$_3$ proceeds to completion after 20 h at 50 °C in HMPA to give the diethyl phenylmalonate complex in over 95% yield. Monitoring the reaction by NMR gave no evidence for an intermediate (e.g. the cyclohexadienyl anion complex); interruption of the reaction by addition of iodine at less than 20 h gave significant amounts of unreacted fluorobenzene. A satisfactory picture is the simple one, that the anion adds reversibly and unfavorably ($k_1 < k_{-1}$), slowly finding itself at the ipso position, then irreversible loss of fluoride gives the substitution product.

Lithio isobutyronitrile is an example of anion type (b). The initial addition to chlorobenzene–Cr(CO)$_3$ is over within minutes at −78 °C, but the substitution product does not appear until the mixture is warmed to 25 °C. Quenching with iodine after a short reaction time leads to a mixture of phenylisobutyronitrile and *o*- and (*m*-chlorophenyl)isobutyronitrile. This appears to be a case of fast addition ortho and meta to the chloride to give cyclohexadienyl anionic complexes, followed by slow rearrangement to the ipso intermediate. Quenching with iodine before equilibration is complete leads to oxidation of the intermediates and formal substitution for hydrogen.

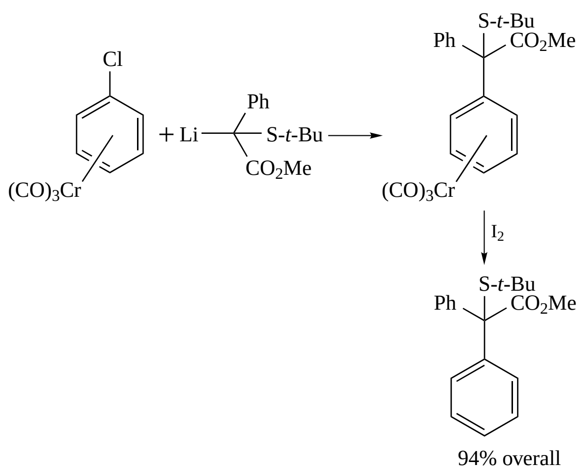
Carbon nucleophiles of type (c) add to the arene ligand and do not rearrange; examples include the very reactive anions such as 2-lithio-2-methyl-1,3-dithiane and less sterically encumbered anions such as lithioacetonitrile and *t*-butyl lithioacetate. In these cases, the anion adds to an unsubstituted position (mainly ortho or meta to Cl) and does not rearrange.



Scheme 39 Pathways for reaction of carbon nucleophiles with arene ligands

Then iodine quenching, even after a long period at 25 °C, gives almost exclusively the products from formal substitution for hydrogen.

Successful substitution for halogen by carbanions requires reversible addition and that sets upper limits on the reactivity of the anion, although steric effects can also favor equilibration (the more substituted equilibrate faster). As before, fluoride is a better leaving group than chloride. An example is shown in equation (104), leading to methyl 2-phenyl-2-(*t*-butylthio)propionate in 94% yield after 15 h at 25 °C. There is an important solvent effect on the rate of equilibration of the carbanions,[171] and the conditions chosen for these early experiments are not necessarily the best; there may be room to expand the scope of useful anions by careful choice of media (less polar solvents should favor equilibration).



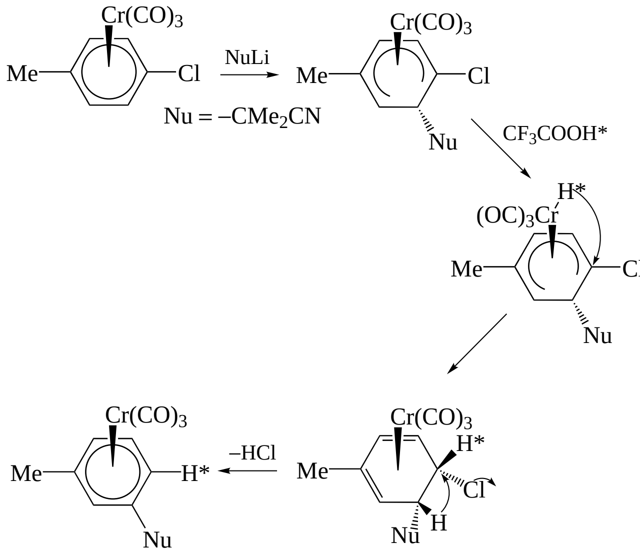
(104)

Except in the formation of minor side products, the replacement of halogen by hydride as nucleophile is not observed. Halide exchange is also not a general process with haloarene–Cr(CO)$_3$ species.

There is an alternative mechanism for halide replacement, following the sequence of nucleophile addition, protonation, and elimination of HX. In this pathway, the addition of the nucleophile need not be at the ipso position; it can be ortho to halide leading to '*cine*' substitution or it can be at the meta or para positions, leading to '*tele*' substitution.[172] The processes depend on the formation of the cyclohexadienyl anion intermediates in a favorable equilibrium (carbon nucleophiles from carbon acids with $pK_a > 22$ or so), protonation (which can occur at low temperature with even weak acids such as acetic acid), and hydrogen shifts in the proposed diene–chromium intermediates. Hydrogen shifts lead to an isomer that allows elimination of HX and regeneration of an arene–chromium complex, now with the carbanion unit indirectly substituted for X (Scheme 40).[173,174]

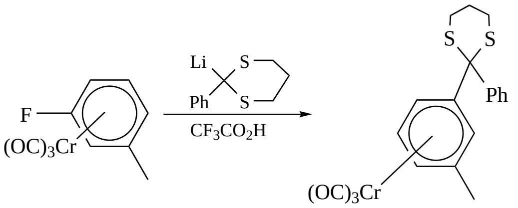
An important example of indirect substitution utilizes alkoxy leaving groups; the intermediate from the reaction of the diphenyl ether–Cr(CO)$_3$ complex and the 2-methyl-1,3-dithiane anion can be induced to eliminate phenol by protonation at low temperature; the result is tele substitution (Scheme 41).[174]

An impressive example is the reaction of 2,6-dimethyl-1-fluorobenzene–Cr(CO)$_3$ with 2-lithio-2-methyl-1,3-dithiane at −78 °C, followed by treatment with trifluoroacetic acid at −78 °C (equation 105).[174] Loss of HF leads to the 1,2,4 (tele)



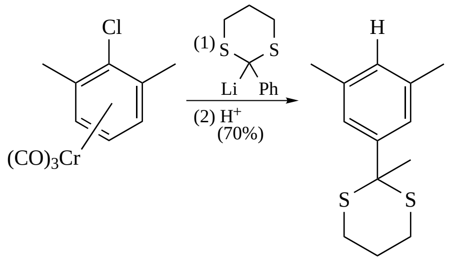
Scheme 40 Indirect cine nucleophilic aromatic substitution

substitution product, in 62% yield.



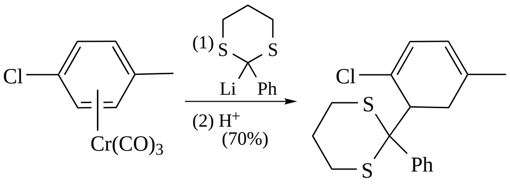
(105)

The directing effects of F (strong meta) versus Cl (weak, o/m; discussed below) allow control over the site of tele substitution; the chloro analog leads to the 1,3,5-substitution pattern (equation 106).[175]

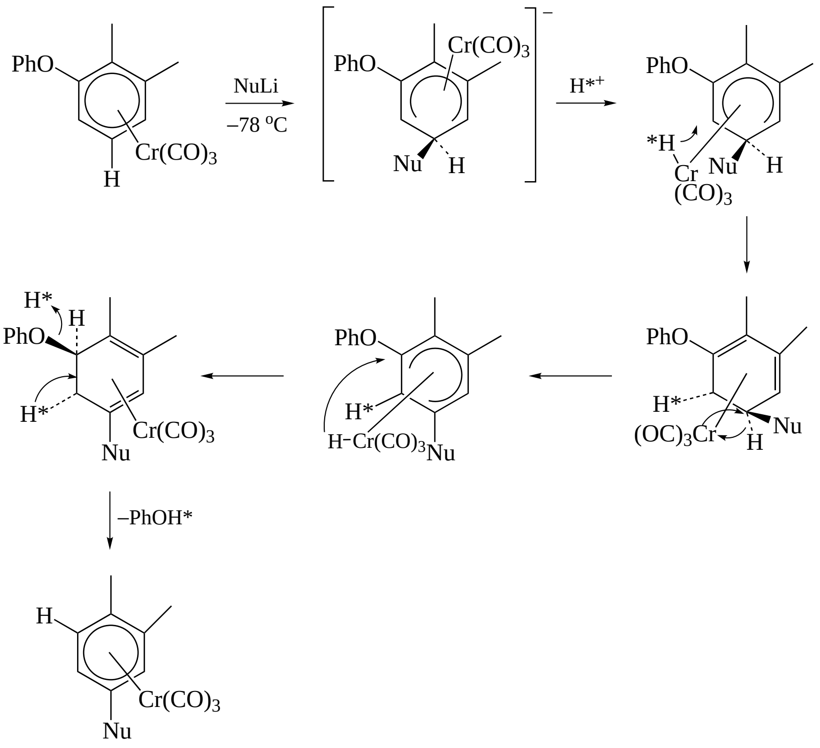


(106)

Under certain conditions, apparently when the $Cr(CO)_3$ unit is spontaneously displaced from the product by a weak donor ligand (solvent), the simple addition product (1,3-cyclohexadiene derivative) can be the major product (equation 107).[175]



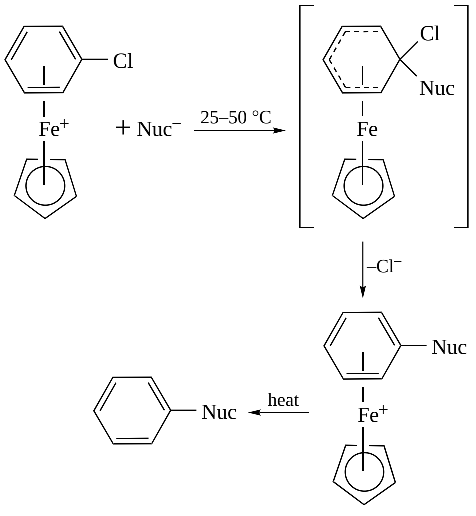
(107)



Scheme 41 Indirect *tele* nucleophilic aromatic substitution

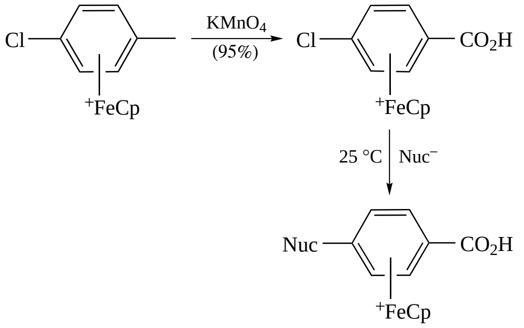
8.5.4 Halide Substitution using Activation with Other Metal–Ligand Systems

While the potential for other metal–ligand activation of arenes in nucleophile substitution for chloride has been demonstrated, the processes have not been fully developed nor applied. The two-stage process of addition/substitution for chloride and arene detachment is exemplified for the iron system in equation (108).



(108)

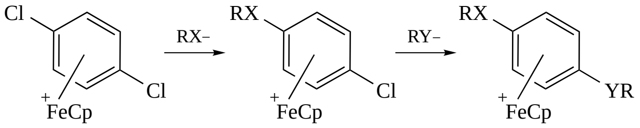
The first stage (addition/elimination) is well known with CN^- and a variety of N, O, and S nucleophiles.[140,176] The detachment of the product arene from the Fe is more difficult. The conversion in equation (109) demonstrates the stability of the arene–Fe bond toward oxidation, as a side-chain methyl is converted to a carboxylic acid, and suggests the generality of heteroatom substitution under mild conditions.[177]



(109)

Nuc = PhS (51%) and EtO (68%)

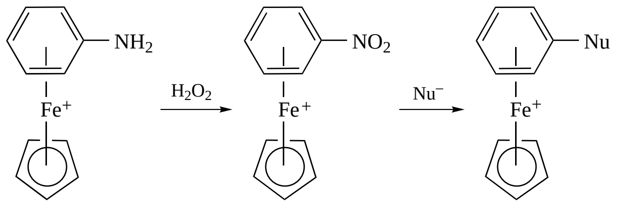
The analogous *p*-dichlorobenzene complex will react rapidly with phenoxide and alkoxide nucleophiles in the first substitution and more slowly in the second; monosubstitution can be readily achieved (equation 110).[178] Simple amines give only monosubstitution, even in the presence of excess amine.



(110)

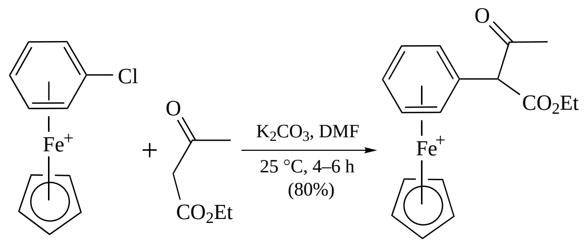
Substitution with amine nucleophiles in the series of chlorotoluene complexes showed that the substitution is direct; no cine or tele substitution was observed.[176] The analogous (fluoroarene)FeCp$^+$ complexes are known, but less well developed. Kinetics studies show that the fluoro derivatives are more reactive compared to the chloro analogs.

A special example is the replacement of a nitro group on η^6-nitrobenzene–FeCp$^+$.[178,179] Reaction with O, S, N, and stabilized C nucleophiles gives overall addition/elimination (equation 111). The nitroarene complexes are prepared by oxidation of the corresponding aniline complexes and are readily available.



(111)

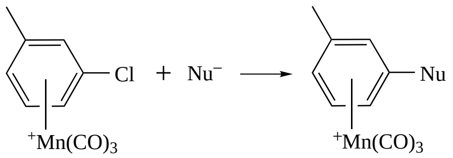
Stabilized carbon nucleophiles (e.g. from β-diketones, β-keto esters, malonate esters, etc.) can be arylated by substitution for chloride on the arene in arene–Fe–Cp cation complexes (equation 112).[179,180] A base is necessary, and two heterogeneous systems are favored: potassium carbonate in dimethyl formamide (DMF) or potassium fluoride prepared on Celite-545. As usual in the CpFe$^+$ system, detachment of the substituted arene requires somewhat extreme conditions, usually pyrolytic sublimation at 200 °C.[140]



(112)

The most reactive of the common arene–metal complexes has been the least developed with regard to nucleophilic substitution for halide. It is only an improved, gentler method of complexation that allowed isolation of the fluorobenzene complex with $Mn(CO)_3{}^+$.[150] The chlorobenzene analog is easily prepared and undergoes substitution with alkoxy,

phenoxy, thiolate, amine, and azide nucleophiles.[150,181] Reaction is complete with aniline (a weak nucleophile) within 3 min at room temperature. In examples with a methyl substituent on the arene as a label, the substitution is shown to be direct (equation 113). The detachment of the substituted arene ligand from the $Mn(CO)_3$ unit is still limited by the requirement for strong oxidizing conditions, a serious limitation if this series is to be put forward in synthesis methodology.



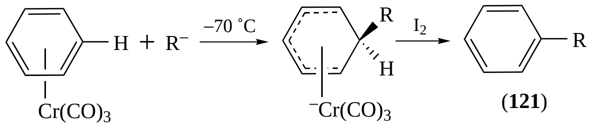
(113)

Nuc⁻ = alkoxy, phenoxy, thiolate, amine, and azide

8.6 Nucleophile Addition/Oxidation: Substitution for Hydrogen

8.6.1 Basic Process and Intermolecular Examples

Once it is recognized that cyclohexadienyl anionic complexes of chromium can be generated by addition of sufficiently reactive nucleophiles and that simple oxidizing techniques convert the anionic intermediates to free substituted arenes, a general substitution process becomes available, which does not depend on a specific leaving group on the arene (equation 114).[169] While no heteroatom nucleophile has been successfully utilized, the process is general for carbanions derived from carbon acids with $pK_a > 22$ or so. Exceptions among the very reactive anions include organolithium reagents (deprotonation of the arene ligand and addition to the CO ligand are favored) and Grignard reagents (addition to the CO ligand is favored). With anions such as ester enolate anions, reaction occurs within minutes at −78 °C and the intermediate cyclohexadienyl complex can be observed spectroscopically.[148] The intermediates are exceedingly air sensitive and are generally quenched directly, without purification. In one case, from the addition of 2-lithio-1,3-dithiane, the adduct has been crystallized and fully characterized by X-ray diffraction analysis. Oxidation with excess iodine (at least 2.5 mol. equiv. of I_2) also proceeds at −78 °C and is complete within hours below room temperature. The products are the substituted arene, HI, Cr^{III}, and CO. Table 2[182] provides a representative sample of the carbanions that have been tested with (η^6-benzene)$Cr(CO)_3$.



(**121**)

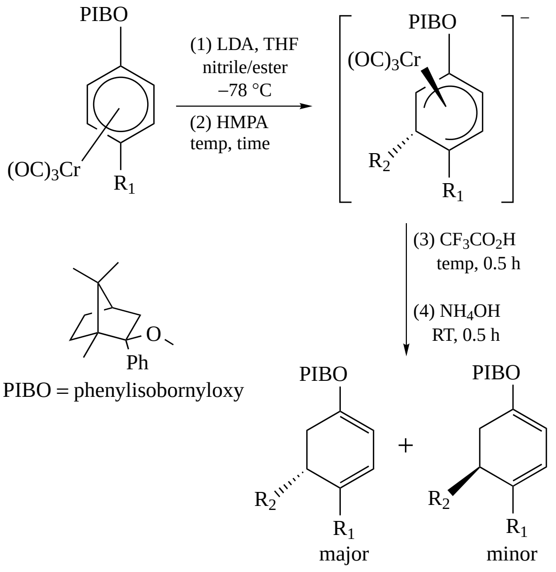
Regioselectivity has been the subject of numerous studies with a variety of mono- and polysubstituted arene ligands. The addition of synthetically interesting carbanions to the typical arene ligand, especially those bearing electron-donating substituents, can be reversible at rates comparable to the rate of addition: it is not always obvious whether to assume kinetic or thermodynamic control.[171,183] However, correlations have been suggested that allow prediction or rationalization of regioselectivity with a modest degree of confidence. With some significant exceptions as discussed below, the difference between the kinetic and thermodynamic selectivity has not been determined or is small.

With arenes bearing a single resonance donor substituent (NR_2, OMe, F), the addition is strongly preferred at the meta position, with small amounts of ortho substitution (0–10%).[184] The meta acylation of anisole, using a carbonyl anion equivalent as the nucleophile, illustrates the unique regioselectivity available with the $Cr(CO)_3$ activation (equation 115).[185]



(115)

However, the selectivity is more complicated with a methyl or chloro substituent (equation 116). Again, meta substitution

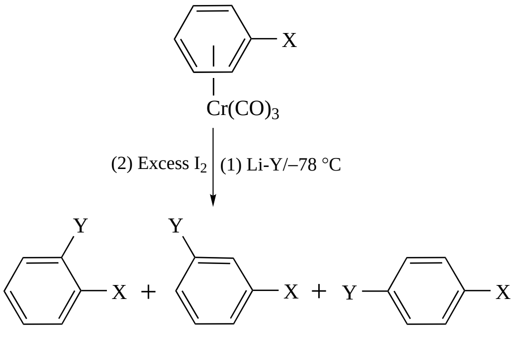
[a]The R group is –CH(Me)(OEt).

is always significant, but ortho substitution can account for 50–70% of the mixture in some cases.[184,186] More reactive anions (1,3-dithianyl) and less-substituted carbanions (e.g. *t*-butyl lithioacetate) tend to favor ortho substitution. Representative examples are shown in Table 3. Entries 2–4 show that variation of reaction temperatures from −100 to 0 °C has no significant effect in that highly selective system. The added activating effect of the Cl substituent allows addition of the pinacolone enolate anion (entry 11), whereas no addition to the anisole or toluene ligand is observed with the same anion. Table 3 also includes results with para-directing substituents, CF_3 and Me_3Si (entries 14 and 15).[186] In general, electron-withdrawing substituents, such as acyl and cyano, are also activated toward nucleophile addition to the substituent (C=O or CN), and this process competes with addition to the ring itself.



(116)

Regioselectivity in *o*-disubstituted arenes is often high and useful. A series of examples is summarized in Figure 4. The resonance donor substituent (OMe) appears to dominate the directing influences, favoring addition at the less-hindered position meta to itself.[186] But with two identical substituents, the addition is preferred in the adjacent position.[186] For example, with the complex of benzocyclobutene, six carbon nucleophiles were tested and each gave addition exclusively at C-3.[183,186] With the complex of indan, selective addition at C-3 was observed with dithianyl anions, but cyano-stabilized anions gave up to 20% of the isomeric product from addition at C-4.[183,186] Substituents at the benzylic carbons in the indan ligand have a strong effect on selectivity, and can lead to the 1,2,4-substitution product.[183]

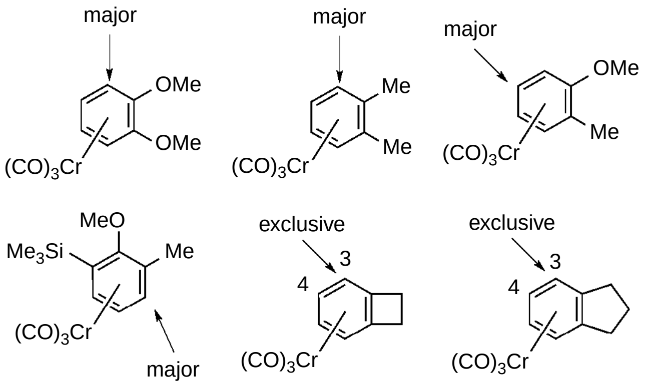


Figure 4 Summary of regioselectivity in addition to substituted arene ligands

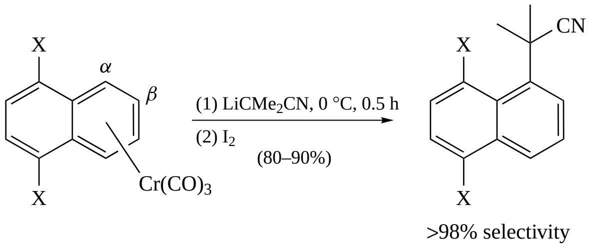
Indole is a particularly interesting case of regioselectivity, because the $Cr(CO)_3$ unit selectively activates the six-membered ring,[187] while in free indole the five-membered ring dominates the (electrophilic addition) reactivity. The selectivity in addition to the $Cr(CO)_3$ complexes of indole derivatives shows a preference for addition at C-4 (indole numbering) and C-7, with steric effects owing to substituents at C-3 (Y in Scheme 42) and N-1 (X in Scheme 42) as well as anion type influencing the selectivity.[187,188] In Scheme 42 example A, a hydrogen substituent at Y and a tertiary carbanion leads to selective C-4 substitution. In example B, the same substrate adds trimethyl(1-propenyl)silane predominantly at C-7. With a trimethylsilylmethyl substituent at Y, the addition is preferred at C-7 (example C). A sufficiently large sterically protecting group as X can disfavor addition at C-7 (example D).

	X	Y	R	C4:C7	Yield
A	NMe	H	CMe_2CN	97:3	73%
B	NMe	H	$CH_2CH{=}CHSi(Me)_3$	16:84	43%
C	NMe	CH_2SiMe_3	CMe_2CN	17:83	82%
D	NCH_2Ph	H	CMe_2CN	100:0	82%

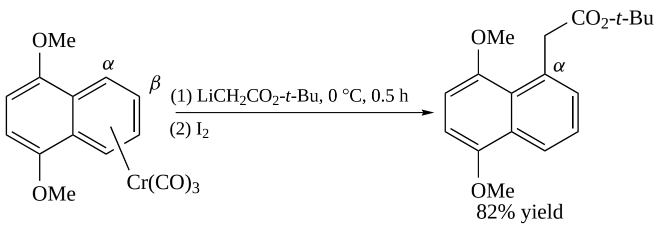
Scheme 42 Selectivity in addition to indole ligands

An example in which the regioselectivity of addition is different under kinetic versus thermodynamic control is the naphthalene series. In the addition of $LiC(Me)_2CN$ to naphthalene–$Cr(CO)_3$, a mixture of products is observed from addition at C-α and C-β in the ratio 42:58 under conditions where equilibration is minimized (0.3 h, −65 °C, THF/HMPA). With the same reactants, but in THF and at 0 °C, the product is almost exclusively the α-substituted naphthalene (equation 117).[183,189]



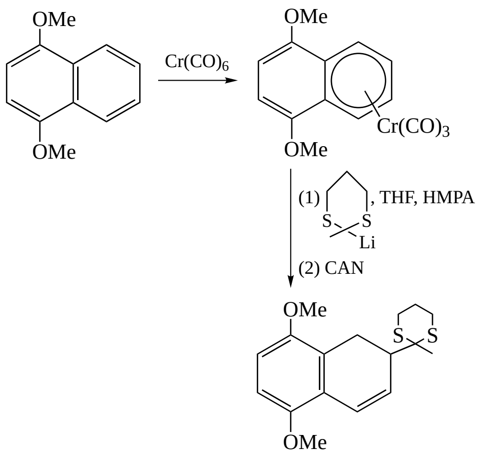
(117)

Using the standard procedures, 1,4-dimethoxynaphthalene is complexed at the less-substituted ring with high selectivity.[171] Again, under conditions of minimum equilibration of anion addition, $LiC(Me)_2CN$ gave a mixture (after iodine oxidation) of the 1,4-dimethoxy-β-substituted and 1,4-dimethoxy-α-substituted products in the ratio 78:22. After equilibration, the α-substitution product was essentially the only product found (equation 118).

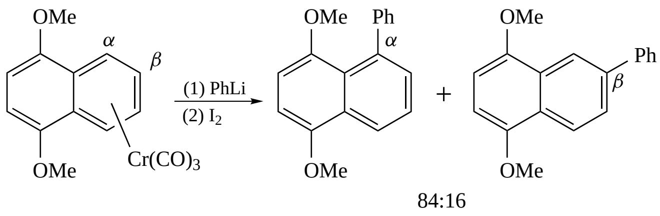


(118)

With the 1,4-dimethoxynaphthalene ligand, cyano-stabilized anions (including cyanohydrin acetal anions) and ester enolates equilibrate even at low temperature and strongly favor addition at the α-position (C-5). The kinetic site of addition is also generally C-α. However, the 2-lithio-1,3-dithiane anion and phenyllithium do not equilibrate over the temperature range −78 to 0 °C. The sulfur-stabilized anions favor addition at C-β (equation 119),[134,190] while phenyllithium gives a mixture favoring C-α (equation 120).



(119)



(120)

Selectivity in polar reactions can be discussed in terms of two features: charge control and orbital control.[191]

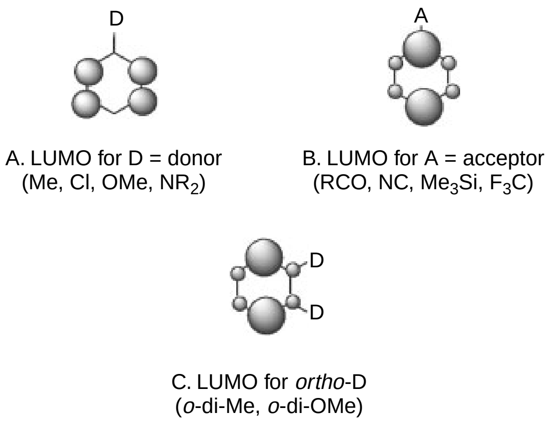


Figure 5 Orbital distributions for substituted benzenes

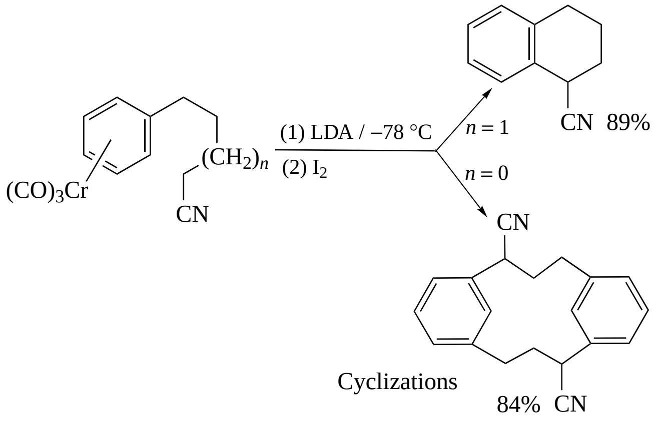


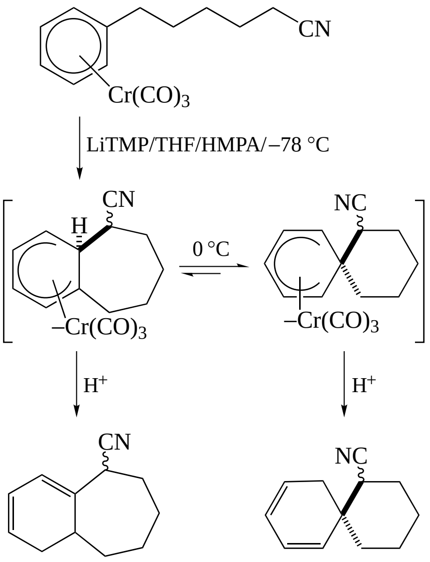
Scheme 43 Cyclizations

Analysis of charge control requires knowledge of charge distribution within the arene ligand. Analysis of orbital control can be approximated by emphasizing interaction of the frontier molecular orbitals: highest occupied molecular orbital (HOMO) for the nucleophile and lowest unoccupied molecular orbital (LUMO) for the arene complex. It was recognized early that the ortho/para selectivity observed with weakly polar substituents, such as Me and Cl, correlated with the LUMO for the free arene, and the assumption was made that the LUMO for the arene ligand has a distribution of coefficients similar to the free arene.[186] This has been supported by computation at the level of extended Huckel theory.[183,192] LUMOs for (uncoordinated) toluene and chlorobenzene are distributed nearly equally at the ortho and meta positions, and show small density at the para position (Figure 5).[193] Similarly for the case of two donor substituents arranged ortho, the LUMO is predicted to be localized at adjacent positions, consistent with the observed selectivity. With electron acceptor substituents (R_3Si, CF_3), LUMO has large coefficients ipso and para, consistent with para-addition selectivity.

However, the frontier orbital picture based on the free arene does not account for nearly exclusive meta selectivity in addition to anisole–$Cr(CO)_3$; the LUMO for anisole shows essentially the same pattern as for toluene.[193] With a strong resonance electron donor, the traditional electronic picture (deactivation of the ortho and para positions) is sufficient to account for the observed meta selectivity. In this case the balance of charge control and orbital control is pushed toward charge control by strong polarization. The same argument applies to the aniline and fluorobenzene complexes.

8.6.2 *Intramolecular Examples*

Intramolecular addition/oxidation with reactive carbanions is generally successful; most of the examples involve cyano-stabilized carbanions. Formation of a six-membered fused ring is efficient, but five-membered fused-ring formation is



Scheme 44 Intramolecular nucleophilic addition to Arene–$Cr(CO)_3$ complexes

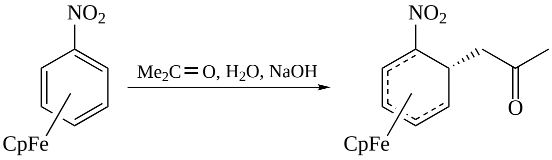
not.[194] The only addition/oxidation product is a cyclic dimer, [3,3]-metacyclophane (Scheme 43).[194]

Reversibility again is apparent with higher homologs, as shown in Scheme 44.[195] At low temperature, a mixture of cyclohexadienyl anionic intermediates is formed. An alternative quenching procedure, using trifluoroacetic acid produces the fused-ring diene shown. If the initial adduct is allowed to warm to 0 °C, rearrangement to the fused-ring spiro adduct occurs, and oxidative quenching gives the spiro[5.5]cyclohexadiene product.

8.6.3 *Addition/Oxidation with Other Complexes*

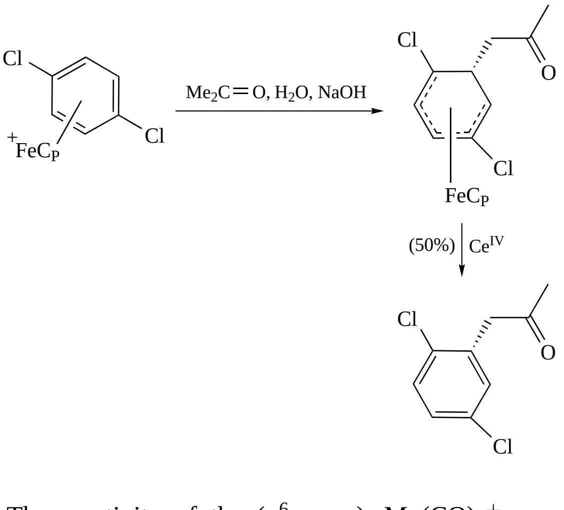
It has been recognized for many years that nucleophiles will add to (η^6-benzene)–$FeCp^+$ complexes.[196] The nucleophiles

range from cyanide anion[197] to metal hydrides and methyllithium; the intermediate neutral [η^5-(6-substituted) cyclohexadienyl]–FeCp complexes can be isolated and characterized. The regioselectivity has been determined for a number of monosubstituted arene ligands. Chloro[196] and carbomethoxy[196] substituents are ortho-directing, while methoxy[196] is a meta director, and a methyl group leads to similar amounts of addition at the o, m, and p positions.[196] In general, electron-withdrawing groups (nitro, halo, benzoyl, cyano, and sulfonyl) favor ortho addition, as exemplified for the addition of the acetone enolate (equation 121).[196,198]



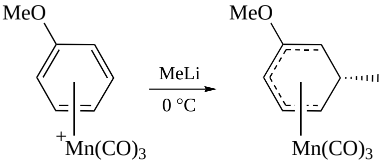
(121)

The primary limitations in applying these complexes are the two-stage detachment of the endo C-6 hydrogen and the detachment of the FeCp unit. Direct abstraction with trityl cation has been employed for the first stage,[196] and oxidation with *N*-bromosuccinimide completes both stages, leading to the substituted arene in the few cases tested.[199] In the cases with electron-withdrawing substituents on the starting arene, Ce^{IV} has been employed to aromatize and detach the arene unit after addition (equation 122).[198] Because of the high reactivity of the arene–$FeCp^+$ complexes, it can be expected that further developments and definition of selectivity features will be forthcoming.



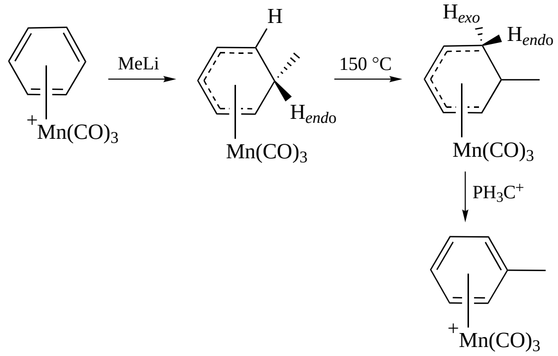
(122)

The reactivity of the (η^6-arene)–$Mn(CO)_3{}^+$ complexes toward addition of nucleophiles is high and general, leading to neutral, isolable [η^6-(6-substituted) cyclohexadienyl]–$Mn(CO)_3$ derivatives (equation 123).[200] The addition of Grignard reagents to anisole and aniline ligands shows good meta selectivity.[201,202] Addition to the chlorobenzene ligand gives similar amounts of ortho and meta (orbital control), while the toluene ligand favors addition at all three positions (o, m, p).[201,202]



(123)

The completion of the substitution process to produce a substituted arene free of the metal has not been worked out in general. Direct abstraction of the endo hydride of the η^5-cyclohexadienyl intermediate with trityl cation is not effective, but an interesting thermal rearrangement has been observed at 130–150 °C to create an isomeric cyclohexadienyl ligand that bears an exo (easily abstracted) hydrogen substituent (equation 124).[202,203]



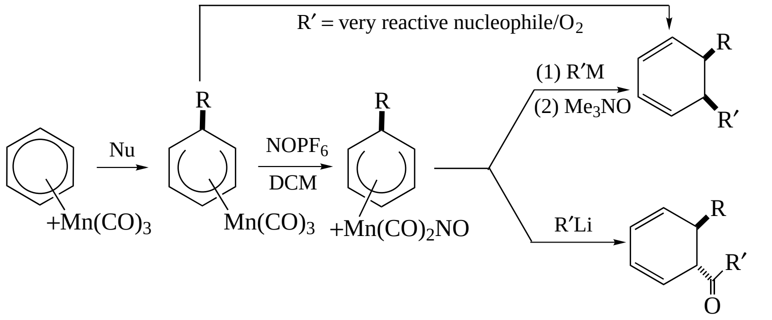
(124)

A general process for double addition to arene–$Mn(CO)_3{}^+$ complexes is shown in Scheme 45.[134,204] The neutral, η^5-cyclohexadienyl–$Mn(CO)_3$ complex obtained from an initial exo nucleophilic addition undergoes a second exo nucleophilic addition with very reactive nucleophiles. Oxidative decomplexation gives a syn disubstituted cyclohexadiene product. Ligand substitution of a CO ligand by NO^+ generates a cationic η^5-cyclohexadienyl–$Mn(CO)_3$ complex that undergoes a second nucleophilic addition to give either a syn disubstituted cyclohexadiene product or an anti disubstituted cyclohexadiene product containing an acylated substituent when using organolithium nucleophiles. In the latter case, nucleophilic attack likely occurs on a CO ligand with subsequent endo transfer of the resulting acyl ligand to the pi-ligand.

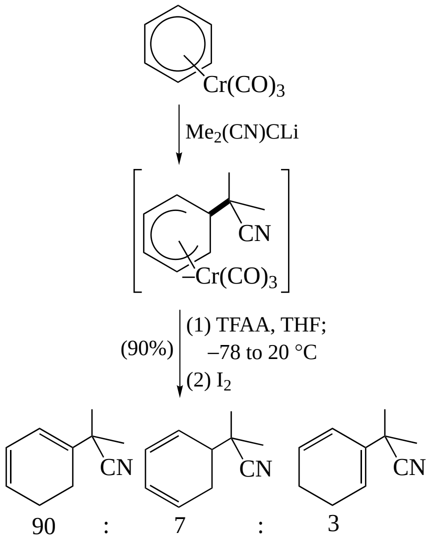
The arene–$Mn(CO)_3{}^+$ system is very promising, but more development work is necessary in order to assess the full possibilities for overall addition/oxidation and substitution for hydrogen.

8.7 Addition/Protonation: Synthesis of Substituted 1,3-Cyclohexadienes

The intermediate η^5-cyclohexadienyl anionic species from nucleophilic addition to the arene–$Cr(CO)_3$ complexes are



Scheme 45 Double addition to arene-Mn(CO)$_3$ complexes



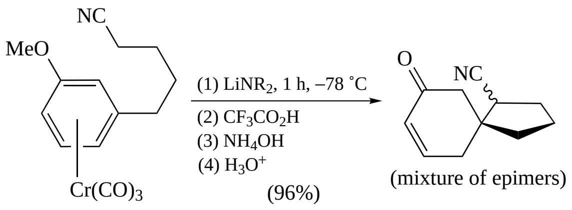
Scheme 46

obviously highly electron rich, and should be susceptible to reactions with electrophiles. Protonation is efficient at low temperature, and is suggested to produce a labile η^4-1,3-cyclohexadiene complex that can undergo H-migration to give the more stable 1,3-cyclohexadiene isomer; in simple systems, the major product is the 1-substituted 1,3-cyclohexadiene (Scheme 46).[134,205]

The reaction appears to be general, although a limited number of examples have been reported. A particularly useful process begins with meta addition to anisole–Cr(CO)$_3$, followed by protonation and hydrolysis of the enol ether unit. The result is a 5-substituted cyclohex-2-en-1-one.[206] This dienol ether can be isolated in high yield before the aqueous hydrolysis.

Other alkene positional isomers of the product enone can be obtained selectively, depending on the conditions of the acid treatment and the acid hydrolysis.[206] The addition/protonation process does not change the oxidation state of the chromium, and a procedure has been defined for recovery of the Cr^0 in order to allow direct recycling.[207]

The intramolecular version of addition/protonation with (m-cyanoalkyl)anisole ligands produces spirocyclic enones (equation 125).[207]

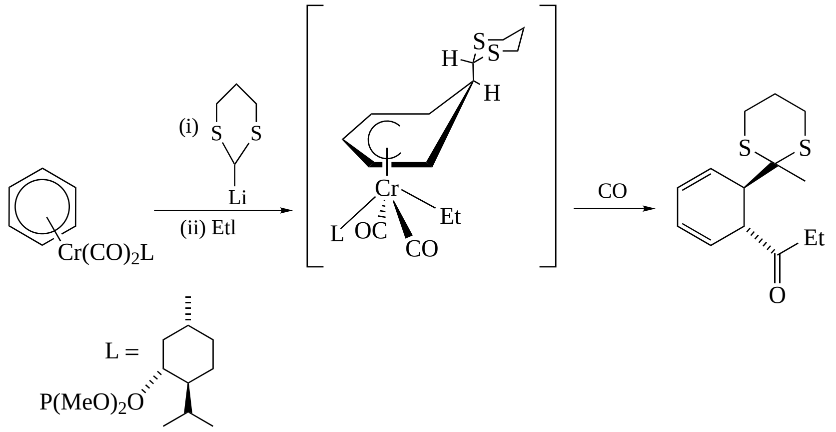


(125)

8.8 Addition/Acylation: Synthesis of Disubstituted 1,3-Cyclohexadienes

The efficient trapping of the cyclohexadienyl anionic intermediates with protons raises the possibility of quenching with carbon electrophiles. The process is not as general as the proton quench. However, when the nucleophile adds essentially irreversibly, quenching with a limited set of carbon electrophiles is successful.[183,208] For example, addition of 2-lithio-1,3-dithiane to benzene–Cr(CO)$_2$L, followed by addition of ethyl iodide and then oxidation or addition of a donor ligand (CO, Ph$_3$P), produces a cyclohexa-1,3-diene substituted by both acetyl (Me + CO) and the nucleophile (Scheme 47).[134,209] The insertion of CO occurs, without exception, with a variety of electrophiles. The insertion is efficient without added CO, but gives somewhat higher yields under a modest pressure ($<$4 bar) of CO during electrophile coupling. The attachment of the electrophile is from the *endo* direction, consistent with initial addition to the metal following by CO insertion and migration up to the arene unit; the products then have the trans arrangement of the new substituents.

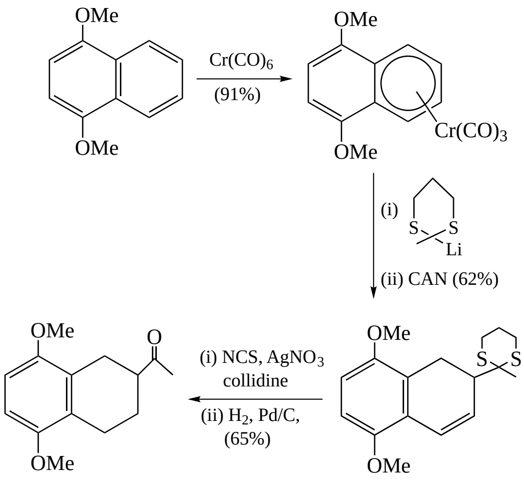
More reactive anions such as the 2-lithio-1,3-dithiane derivatives, phenyllithium, and t-butyllithium do not require a special solvent and proceed in high yield in THF. While HMPA is known to suppress the migratory insertion to CO in anionic complexes, it does not deter the CO insertion in these cases; no example of direct alkylation is reported. The only electrophile that adds without CO insertion is the proton,



Scheme 47 Nucleophilic addition to Arene–$Cr(CO)_3$ complexes

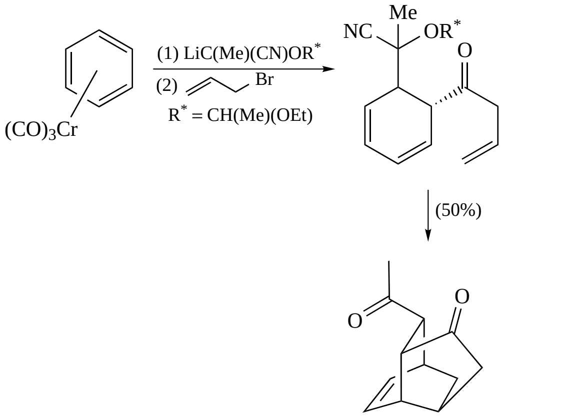
as discussed above. Good alkylating agents (primary iodides and triflates, allyl bromide, benzyl bromide) react below 0 °C, but ethyl bromide requires heating at 50 °C. The reaction is selective for a primary alkyl iodide in the presence of an ester or a ketone unit.

While the addition/oxidation and the addition/protonation procedures are successful with ester enolates as well as more reactive carbon nucleophiles, the addition/acylation procedure requires more reactive anions and the addition of a polar aprotic solvent (HMPA has been used) to disfavor reversal of anion addition. Under these conditions, cyano-stabilized anions and ester enolates fail (simple alkylation of the carbanion), but cyanohydrin acetal anions are successful. The addition of a cyanohydrin acetal anion to 1,4-dimethoxynaphthalene–$Cr(CO)_3$ occurs by kinetic control at C-β in THF/HMPA and leads to the α,β-diacetyl derivative after methyl iodide addition and hydrolysis of the cyanohydrin acetal. Monoacylation of 1,4-dimethoxynaphthalene–$Cr(CO)_3$ has been achieved using the sequence of reactions shown in equation (126).[134,210]



(126)

Addition of a cyanohydrin acetal anion to benzene–$Cr(CO)_3$ followed by reaction with allyl bromide produces the cyclohexadiene derivative in 94% yield, which undergoes a Diels–Alder reaction rapidly to give the tricyclic framework. After quenching with methyl iodide and disassembling of the cyanohydrin group, the diketone is obtained in 50% yield overall (equation 127).[208]



(127)

8.9 Summary

Coordination of a metal to the π-orbitals of an arene opens pathways for nucleophile addition to the arene. The power of the effect is related to the oxidation state (Cr^0, Mn^I, Fe^{II}) and peripheral ligands (Cp or CO). Under suitable conditions, both heteroatom and carbon-based nucleophiles add rapidly under mild conditions. The fate of the cyclohexadienyl intermediate depends on the conditions of the next stage of the batch-wise process. Loss of an electronegative leaving group leads to an analog of

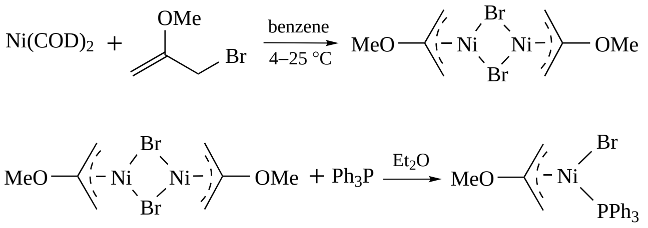
conventional nucleophilic aromatic substitution, but there are procedures for oxidation/loss of a hydrogen substituent, protonation to give a monosubstituted 1,3-diene, and acylation to give a disubstituted 1,3-diene.

9 COUPLING OF ALLYL–Ni^{II} COMPLEXES WITH ORGANIC HALIDES

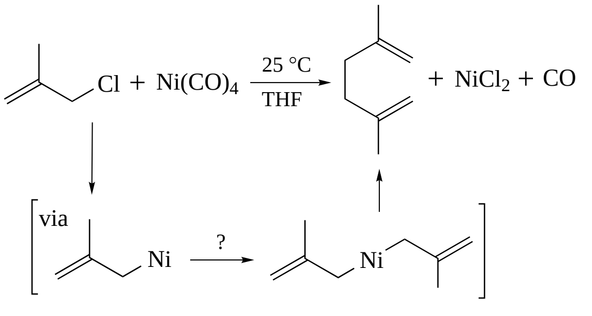
9.1 Basic Reaction

Before the modern era of organotransition metal reactivity, it was observed that nickel carbonyl reacted with 2-methallyl chloride in methanol to give methyl 3-methyl-3-butenoate and 2,5-dimethyl-1,5-hexadiene as a by-product.[211] In THF at 25 °C, the diene was the exclusive product. This mild formation of a carbon–carbon bond, and the interest in the synthesis of terpene-based natural products led to efforts to test the scope and limitations of the process. An obvious pathway involves stepwise oxidative addition of each allyl unit followed by *Reductive Elimination*. As discussed below, the key intermediates (left vague in Scheme 48) are likely to involve Ni^{I}–Ni^{III} couples.

This pathway suggests that unsymmetrical coupling and perhaps coupling with other types of organic halides might be possible if the process could be interrupted after the first oxidative addition and allow isolation of the allyl–Ni complex. A remarkable solvent effect began to be delineated when it was reported that in benzene, reaction of allylic halides with nickel carbonyl leads to the η^3-allyl–NiBr species as a bridged dimer. Subsequently, it has been reported that many of forms of Ni^0, including bis(1,5-cyclooctadiene)Ni^0 and ‘Rieke’ nickel, react at room temperature or below in many solvents to produce the same allyl–nickel complexes in high yield. Such η^3-allyl–NiBr dimers dissociate into monomeric complexes when treated with Lewis bases like PPh$_3$ (equation 128).[212]



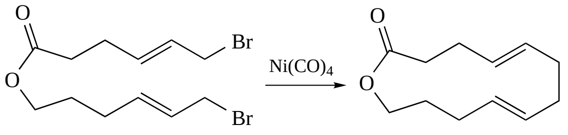
(128)



Scheme 48

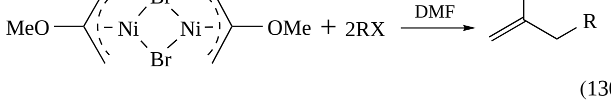
The complexes are typically deep red, soluble in organic solvents, and moderately air sensitive. The solids can be handled in air for short periods, but routine manipulations should be done under inert atmosphere conditions. The coupling reactions are strongly inhibited by oxygen. It is not generally possible to carry out organic transformations on the organic ligand, and they are simply used directly in coupling with organic halides. Complexation can be accomplished in the presence of numerous functional groups, including ester, alkoxy, and so on, and it is unlikely that the list has been fully elaborated. The allyl–Ni^{II} complexes are relatively inert toward all common functional groups, including acyl halides and phenolic hydroxyl. Stronger acid will protonate the ligand to give the propene derivative.

The symmetrical coupling of allylic halides (Scheme 48) is very general and compatible with most common functional groups.[211] It is limited by rapid equilibration of the configuration of the allyl double bond during coupling and production of the more stable diene configuration. For simple allyl units, a mixture of the possible geometrical isomers results. Symmetrical coupling does not lead to a versatile synthesis method, but intramolecular applications have been impressively successful (equation 129).[213,214] Medium-sized rings can be formed, although there is no significant evidence for features that favor such rings and high dilution is generally employed.

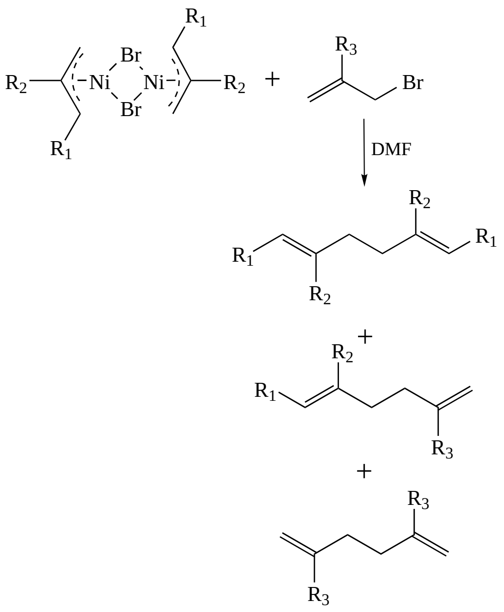


(129)

Attempts to bring about cross coupling of different allylic halides invariably led to mixtures suggesting exchange of the allylic units before coupling. This problem in synthesis is better solved by cross coupling of an allylic halide and an allylic derivative of a main group metal.[212,215] However, electrophilic alkylation of η^3-allyl–NiBr dimers by simple alkyl halides is successful (equations 130 and 131).

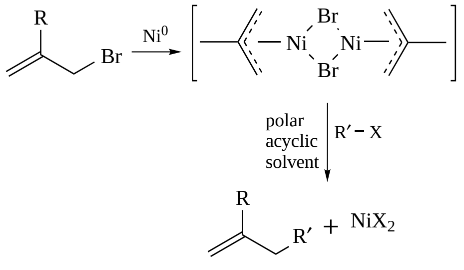


(130)



(131)

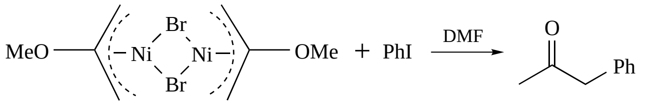
The utility of the allyl–Ni^{II} complexes lies in that fact that nonallylic halides undergo cross coupling with high selectivity.[211,212] Moreover, the pattern of reactivity of organic halides was unlike any other synthesis methodology available at that time (1967), and opened new opportunities. The method is summarized by the general equation (132). It is a stoichiometric process, but easy to carry out. The first step is most economically done with excess nickel tetracarbonyl in toluene (80 °C, 0.5 h) and most conveniently with bis(1,5-cyclooctadiene)nickel (0 °C in ether). After the complex is formed, the volatile material can be removed and the residue taken up in DMF, a strongly activating solvent for the next step. Alternatively, the residue can be crystallized, typically from ether, and isolated by filtration as usual.[216]



(132)

9.2 Pattern of Reactivity in the Organic Halide

The reactivity series for R′–X is summarized in Figure 6 and the special case is exemplified in equation (133).[212]



(133)

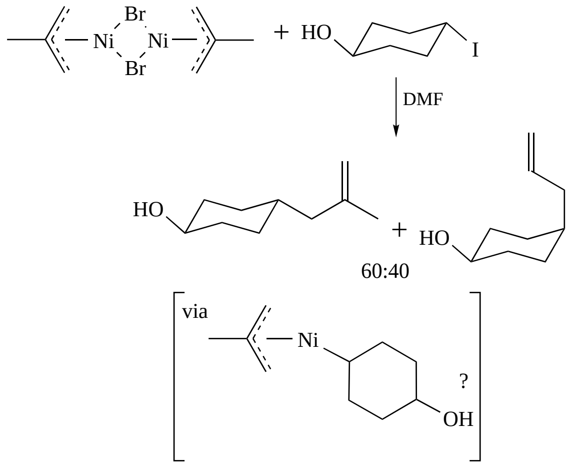
Structure of R′: allyl > benzyl > aryl > vinyl > methyl > alkyl
R′: = Alkyl: primary > secondary > tertiary
Leaving group: I > Br > Cl (OTs unreactive)

Figure 6 Reactivity series for organic electrophiles in reaction with allyl–Ni^{II} complexes

The relatively high reactivity of the allyl–Ni^{II} complexes toward aryl halides, especially bromides, is unusual among traditional organic mechanisms and represented one of the first observations of this special feature in transition metal reactions. An S_N2 mechanism for activation of the halide is clearly ruled out, and the reactivity correlates better with an electron-transfer mechanism. The rates are roughly correlated with ease of reduction of the organic halide. This also is consistent with the low reactivity of *p*-toluenesulfonate esters, compared to bromides.[211]

9.3 Selectivity Issues

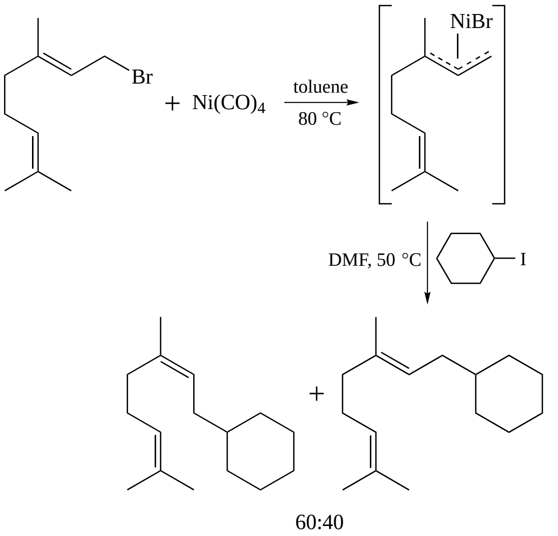
A revealing example is the reaction of 4-iodocyclohexanol with 2-methallyl–NiBr.[211] The product is a mixture of epimers, symbolizing the general result that the configuration of the halide undergoing coupling is equilibrated during the reaction. The hydroxyl group is not protected and does not interfere. This is a secondary halide, very prone to β-hydride elimination, and yet no elimination is observed. Presumably, the key intermediates bearing a σ-cyclohexyl unit are coordinatively saturated or undergo intramolecular processes faster than β-elimination. The process must involve an intermediate related to the allyl–Ni–cyclohexyl species shown in equation (134).



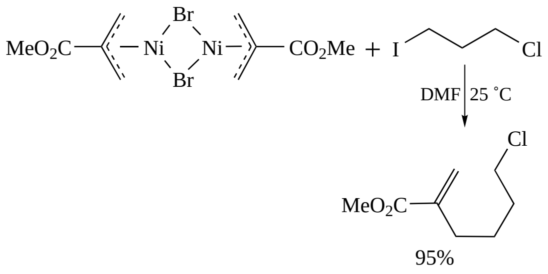
(134)

A related selectivity question is answered with the reactions of (*E*)-geranyl bromide (equation 135).[211] Complexation gives a noncrystalline residue that couples with cyclohexyl iodide on heating in DMF, but the coupled product shows

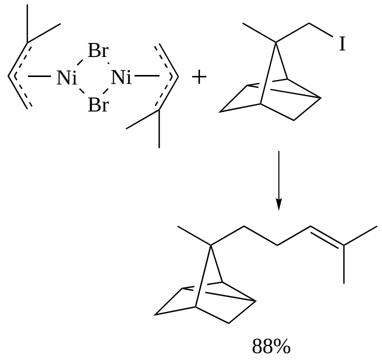
evidence of equilibration of the double bond in the starting halide. Isomerization of the allylic π-bond is a general feature of the allyl–Ni coupling process. The difference in reactivity of the halides is large.[211] Selective reaction of iodide in the presence of either chloride or bromide is easy to predict (equation 136). Even neopentyl halides, normally very resistant to coupling by any mechanism, will react under forcing conditions and with good efficiency (equation 137).[211]



(135)



(136)

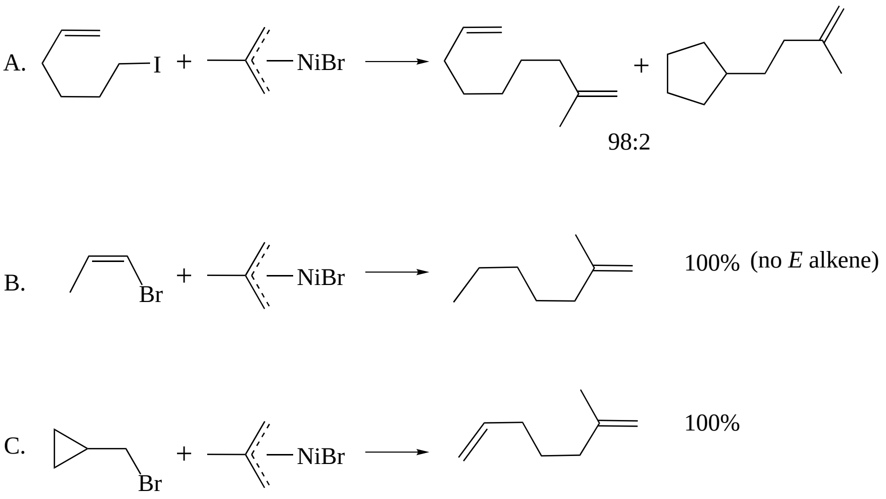


(137)

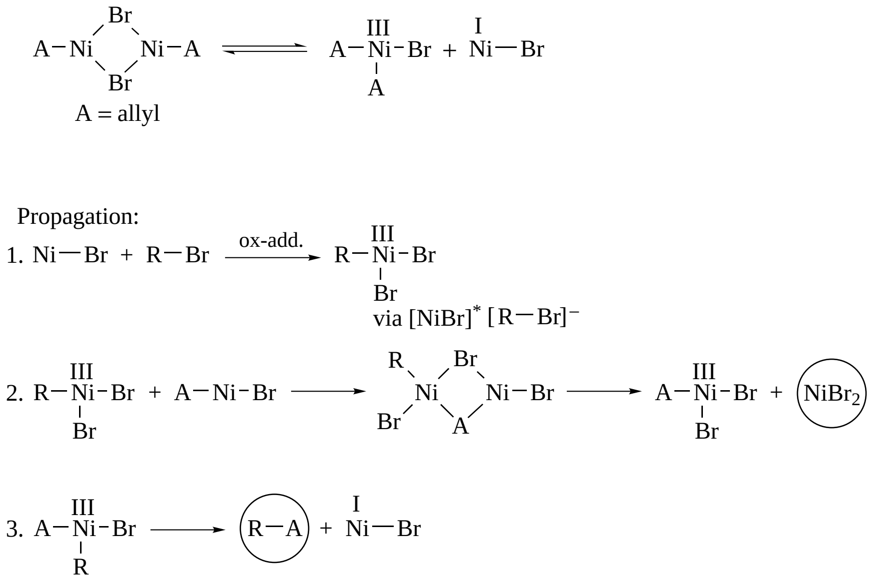
9.4 Mechanism

A simple mechanism for the process was proposed in the original papers, involving oxidative addition to give a Ni^{IV} species. However, it did not explicitly account for a number of observations, and difficult questions continued to accumulate.[217] In summary, mechanistically significant observations are:

1. Complete equilibration of configuration of the halide undergoing coupling. This has been verified with the racemization of 2-octyl bromide during coupling.
2. Inhibition of the coupling reaction by oxygen, *m*-dinitrobenzene, and other conventional radical chain inhibitors.
3. None of the typical products of radicals (R· from R–X) have been observed (coupling or elimination).
4. Radical rearrangement products from, for example, 6-hexenyl iodide and vinyl iodide are minimal, although the cyclopropylcarbinyl example (Scheme 49) shows the nearly complete rearrangement typical of a cyclopropylcarbinyl radical.



Scheme 49 Radical clock experiments to detect radical intermediates

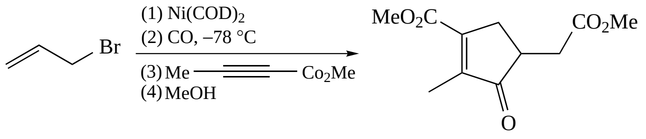


Scheme 50 Mechanism of the allyl–Ni coupling reaction

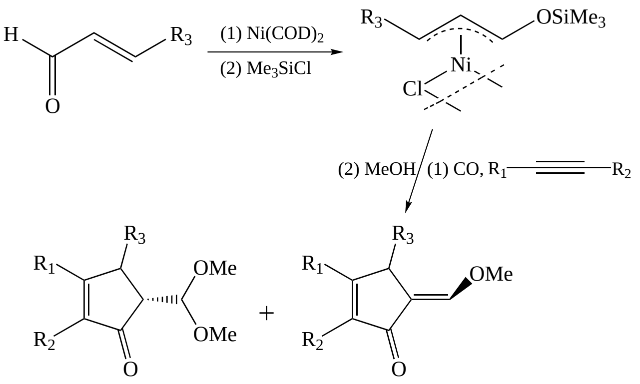
In these 'radical clock' experiments, the observations are somewhat contradictory: a vinyl radical should rearrange to the other geometrical isomer (Z to E in this case) at least as rapidly as the cyclopropylcarbinyl radical rearranges to the allylcarbinyl radical. A simple explanation is that the putative cyclopropylcarbinyl–nickel intermediate has a low-energy pathway for rearrangement to the allylcarbinyl ligand, not involving radicals. Overall, the reactions in Scheme 50 are taken as evidence against radical intermediates generated from R–Br.[217]

A consistent picture is presented in Scheme 50.[217] Initial formation of a Ni^{I} species occurs by an unspecified mechanism (initiation); one possibility is 'redox disproportionation' with the dimer Ni^{II} complex giving rise to Ni^{I} and Ni^{III} species. The Ni^{I} derivative is expected to be a good electron donor, and can transfer an electron to the organic halide. Then the radical anion of the organic halide can fragment rapidly to produce the organic radical, now coordinated with the Ni, and the halide anion. The resulting Ni^{III} species can undergo a ligand exchange through a bridging interaction with the starting Ni^{II} allyl species, leading to a Ni^{III} unit with both the R group and the allyl group attached. Then reductive elimination gives the coupled product, R–allyl, as well as a new Ni^{I} unit. This scheme does not involve R· and can be shown to operate at a very high rate in the absence of radical inhibitors. The loss of configuration is not readily apparent from this scheme; it requires some mechanism for racemization of the carbon attached to Ni during the coupling.[217]

Trihapto-allyl–Ni complexes have been used in Pauson–Khand cycloadditions to form cyclopentenones (see equations 138 and 139).[218,219] In the reactions shown, $Ni(COD)_2$ is the source of Ni^0 to give allyl–Ni intermediates through oxidative addition of an allylic halide or silylation of a coordinated enone. Carbonylation reactions of allyl halides by $Ni(CO)_4$ have also been examined theoretically.[220]



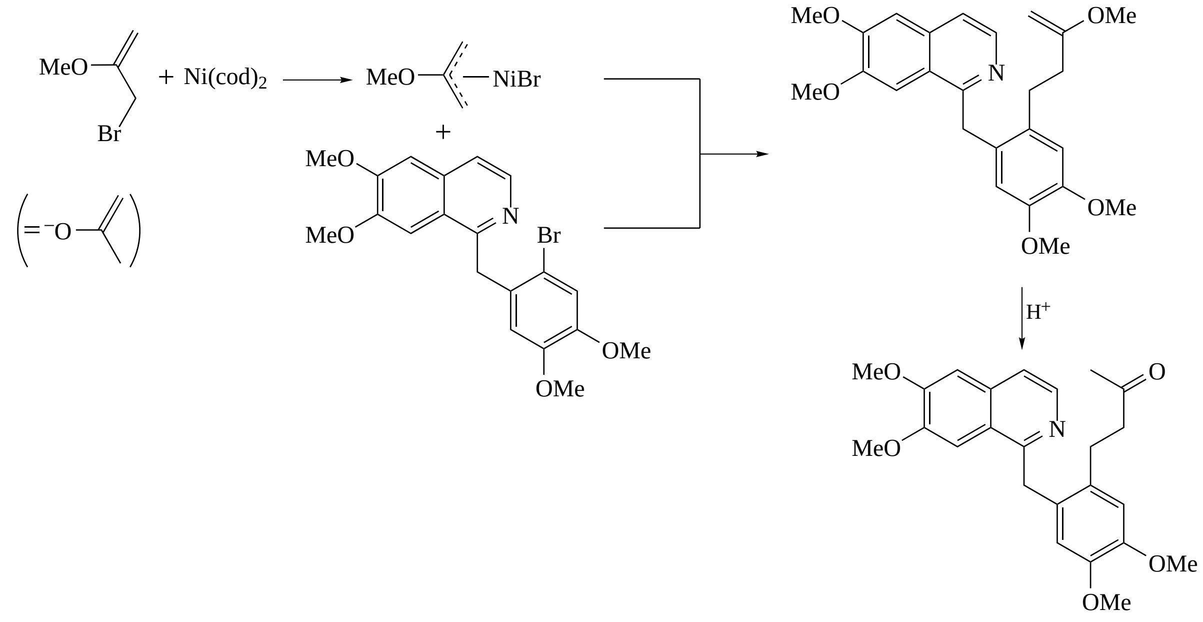
(138)



(139)

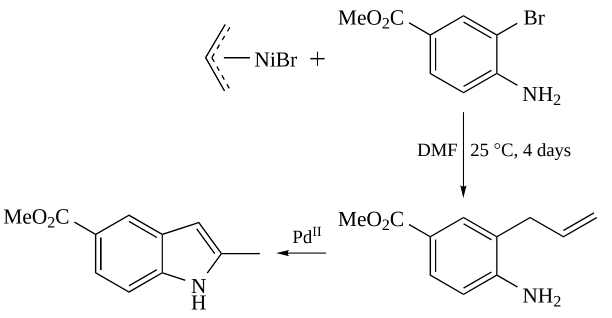
9.5 Applications

A particularly interesting combination of allyl ligand structure and the high reactivity toward aryl halides leads to the synthesis equivalent of nucleophilic aromatic substitution by enolate anions, but under completely different conditions (Scheme 51).[221] In this example, the 2-methoxyallyl ligand is equivalent to an acetone enolate anion, but reacts with very different functional group compatibility (no polar



Scheme 51 Synthesis equivalent of nucleophilic aromatic substitution

reactions) and with aromatic halides, even if electron rich. The selective coupling of an allyl ligand in the presence of a free amino group and an ester demonstrates the chemoselectivity of these reagents, and leads to an intermediate that can be oxidatively cyclized with Pd^{II} to give indoles (equation 140).[222]



(140)

The discussion above emphasizes that the allyl–Ni^{II} reagents are quite selective for carbon–halogen bonds, especially allyl, vinyl, and aryl halides. At the same time, modest reactivity as nucleophiles toward reactive carbonyl derivatives has been reported.[211,219,223] Simple aldehydes, the more reactive ketones (such as cyclopentanone and benzoquinone), and certain epoxides will undergo 1,2-addition of the allyl ligand to the carbonyl group. Esters, amides, and, most remarkably, acyl halides are inert toward the allyl–Ni^{II} reagents under conditions where the reagents do not decompose thermally (<80 °C or so).

9.6 Summary

The coupling of the allyl–Ni^{II} reagents with organic halides opens special reactivity patterns not available by traditional organic methods. The high reactivity of aryl and vinyl halides is particularly useful. The functional group compatibility is very high, although rapid epimerizations and double bond inversions limit the selectivity. There is no catalytic version, but the processes are convenient to carry out on a large scale stoichiometrically, and the Ni^{II} by-products can be recycled or disposed of easily.

1 INTRODUCTION

Osmium (Os) was first isolated as the tetraoxide, OsO_4, by Smithson Tennant[1] in 1803 by distillation of a mixture of platinum group metals (Ru, Os, Rh, Ir, Pd, Pt) oxidized with aqua regia. This reflects the general feature that Os and many of its compounds can be readily oxidized to form the pungent, highly volatile OsO_4 (osmium: from $o\sigma\mu\acute{\eta}$, osme: a smell). Os has *Atomic Number* 76, *Atomic Mass* 190.2 with *Electron Configuration* [Xe]$4f^{14}6s^25d^6$, and has seven naturally occurring isotopes, ^{184}Os 0.02%, ^{186}Os 1.58%, ^{187}Os 1.6%, ^{188}Os 13.3%, ^{189}Os 16.1%, ^{190}Os 26.4%, and ^{192}Os 41.0%. Os is a rare element with an estimated abundance in the Earth's crust of some 0.005 ppm. It is found with other platinum group metals in ores in South Africa, the Urals, and Canada.

2 GENERAL FEATURES

Several reviews and texts on the coordination chemistry (*see* ***Coordination & Organometallic Chemistry: Principles***) of Os have been published. The works of Gmelin[2] give comprehensive coverage of the literature up to 1980, with the review of Griffith[3] giving an excellent account of Os coordination chemistry up to 1987, with updated reviews published in 2003.[4] For organometallic chemistry of Os, *see* ***Osmium: Organometallic Chemistry***, and for its cluster chemistry, *see Metal Clusters*; several inorganic texts dealing with aspects of Os chemistry have been published.[5] Review articles on specific areas of Os chemistry are cited in the text.

The coordination chemistry of Os features a very wide variety of oxidation states (*see Oxidation Number*) from high oxidation state VIII d^0 Os^{VIII} to low oxidation state −II d^{10} Os^{-II}. High oxidation state metal complexes are associated with strong σ-donor and π-donor (*see π-Base*) ligands such as O^{2-} ($Os^{VIII}O_4$), N^{3-} ($[Os^{VIII}O_3N]^-$), and F^- ($Os^{VII}F_7$), while low oxidation state species are stabilized by strong π-acceptor ligands such as CO (e.g. $[Os^0(CO)_5]$), NO^+, and PPh_3 (e.g. $[Os^{-II}(NO)_2(PPh_3)_2]$). The most common oxidation states for Os are II, III, and IV, with the stability of each oxidation state controlled by the types of ligand bound to the metal. Thus π-acceptor ligands such as bipy, phen, terpy, CN^-, and CO will tend to stabilize Os^{II}, for example, $[Os^{II}(bipy)_3]^{2+}$ and $[Os^{II}(bipy)_2(CN)_2]$, while ligands such as Cl^-, NH_3, en, and H_2O will tend to stabilize III and IV as in $[Os(NH_3)_6]^{3+}$ and $[OsCl_6]^{3-/2-}$.

Associated with these oxidation states are a variety of coordination geometries (*see* ***Coordination Numbers & Geometries***), among which octahedral coordination (*see Octahedral*) dominates overwhelmingly. Tetrahedral coordination (*see Tetrahedral*) is rare, although it is observed for the very important OsO_4. There are examples of five-coordinate, square-based pyramidal or trigonal bipyramidal complexes, for example, $[OsNCl_4]^-$, $[OsO_2(OAc)_3]^-$, $[OsCl_2(PPh_3)_3]$, and $OsO_4{\cdot}py$ (*see Square Pyramidal*; *Trigonal Bipyramidal*). Seven and eight coordination, although rare, have been observed in OsF_7, $[Os(EDTA)(H_2O)]$, and certain polyhydrides such as $[OsH_4(PMe_2Ph)_3]$, $[OsH_3(PPh_3)_4]^+$, and $[OsH_6(PPhR_2)_2]$ (R = *i*-Pr). Table 1 illustrates the oxidation states observed for some Os coordination compounds.

Os shares the group 8 triad with Fe and Ru. The highest available oxidation state for Fe is usually regarded as VI in the ferrate dianion $[FeO_4]^{2-}$, while the VIII oxidation state for Ru in RuO_4 is much more oxidizing than OsO_4. This reflects the stabilization of high oxidation states for the third-row transition element (Os) compared to its second- (Ru) and first-row (Fe) congeners. Likewise, Os^{VI} complexes tend to be more stable and are therefore more common than Ru^{VI} analogs. Thus, compared with Ru, the higher oxidation states are more stable for Os, while the lower oxidation states

Table 1 Examples of coordination compounds of osmium

Oxidation state	Complex
VIII	OsO_4, $[OsO_3N]^-$, $OsO_4{\cdot}py$, $[OsO_2F_4]^{2-}$, $[OsO_4Cl]^-$
VII	OsF_7, $[Os(EDTA)(H_2O)]^a$
VI	$[OsO_2(en)_2]^{2+}$, $[OsO_2(OEP)]$, $Os_2O_6(py)_4$, $[OsO_2(OAc)_3]^-$, OsF_6, $[OsNX_5]^{2-}$, $[OsNX_4]^-$
V	$[OsCl_6]^-$, $[OsF_6]^-$, Os_2Cl_{10}
IV	$[OsCl_6]^{2-}$, $[OsCl_5(H_2O)]^-$, $[Os_2OCl_{10}]^{4-}$, $[Os(OEP)(OR)_2]$.
III	$[Os(NH_3)_6]^{3+}$, $[OsCl_6]^{3-}$, $[Os(NH_3)_5Cl]^{2+}$, $[Os(bipy)_2(OH)_2]^+$
II	$[Os(bipy)_3]^{2+}$, $[Os(CN)_6]^{4-}$, $[Os(bipy)_2(CN)_2]$, $[Os(NH_3)_5(N_2)]^{2+}$, $[Os(OEP)CO(py)]$, $[Os(NH_3)_5(NO)]^{3+}$, $[OsCl_2(PPh_3)_3]$
I	$[OsCl_2(NO)(PPh_3)_2]$
0	$[Os(CO)_5]$, $[Os_3(CO)_{12}]$, $[OsCl(NO)(PPh_3)_2]$, $[Os(NO)H(PR_3)_2]$
−I	$[Os(NO)(depe)_2]$
−II	$[Os(NO)_2(PPh_3)_2]$

[a]EDTA = Ethylenediaminetetraacetic acid.

are relatively less stable. All Os complexes are low-spin species, reflecting the large ligand field splittings expected for complexes of a third-row transition element (*see Transition Metals*). There is much interest in the use of platinum group metals in catalysis, and the area of homogeneous catalysis by osmium complexes, including the reduction of aldehydes, the selective reduction of alkynes to alkenes, asymmetric dihydroxylation and catalysis by carbonyl clusters, has been reviewed.[6]

3 OSMIUM(VIII)

3.1 Oxo Complexes

OsO_4 (Figure 1) is an extremely important Oxo Complex of Os. It is used industrially for the cis-hydroxylation of alkenes to cis-diols, and in biology for the fixation of biological tissue. OsO_4 is tetrahedral with the Os=O = 1.711(3) Å in the gas phase,[7] and 1.684(7), 1.710(7) Å, O=Os=O = 106.7(4), 110.7(3)° in the solid state.[8] It can be prepared by oxidation of the metal or of simple Os salts, and its high volatility allows it to be readily sublimed. It is a yellow solid which is soluble in water and CCl_4 to give pale yellow solutions. OsO_4 is highly oxidizing and is readily reduced, particularly in alcoholic solutions, to give insoluble OsO_2 and other reduced forms of Os. OsO_4 is toxic (TLV 2.5 ppm; OEL 0.002 mg m^{-3}) and is usually stored in sealed ampoules at reduced temperatures.

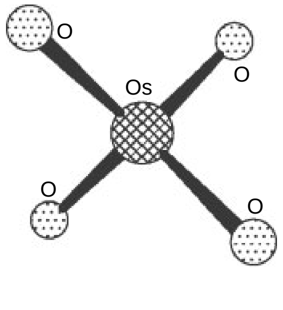

Figure 1 The structure of osmium tetroxide

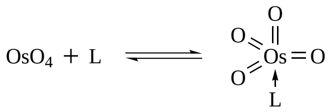
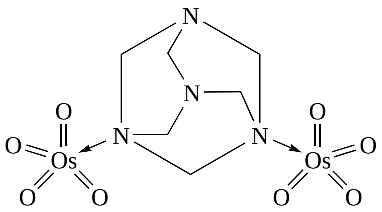
OsO_4 is formally a 16-electron species and can therefore form five-coordinate, 18-electron adducts (*see Eighteen Electron Compounds*) $OsO_4{\cdot}L$ with certain tertiary N-donor ligands (L) such as py and quinuclidine (equation 1). The structure of the 2:1 hexamethylenetetramine adduct (*see Addition Compound*) $[OsO_4]_2{\cdot}N_4C_6H_{12}$ (**1**) shows each Os to be five-coordinate, with a distorted trigonal bipyramidal (TBP) structure in which the N-donor of the tetramine occupies an apical site.[9] This complex has a much lower vapor pressure than that of OsO_4 but, importantly, retains the reactivity of OsO_4 itself. The complex can, therefore, be regarded as a safer form of OsO_4 and one that can be stored easily and used as a biological preservation and staining agent when required.[10] The action of OsO_4 in biological tissues is complicated with interactions with unsaturated phospholipids, proteins, catechols, and alkaloids being proposed.



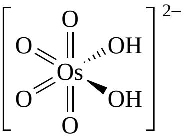
(1)

Reaction of OsO_4 with alkali metal hydroxides affords the *cis*-perosmate salts $M_2[OsO_4(OH)_2]$ (M = Li, Na, K, Rb, Cs) (**2**) and $M[OsO_4(OH)_2]$ (M = Ca, Sr, Ba). Reaction of OsO_4 with CsF affords $[OsO_4F_2]^{2-}$, while with Ph_4PCl the complex $[OsO_4Cl]^-$ can be isolated. Reaction of OsO_4 with KrF_2 gives the Os^{VIII} oxide $[OsO_2F_4]$ (**3**).[11] Os^{VIII} oxofluorocations have

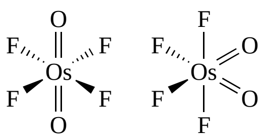


(1)

been investigated via the reaction of *cis*-$[OsO_2F_4]$ with strong fluoride acceptors such as AsF_5 and SbF_5. An X-ray structure of one complex shows discrete fluoride bridging between $[(cis\text{-}OsO_2F_3)_2]^+$ and $Sb_2F_{11}^-$ ions.[12]



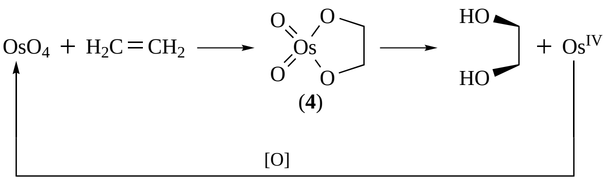
(2)



(3)

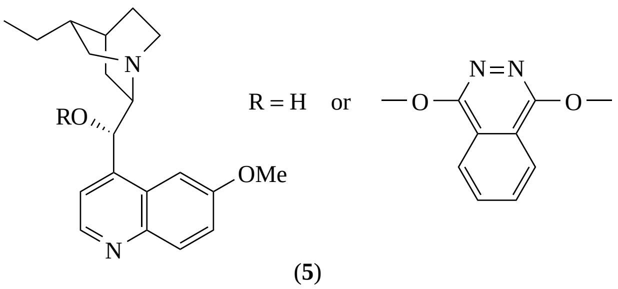
3.2 Cis-hydroxylation of Alkenes

OsO_4 can be used stoichiometrically or catalytically for the cis-dihydroxylations of alkenes to cis-diols (equation 2).[13] The ester species (**4**) represents an Os^{VI} intermediate, which can be hydrolyzed to afford the corresponding cis-diol in fair to good yield. The structures of Os^{VI} ester complexes are discussed in Section 5. Hydrolysis of intermediate Os^{VI} esters can be achieved reductively, for example with SO_3^{2-}, to form insoluble Os–sulphito species. Oxidative hydrolysis can occur with IO_4^-, organic peroxides, or N-oxides to regenerate OsO_4, thus making the process catalytic in terms of OsO_4. The X-ray structures of OsO_4 with the cooxidant N-methylmorpholine N-oxide and its reduced form N-methylmorpholine confirm coordination via the N-oxide oxygen and amine N-donor, respectively.[14] Addition of tertiary amines L leads to a marked increase in the rate of Os^{VI} osmyl ester formation, and an overall increase in rate of cis-hydroxylation. Through the addition of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) to OsO_4 a directed dihydroxylation reaction can be realised with a range of homoallylic alcohols and amides. The course of the reaction appears to be influenced by hydrogen-bonding between the oxo group of the active intermediate and an alcohol or an amide of the substrate.[15]



(2)

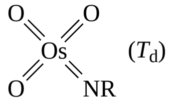
By using OsO_4 in the presence of chiral auxiliaries such as (**5**) the asymmetric dihydroxylation of a range of organic substrates can be achieved.[16] Kinetic studies on the Sharpless enantioselective dihydroxylation of terminal olefins support a [3 + 2] cycloaddition pathway and a U-shaped binding pocket to favor one enantiomer of the product.[17] In recent work, Sharpless and coworkers have demonstrated[18] that certain alkenes, for example, unsaturated carboxylic acids, can be rapidly converted almost quantitatively by a second cycle of asymmetric dihydroxylation, which has traditionally been avoided. Indeed, using N-toluene sulfonyl derivatives of α, β-hydroxyamino acids, ee's of up to 42% have been achieved using the second cycle, where the ligand remains bound throughout.[18]



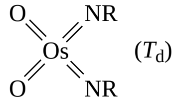
(5)

3.3 Nitrido and Imido Complexes

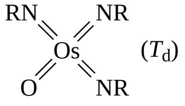
Treatment of OsO_4 with concentrated KOH (to form $[OsO_4(OH)_2]^{2-}$) followed by addition of NH_4OH affords a unique nitrido complex containing the osmiamate anion, $[OsO_3N]^-$. The structure of $Cs[OsO_3N]$ (Figure 2) shows Os=O = 1.739(8) and Os≡N = 1.676(15)Å.[19] Reaction of OsO_4 with amines under controlled conditions affords the Os^{VIII}–imido complexes $[OsO_3(NR)]$ (**6**), $[OsO_2(NR)_2]$ (**7**), $[OsO(NR)_3]$ (**8**), and $[Os(NR)_4]$ (**9**) (R = for example, *t*-Bu, *t*-oct, 1-adamantyl).[20] The structure of $[OsO_3(N\text{-}1\text{-adamantyl})]$ (Figure 3) shows the complex to be tetrahedral with Os=O = 1.714(4), Os=N = 1.697(4)Å.[21] The relatively short Os=N bond length may suggest some triple bond character.



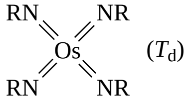
(6)



(7)



(8)



(9)

The oxyamination (equation 3) and diamination (equation 4) of alkenes using these imido complexes have been

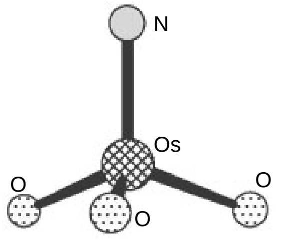


Figure 2 The structure of the osmiamate anion

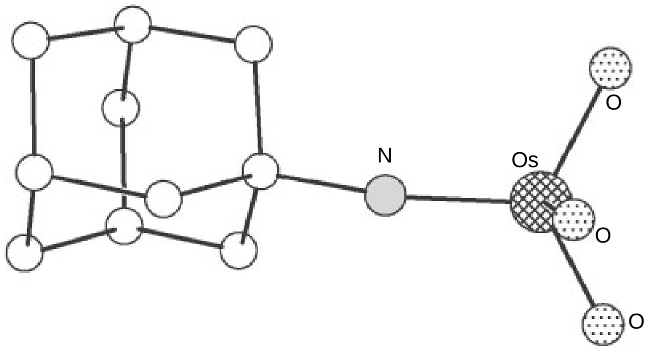

Figure 3 The structure of $[OsO_3(N\text{-}1\text{-adamantyl})]$

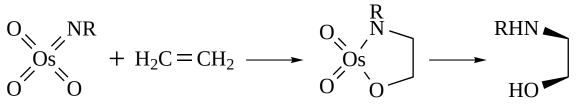
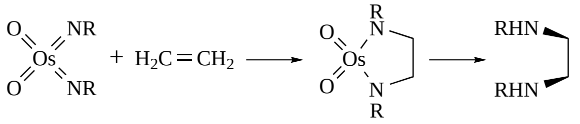
reported; these reactions can be made catalytic in the presence of argentocarbamates and chloramine-T.[22] Asymmetric aminohydroxylation reactions using Os substrates has been recently reviewed.[23]



(3)



(4)

4 OSMIUM(VII)

Osmium(VII) complexes are rare and would be expected to be paramagnetic (*see Paramagnetism*), having a d^1 configuration. OsF_7 (**10**) can be made by fluorination of osmium metal with F_2 at elevated temperatures and high pressure. It shows a magnetic moment (*see Magnetic Susceptibility*) of $\mu_{eff} = 1.08$ BM, and is proposed to have a pentagonal bipyramidal structure (*see Pentagonal Bipyramid*).[24] Reaction of osmium metal with a mixture of F_2 and O_2 at 300 °C at 5 atm pressure affords the green, paramagnetic ($\mu_{eff} = 1.47$ BM at 298 K) complex $[OsOF_5]$ (Figure 4), which has a C_{4v} structure with Os=O = 1.74(3),

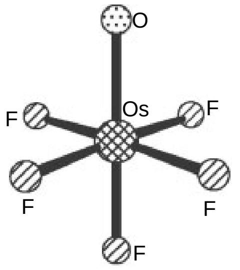


Figure 4 The structure of $[OsOF_5]$

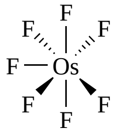
Os–F = 1.78(3), 1.72(3) Å.[25] Chemical or electrochemical reduction of OsO_4 under controlled conditions affords $[OsO_4]^-$ ($\mu_{eff} = 1.37$ BM at 298 K).[26]



(**10**)

The crystal structure of $[Os(NBu^t)_2(\mu\text{-}NBu^t)]_2{}^{n+}$ ($n = 0$ or 2) has been reported in both the (VII) and (VI) oxidation states; the Os–Os separation is 2.68 Å in the former and 3.1 Å in the latter. This is consistent with the formation of an Os–Os single bond in this rare osmium(VII) dimer.[27]

5 OSMIUM(VI)

5.1 Oxo Complexes

A wide range of d^2 Os^{VI} complexes has been prepared and characterized. These complexes are usually diamagnetic (*see Diamagnetism*) and often incorporate the osmyl *trans*-O=Os=O dioxo unit or the monooxo Os=O unit, often with halide, N-, or O-donor ligands. They are more stable and less oxidizing than their Ru analogs, and are often prepared by reduction of OsO_4 or, in certain cases, by controlled oxidation of Os^{IV} and Os^V precursors.

Reaction of $[OsO_4(OH)_2]^{2-}$ (**2**) with EtOH as a reducing agent affords the Os^{VI} *trans*-dioxo complex $[OsO_2(OH)_4]^{2-}$. A range of related complexes of type $[Os^{VI}O_2(X)_4]^{x-}$ incorporating the *trans*-dioxo O=Os=O unit have been prepared by controlled reduction of OsO_4 in the presence of X (X = for example, Cl, OMe, OAc, $\frac{1}{2}$OX, $\frac{1}{2}$cat, CN). Neutral species such as $[OsO_2Cl_2(PPh_3)_2]$ and cationic species such as $[OsO_2(NH_3)_4]^{2+}$ and $[OsO_2(en)_2]^{2+}$ have also been reported. These osmyl complexes typically show bands in the IR spectrum (*see Infrared Spectroscopy*) in the regions 840–820

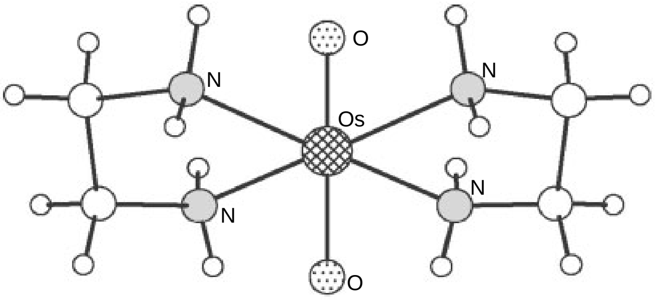


Figure 5 The structure of *trans*-$[OsO_2(en)_2]^{2+}$

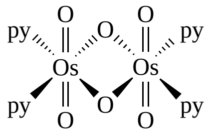
and 290–310 cm^{-1}, assigned to the asymmetric O=Os=O stretching vibration and the O=Os=O bending mode, respectively. The symmetric O=Os=O stretching vibration is also observed in the Raman spectrum (*see Raman Spectroscopy*) in the region 860–910 cm^{-1}, at higher frequency than the asymmetric vibration. The assignment of these complexes as trans-dioxo complexes has been confirmed by structural studies. For example, the single crystal X-ray structure of *trans*-$[OsO_2(en)_2]^{2+}$ (Figure 5) shows[28] Os=O = 1.74(1) Å with a linear O=Os=O unit. A similar structure is observed for *trans*-$[OsO_2(OEP)]$ (OEP = octaethylporphyrin) (Figure 6), which shows[29] Os=O = 1.745(5) Å; reduction of OsO_4·py affords the binuclear species $Os_2O_6py_4$ (**11**), which incorporates an OsO_2Os bridging unit.[30] The synthesis and photophysics of a range of dioxo–Os^{VI} complexes of tetraaza macrocyclic ligands have been reviewed.[31] A cis-dioxo complex $[OsO_2(OAc)_3]^-$ (Figure 7) has also been reported.[32]



(**11**)

A range of Os^{VI} oxo ester complexes can be isolated from the reaction of OsO_4 with alkenes, dienes, and alkynes. These ester complexes represent the Os^{VI} intermediates in the cis-hydroxylation of alkenes to cis-diols by OsO_4. In the absence of tertiary amines, reaction of OsO_4 with alkenes affords the oxo ester complexes (**12**), (**13**), and (**14**). In the presence of tertiary amines (L), oxo ester complex formation is rapid, and trans-dioxo complexes of type (**15**; L = py) and the binuclear species (**16**; L = quinuclidine) can be isolated.[33] The dioxosmium(VI) cation (**17**) has been stabilized via complexation to a tetra-deprotonated amide ligand, which also serves to stabilize the dioxo unit through the formation of weak hydrogen-bonds to the urea NH groups. The complex shown displays reversible oxidative chemistry, whereas the related complex with one N–H hydrogen-bonding group

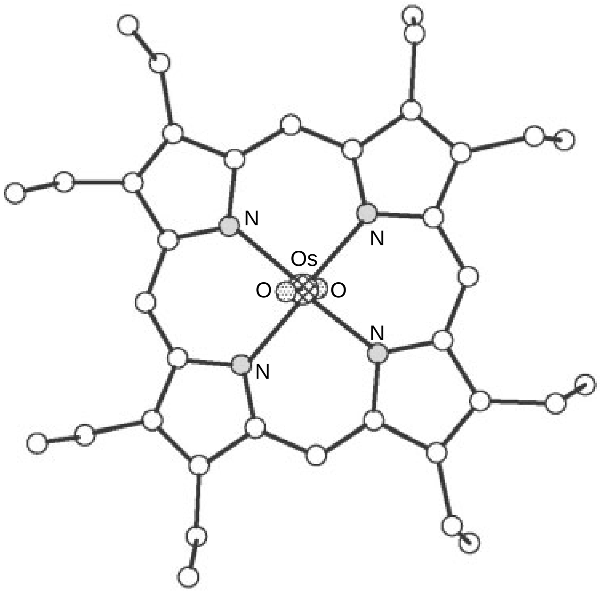


Figure 6 The structure of *trans*-$[OsO_2(OEP)]$

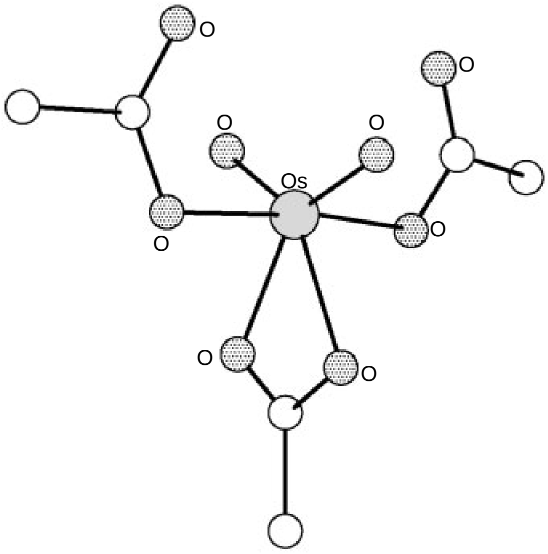

Figure 7 The structure of the *cis*-dioxo complex $[OsO_2(OAc)_3]^-$

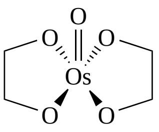
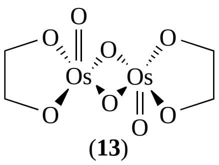
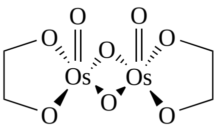
removed displays an irreversible oxidative wave by cyclic voltammetry.[34]



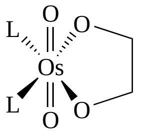
(**12**)



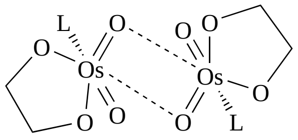
(**13**)



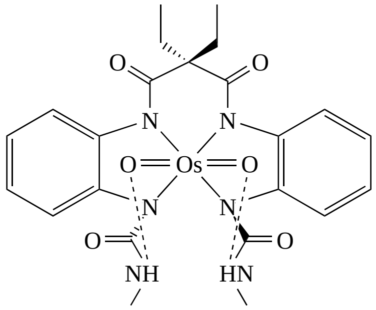
(**14**)



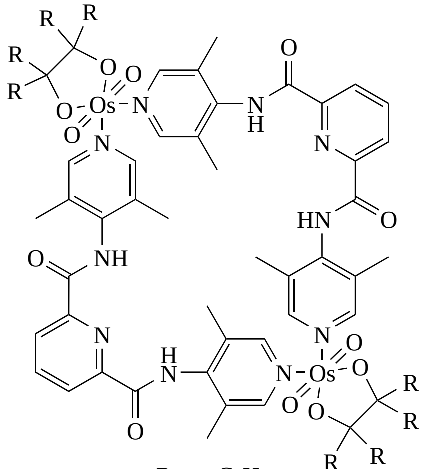
(15)



(16)



(17)

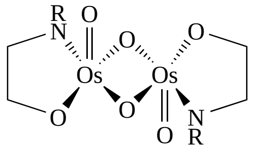


R = n-C_4H_9

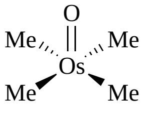
(21)

The reaction of OsO_4 with Buckminsterfullerene C_{60} gives the corresponding osmyl ester species[35] (*see* ***Carbon: Fullerenes***).

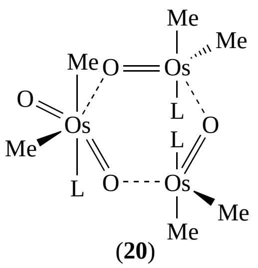
Analogous Os^{VI} imido esters such as (**18**) can be isolated from the reactions of $[OsO_3(NR)]$ with alkenes. Reaction of $[OsO_3(N\text{-}t\text{-}Bu)]$ with alkylating agents such as MgR_2 affords the unusual Os^{VI} alkyl species OsO_2R_2,[36] while related oxoalkyl complexes of Os^{VI} have also been prepared.[37] Alkyl Os^{VI} species including $[OsO(Me)_4]$ (**19**) and an unusual trinuclear species $[OsO_2(Me)_2py]_3$ (**20**) have been isolated.[38]



(18)



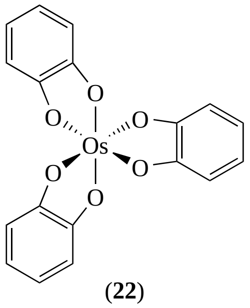
(19)



(20)

Os^{VI}-bridged macrocycles (**21**) have been assembled via reaction of OsO_4, alkenes, and L-shaped bispyridyl ligands. The resulting osmate ester-bridged binuclear macrocycles act as hosts for guests such as adipamide and terephthalamide, but not for guests such as benzamide and isophthalamide.[39]

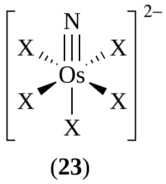
Nonoxo containing Os^{VI} species of the type $[Os(L)_3]$ (L = catechol and substituted catechol) (**22**) showing D_{3h} symmetry can be prepared by reaction of OsO_4 with L.[40] $[Os(L)_3]$ can be reduced electrochemically to $[Os(L)_3]^-$ and $[Os(L)_3]^{2-}$.



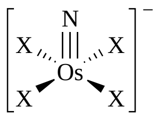
(22)

5.2 Nitrido and Imido Complexes

A range of Os^{VI} nitrido species incorporating the Os≡N unit can be synthesized including $[OsNX_5]^{2-}$ (**23**; X = Cl, Br) and $[OsNX_4]^-$ (**24**; X = Cl, Br, I). $[OsNX_5]^{2-}$ (X = Cl, Br) can be prepared by reaction of osmiamate $[OsO_3N]^-$ with HX, the product reacting with water to give $[OsNX_4(H_2O)]^-$. The complexes $[OsNX_5]^{2-}$ are six-coordinate while the species $[OsNX_4]^-$ (X = Cl, Br, I) show square-based pyramidal structures with the Os≡N occupying the apical site; Os≡N = 1.640(10), 1.583(15), 1.626(17) Å for X = Cl, Br, I, respectively.[41]



(23)



(24)

The complexes $[OsNX_5]^{2-}$ (X = Cl, Br) and $[OsNX_4]^-$ (X = Cl, Br, I) are very useful starting materials for the synthesis of a wide range of substituted Os^{IV} and Os^{III} halophosphine complexes, and species incorporating phosphineiminato, Os=N–PR_3, functionalities. The electrochemical oxidation of *cis*- and *trans*-$[Os(terpy)(Cl)_2NH_3](PF_6)$ and $[Os(terpy)(bpy)(NH_3)](PF_6)_2$ is metal based at low pH. However, at high pH proton loss and oxidation of bound ammonia occurs to yield either $[Os(terpy)(Cl)_2(N)](PF_6)$ via a four-electron process or $[Os(terpy)(bpy)(NO)](PF_6)_3$ by a six-electron process.[42]

The hydrazido complexes *trans*-$[Os(terpy)(Cl)_2(NNR_2)]^{n+}$ (NR_2 = morpholide, terpy = 2,2′:6′,2″-terpyridine) have been structurally characterised in the (VI), (V), and (IV) oxidation states. The systematic structural changes observed are accounted for by a generalized bonding model in which Os^{IV} is converted to Os^{VI} and then the ligand is converted from a four-electron to a six-electron donor, with the Os^{V} complex being intermediate between the two.[43] Osmium hydrazido complexes have been reported to display oxo-like reactivity related to Ru^{IV}-oxo chemistry. For example, *trans*-$[Os(terpy)(Cl)_2(NNR_2)]^{2+}$ (NR_2 = morpholide) is able to oxidize benzylalcohol to benzaldehyde.[44] Furthermore, under remarkably mild conditions, a number of ring substituted terpy products have been obtained from the reaction of *trans*-$[Os(terpy)(Cl)_2(NNR_2)]^{2+}$ with a series of nitrogen and oxygen bases. One example *trans*-$[Os(4'\text{-}O(CH_2CH_2)_2Nterpy)(Cl)_2(NNR_2)]^{2+}$ has been characterised crystallographically and further substitution at both the 4- and 4″-positions is possible in this system.[45] Additionally, in MeCN the Os^{VI} complex *trans*-$[Os(terpy)(Cl)_2(N)]^+$ reacts with excess azide to form the Os(III) product $[Os(terpy)(Cl)_2(5\text{-}CH_3\text{-tetrazolate})]$ which has been structurally characterised as the first osmium-tetrazolato complex.[46]

The Os^{VI} nitrido complex $TpOs(N)Cl_2$ [Tp = hydrotris (pyrazol-1-yl)borate] reacts rapidly with either PhMgCl or arylboranes to transfer one organic group to the nitrogen center to afford $TpOs[N(Ph)(BPh_2)]Cl_2$. It was suggested that there may be a general preference for nucleophiles to add directly to the metal-ligand multiple bond rather than binding to the metal first followed by a migration.[47]

Reaction of OsO_4 with ArNCO affords the highly unusual Os^{VI} imido complex $[Os(NAr)_3]$ (Ar = 2,6-*i*-PrC_6H_3) (Figure 8), the crystal structure of which shows Os–N distances of 1.736(5), 1.736(5), and 1.738(7) Å.[48] Reduction of $[Os(N\text{-}t\text{-}Bu)_4]$ affords a series of imido bridged complexes such as $[Os_2(N\text{-}t\text{-}Bu)_4(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ (Figure 9).[49] Related Os^{VI} complexes $[Os(porph)(O)(N\text{-}t\text{-}Bu)]$ and $[Os(porph)(N\text{-}t\text{-}Bu)_2]$ (*see Porphyrin*) have been isolated.[50]

The heterobimetallic complex $[Os(N)Me(CH_2SiMe_3)(\mu\text{-}O)CrO_2]^-$ has been characterised structurally and shown to be active in the catalysis of the oxidation of benzyl alcohol by molecular oxygen. Kinetic data are consistent with a mechanism involving initial binding of the alcohol to Os, followed by a proton transfer to a bridging oxo and finally a β-hydrogen elimination.[51] A mixed valence Os^{VIII}-Os^{VI} dimer $[OsN\{N(SPPh_2)_2\}]_2(\mu\text{-}N)(OsO_3)$ can be isolated from the reaction of *trans*-$[OsN\{N(SPPh_2)_2\}]_2(Cl)$ and $[NBu_4][OsO_3N]$ in the presence of $AgBF_4$.[52] Furthermore, *trans*-$[OsN\{N(SPPh_2)_2\}]_2(Cl)$ can be used to synthesize the first osmium(VI)-polyoxometallate complexes, *trans*-$[OsN\{N(SPPh_2)_2\}]_2(M_6O_{19})$ (M = Mo or W).[53]

Generally high-valent Os complexes are less oxidizing than their Ru analogs; however, the oxidizing power of Os-oxo and Os-nitride complexes can be enhanced by excitation

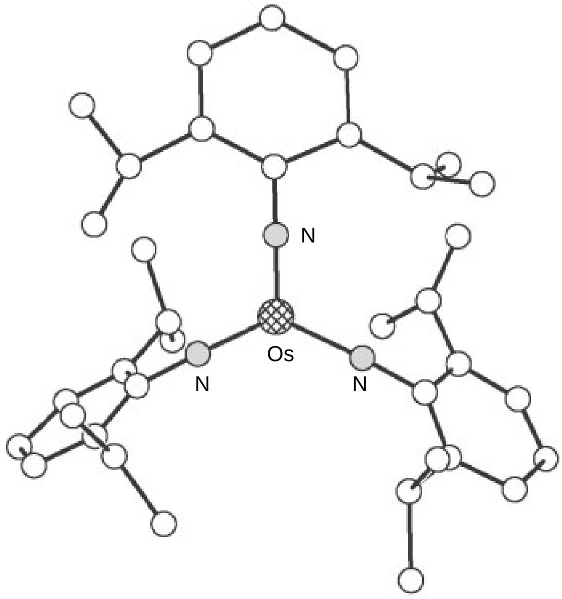


Figure 8 The structure of $[Os(NAr)_3]$ (Ar = 2,6-*i*-PrC_6H_3)

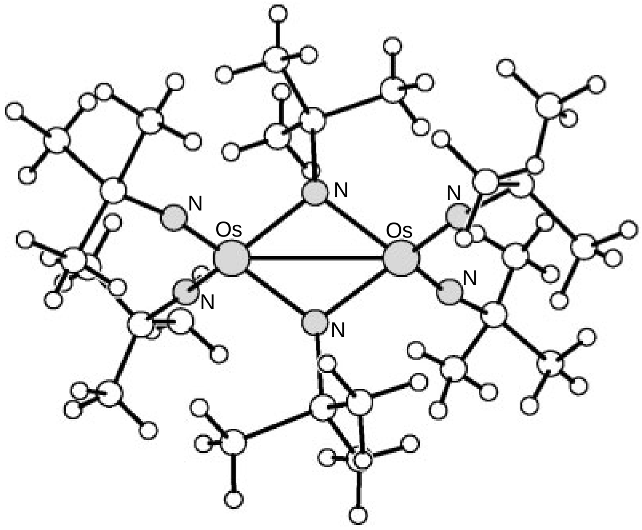

Figure 9 The structure of $[Os_2(N\text{-}t\text{-}Bu)_4(\mu\text{-}N\text{-}t\text{-}Bu)_2]$

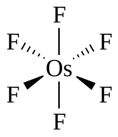
with UV-vis light. Consequently, the rich redox chemistry of the $^3[(d_{xy})^1(d_{xz},d_{yz})^1]$ excited states of some Os(VI)-oxo and Os(VI)-nitrido complexes has been reported.[35]

5.3 Halide and Hydrido Complexes

OsF_6 (**25**) is prepared by fluorination of OsO_4 and has been shown to be octahedral in the gas phase, with Os–F = 1.831(8) Å. Treatment of OsF_6 with FNO affords $[OsF_7]^-$.



(**25**)

Hydrido complexes such as $[OsH_6(PR_3)_2]$ (*see* ***Hydride Complexes of the Transition Metals***) can be prepared by reaction of $[OsO_2Cl_2(PR_3)_2]$ with $LiAlH_4$, and are related to the Os^{IV} hydrido complexes $[OsH_4(PR_3)(\eta^2\text{-dppm})]$ and $[OsH_4(PR_3)_2(\eta^1\text{-dppm})]$.[54]

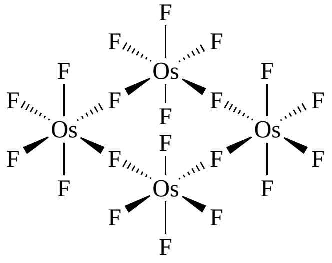
6 OSMIUM(V)

Coordination complexes of d^3 Os^V are relatively rare and are generally limited to certain simple halide and mixed halide complexes of the type $[OsF_6]^-$ and $[OsF_5]_4$ (**26**), the magnetic moment of the latter complex being 1.73 BM at 102 K and 2.06 BM at 295 K. $[OsX_6]^-$ can be prepared by oxidation of $[OsX_6]^{2-}$ (X = Cl, Br); the structure of $[OsCl_6]^-$ shows an average Os–Cl distance of 2.284 Å compared to a value of 2.332 Å for $[OsCl_6]^{2-}$.[55] Reaction of OsF_6 with BCl_3 or OsO_4 with SCl_2 affords $[Os_2Cl_{10}]$ (**27**).[56] $[Os_2Cl_{10}]$ (μ_{eff} = 2.54 BM per Os) is a chloro bridged dimer (*see Bridging Ligand*) with an Os–Os distance of 3.63 Å. The stabilization of the Os^V oxidation state has been achieved electrochemically in tetraaza macrocyclic complexes.

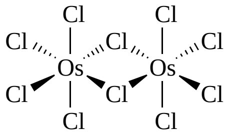
The Os^V-imido complex $[Os(Tp)(Cl)_2(NH)]$ (Tp = hydrotris(pyrazol-1-yl)borate) has been synthesized in MeCN by the one-electron reduction of $[Os(Tp)(Cl)_2(N)]$. The complex $[Os(Tp)(Cl)_2(NH)]$ disproportionates in aqueous solution to form $[Os(Tp)(Cl)_2(N)]$ and $[Os(Tp)(Cl)_2(NH_3)]$.[57]

7 OSMIUM(IV)

Os^{IV} has a d^4 configuration and its coordination chemistry is dominated by polyhalide complexes.



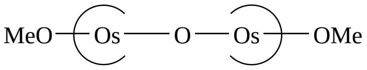
(**26**)



(**27**)

7.1 O-donor Complexes

Oxo complexes containing the terminal Os=O linkage are relatively rare for Os^{IV}, the tendency for this oxidation state being the formation of Os–O–Os bridged species. A wide range of such complexes has been prepared, a good example being the diamagnetic $[Os_2OCl_{10}]^{4-}$ anion (Figure 10). The structure of $[Os_2OCl_{10}]^{4-}$ shows a linear Os–O–Os unit with Os–O = 1.778(15) Å.[58] The Os–Cl distance for the Cl^- *trans* to O is elongated compared to the *cis*-Cl^- ligands, reflecting the trans influence of the μ^2-O bridge. A similar type of μ^2-O bridge, Os–O–Os = 1.808(3) Å, is observed in $[Os_2O(OEP)_2(OMe)_2]$ (**28**).[59] Related oxo bridged Os^{IV}/Os^{IV} complexes have been prepared with related porphyrin and polydentate ligands.



(**28**)

Mononuclear Os^{IV} porphyrin complexes of type [Os(porph) L_2] (L = OR, SR, Br) have been prepared and their

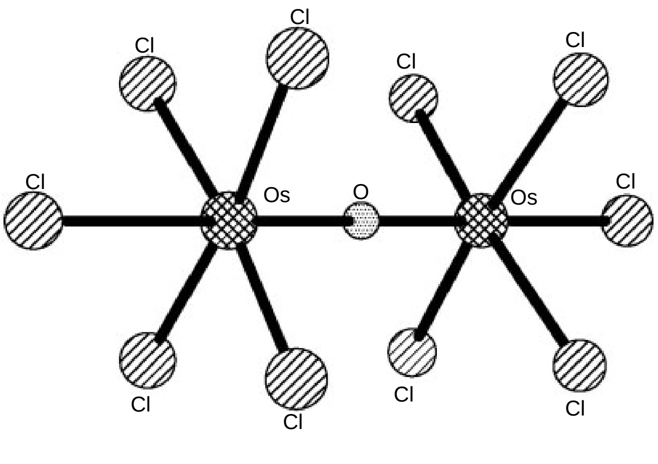


Figure 10 The structure of the diamagnetic anion $[Os_2OCl_{10}]$

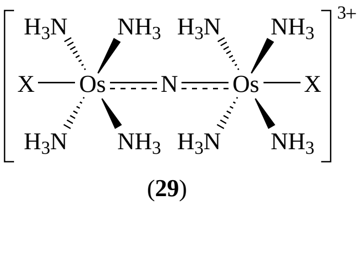
electrochemical oxidation to Os^{V} species assessed.[60] The convenient synthesis of bis(aliphatic amine)osmium(II), bis(arylamido)osmium(IV), and bis(imido)- and oxo(imido) osmium(VI) tetraphenylporphyrins have been reported. The latter two types of complexes were structurally characterised for the *t*-butylimido derivatives.[61]

The first X-ray structure of an Os^{IV} oxo complexes, *trans*-$[OsCl(O)(dcpe)_2]^+$ (dcpe = 1,2-bis(dicyclohexylphosphino) ethane), has been reported. Its formation proceeds via the activation of O_2 to form $[OsCl(\eta^2\text{-}O_2)(dcpe)_2]^+$, which then reacts with HCl gas. Although the complex $[OsCl(\eta^2\text{-}O_2)(dcpe)_2]^+$ readily displays oxo-transfer chemistry, for example, with phosphines, the oxo complex *trans*-$[OsCl(O)(dcpe)_2]^+$ is surprisingly stable and unreactive towards standard reducing agents such as phosphines.[62]

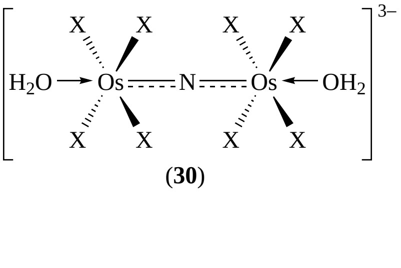
Trans-$[Os(en)_2(\eta^2\text{-}H_2)H_2O]^{2+}$ is readily converted in water to *trans*-$[Os(en)_2(\eta^2\text{-}H_2)\ Fe(CN)_6]^{2-}$, an Os^{II}–Fe^{II} species, which oxidises in air to afford $[Os(en)_2(H)H_2O\ Fe(CN)_6]$, an $Os^{IV-}Fe^{II}$ complex, in which it was suggested that the Os center can assume a coordination number of 7. The characteristics of the absorption spectrum indicate that the mixed valence molecule is localized and the absorption bands are associated with a $Fe(CN)_6{}^{4-} \rightarrow Os(IV)$ electron transfer.[63]

7.2 N-donor Complexes

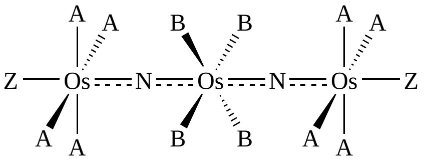
The most studied Os^{IV} complexes with N-donors are binuclear species incorporating linear Os–N–Os units. A range of complexes $[Os_2N(NH_3)_8X_2]^{3+}$ (**29**; X = Cl, Br, I, N_3, NO_3, NCS) and $[Os_2NX_8(H_2O)_2]^{3-}$ (**30**; X = Cl, Br, I) has been prepared and related to their Ru analogs. These complexes can be prepared conveniently from $[OsX_6]^{2-}$ (X = Cl, Br, I). Highly colored (violet) trinuclear species (**31**) incorporating a linear Os–N–Os–N–Os backbone can also be prepared by similar routes. As for the binuclear analogs, the ligands trans to the μ^2-N bridge are more labile than those at *cis* positions reflecting the high trans influence of μ^2-N bridges.[64]



(**29**)



(**30**)



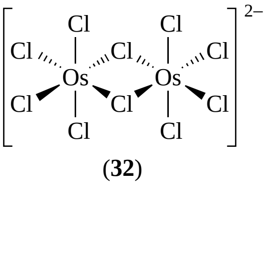
(**31**)

Mononuclear Os^{IV} complexes of amines have been reported although they remain, in general, ill-defined since deprotonation of the coordinated amine(s) occurs very readily. This reflects the relatively high positive charge at Os^{VI} and Os^{IV} and the resultant high pK_a of N–H protons in this environment. For example, $[Os(en)_3]^{4+}$ has been reported, although it is unstable with respect to deprotonation. A very unusual dihydrido complex thought to be $[Os(en)_2(H)_2]^{2+}$ (*see **Hydride Complexes of the Transition Metals***) can be prepared by reduction of the dioxo–Os^{VI} species $[OsO_2(en)_2]^{2+}$ (Figure 5) with Zn and HCl;[65] however, this complex was subsequently reassigned as $[Os(en)_2(\eta^2\text{-}H_2)Cl]^+$ (see below).

A novel example of oxygen activation based upon the ligand reactivity has been described in the Os^{IV}-sulfoximido complex, *cis*-$[(terpy)(Cl)_2Os{=}NSOC_6H_3Me_2]$. Upon addition of acid oxygen evolution is observed to form *cis*-$[(terpy)(Cl)_2Os{=}NSHC_6H_3Me_2]$, which, upon addition of bipyridine as base, reforms the initial complex in the presence of air.[66]

7.3 Halide and Hydride Complexes

A large literature has built up describing the synthesis, spectroscopic, and magnetic properties of the Os^{IV} hexahalo and mixed halo complexes $[OsX_6]^{2-}$ (X = Cl, Br, I). The complexes $[OsX_6]^{2-}$ (X = Cl, Br, I), in particular $Na_2[OsCl_6]$, are useful starting materials for a very wide range of Os^{II} and Os^{III} complexes.[3,4] Hydrolysis of $[OsX_6]^{2-}$ affords $[OsX_5(H_2O)]^-$ and $[OsX_5(OH)]^{2-}$ with other mixed aqua/hydroxy species postulated to exist in solution. The synthesis of the binuclear species $[Os_2X_{10}]^{2-}$ and $[Os_2X_8]$ (X = Cl, Br, I) from mononuclear precursors has been reported. The structure of $[Os_2X_{10}]^{2-}$ (X = Cl, **32**) shows an Os–Os distance of 3.626(1) Å, which increases to 3.788(3) Å for X = Br.[67] Electrochemical interconversion of $[Os_2Br_{10}]^{2-}$, $[Os_2Br_{10}]^{3-}$, $[Os_2Br_{10}]^{4-}$, and $[Os_2Br_{10}]^{5-}$ has been monitored; the latter species is unstable via loss of Br^- to afford $[Os_2Br_9]^{4-}$.[68]



(**32**)

Although tertiary phosphines PR_3 tend to stabilize lower valent states, particularly Os^{III} and Os^{II}, a number of Os^{IV} hydrido phosphine complexes are known. These include $[OsH_4(PR_3)_3]$, $[OsH_4(PR_3)(\mu^2\text{-dppm})]$, and $[OsH_4(PR_3)_2(\mu^1\text{-dppm})]$. The assignment of these complexes as terminal hydride or H_2 complexes is an important aspect of these systems. A series of Os^{IV} species $[OsX_4(L)_2]$ (X = Cl, Br; L = PEt_3, PPh_3, $PPhEt_2$, PPh_2Et, $AsPh_3$, $SbPh_3$, $SeMe_2$, py) has been reported.[69]

8 OSMIUM(III)/(II)

The vast majority of the coordination compounds of Os that have been prepared are in the oxidation states II and III. Moreover, many of these compounds show reversible or well defined $Os^{II/III}$ couples in which the electronic and redox properties at the metal are controlled by the σ-donor, π-acceptor, and π-donor properties of the ligands. Indeed, the study of the redox behavior in $Os^{II/III}$ and $Ru^{II/III}$ species, metal ions in which octahedral coordination is almost universally retained in both redox partners, has been central in recent developments to parameterize metal centered redox processes as a function of ligand donor and acceptor capacity.[70] The chemistries of Os^{II} and Os^{III} are, therefore, intimately linked, and have been extended to studies of important mixed valence $Os^{II/III}$ binuclear and polynuclear species (*see* ***Mixed Valence Compounds***). For the purposes of brevity and convenience, this section will deal with Os^{III} and Os^{II} complexes together. The extensive literature on $Os^{III/II}$ complexes has been developed with a very wide range of donor ligands; a comprehensive assessment of this work is beyond the scope of this article, and the reader is directed to published comprehensive reviews.[3,4]

In general, paramagnetic d^5 Os^{III} is stabilized by relatively good π-donor ligands such as halides, together with O-donor and certain thiolate S-donor ligands, while π-acceptor ligands such as bipy, phen, terpy, CN^-, thioethers, nitriles, and tertiary phosphines stabilize diamagnetic d^6 Os^{II}. The coordination geometries about Os^{III} and Os^{II} are almost invariably octahedral with electronic configurations $t_{2g}{}^5$ and $t_{2g}{}^6$ respectively.

8.1 Cyanide Complexes

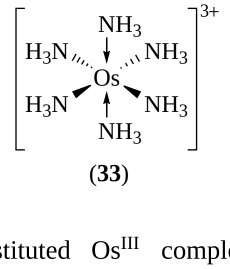
The CN^- ligand is a good π-acceptor and therefore stabilizes Os^{II} as in $[Os(CN)_6]^{4-}$. The 10 *Dq* value for $[Os(CN)_6]^{4-}$ is $>34\,000\,cm^{-1}$, significantly greater than for the Ru and Fe analogs. Interestingly the $M^{II/III}$ couples for the low-spin $t_{2g}{}^6$ complexes $[M(CN)_6]^{4-/3-}$ follow the order +0.12 (M = Fe), +0.62 (M = Ru), +0.36 V (M = Os) vs. Fc/Fc^+. The observation that the $Ru^{II/III}$ couple occurs at the most anodic potentials has also been observed for other homoleptic low-spin complexes (*see Homoleptic Compound*) of bipy, phenanthroline, and [9]aneS_3 (see below) and reflects the spatial and energy matches between the metal ion and the ligand donor sets.[71] CN^- coordination is also found in higher oxidation state species such as $[Os(CN)_6]^{3-}$, $[OsO_2(CN)_4]^{2-}$, and $[OsN(CN)_4(H_2O)]^-$.

8.2 N-donor Complexes

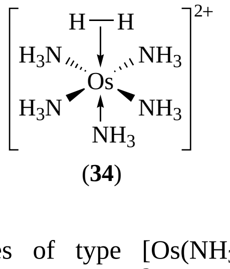
There is a large literature based on the coordination of ammines, monodentate and chelate amines (*see Monodentate Ligand*; *Chelating Ligands*), monodentate and chelate heterocycles, and porphyrin and mixed N/O and N/S donor ligands (*see* ***Mixed Donor Ligands***) to Os^{II} and Os^{III}. This is only surpassed by the even larger body of work on Ru^{II} and Ru^{III} analogs. Indeed, studies on N-donor complexes of Os parallel the work on Ru coordination compounds, particularly with respect to the photophysics of $[Ru(bipy)_3]^{2+}$ and electron transfer in Ru^{II}–Ru^{III} mixed valence complexes (*see also* ***Ammonia & N-donor Ligands***).[50]

8.2.1 Ammine Complexes

Reduction of Os^{IV} salts such as $[OsCl_6]^{2-}$ in the presence of NH_3 affords the stable $[Os(NH_3)_6]^{3+}$ (**33**); the analogous Os^{II} species $[Os(NH_3)_6]^{2+}$ is unstable with respect to oxidation to the Os^{III} complex. Thus for Os, the NH_3 ligand stabilizes the $t_{2g}{}^5$ rather than $t_{2g}{}^6$ configuration. This contrasts with the chemistry of Ru where $[Ru(NH_3)_6]^{2+}$ is a stable isolable complex. In order to stabilize Os^{II} in the presence of ammine ligands, π-acceptor ligands must also be present; thus $[Os(NH_3)_5(L)]^{2+}$ (L = CO, N_2, H_2, alkene) and $[Os(NH_3)_5NO]^{3+}$ (a complex containing formally NO^+ as a ligand) can be prepared. The complex $[Os(NH_3)_5(\eta^2\text{-}H_2)]^{2+}$ (**34**) is particularly intriguing and has been compared to the related H_2 complexes *trans*-$[Os(en)_2X(\eta^2\text{-}H_2)]^+$ (X = Cl, Br) and *trans*-$[Os(en)_2(\eta^2\text{-}H_2)py]^{2+}$.[72] The hydrogenation of naphthalene is catalyzed by the $[Os(NH_3)_5]^{2+}$ fragment under H_2[73] (*see* ***Hydrogenation & Isomerization of Alkenes***). Some coordination chemistry of Os–ammine complexes is summarized in Scheme 1.

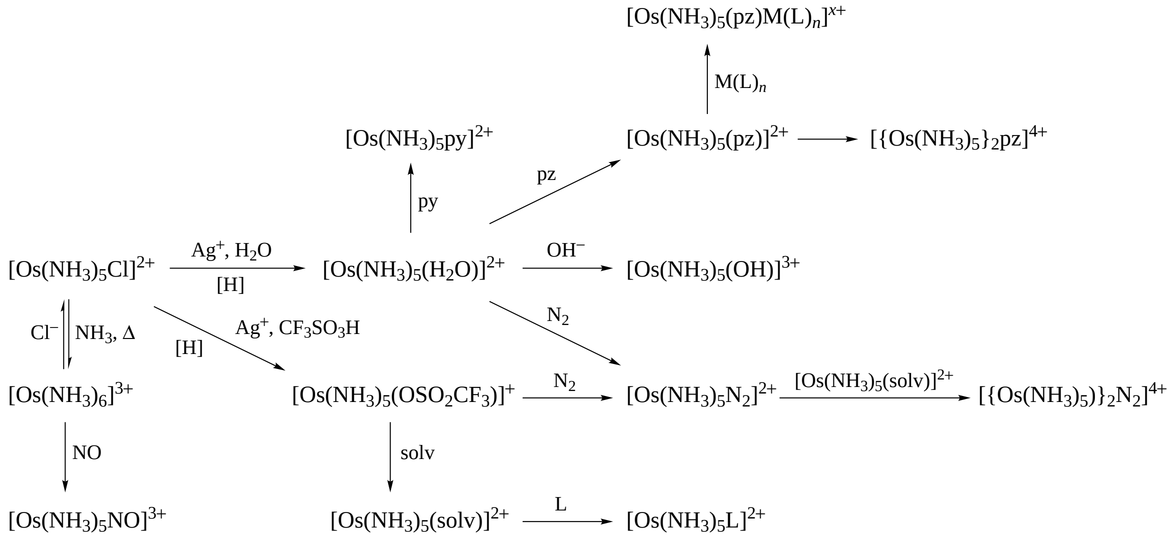


(**33**)



(**34**)

Substituted Os^{III} complexes of type $[Os(NH_3)_5X]^{2+}$ (X = Cl, Br, I, OH) and $[Os(NH_3)_5(H_2O)]^{3+}$ can also be prepared. Oxidation to Os^{IV} species such as $[Os(NH_3)_3Cl_3]^+$ and $[Os(NH_3)_4Cl_2]^{2+}$ has been reported, although these relatively high oxidation state materials tend to deprotonate

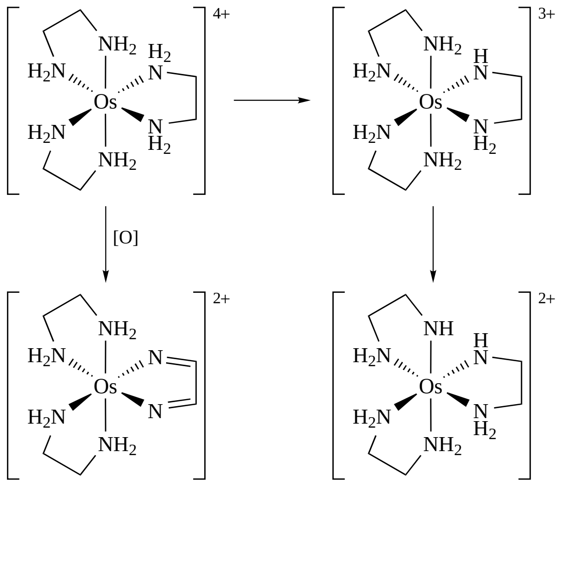


Scheme 1

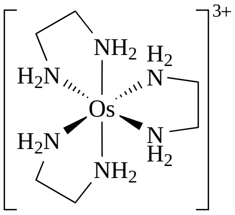
at the coordinated ammine and therefore are stabilized by acidic media.

8.2.2 Amine Complexes

Like NH_3, amine ligands, RNH_2, tend to stabilize Os^{III} rather than Os^{II}, for example, $[Os(en)_3]^{3+}$ (**35**). Oxidation of $[Os(en)_3]^{3+}$ affords Os^{IV} species which tend to be unstable, owing to deprotonation of the coordinated amine to give deprotonated en (en-H) complexes such as $[Os(en)_2(en\text{-}H)]^{3+}$ and $[Os(en\text{-}H)_2(en)]^{2+}$ (equation 5). The resultant amido ligands are strong π-donors, reflecting the net stabilization of Os^{IV} in these species. One such complex, $[Os^{IV}(en\text{-}H)_2(en)]^{2+}$ (Figure 11), has been structurally characterized and shows shortened Os–N(amido) bond lengths, suggesting multiple M=N bond character.[74] Additionally, imino and diimino complexes incorporating C=N linkages can be isolated. These species are formed via oxidative dehydrogenation of coordinated amines; this reactivity is paralleled in Ru chemistry.



(5)



(**35**)

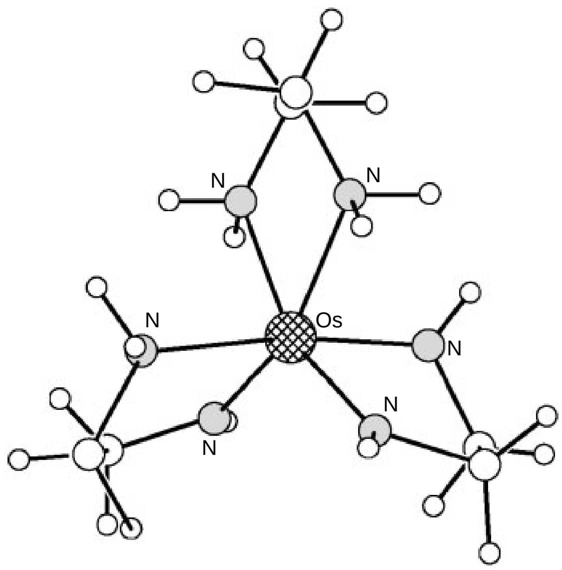


Figure 11 The structure of $[Os(en\text{-}H)_2(en)]^{2+}$

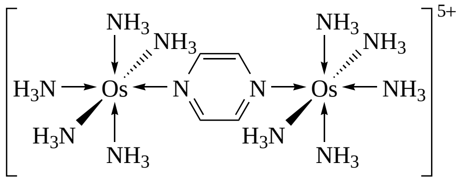
In general, Os complexes are highly effective for the oxidative dehydrogenation of coordinated amine and alcohol

ligands. This is due to their ability to attain oxidation states that are two electrons apart. This is stabilized by deprotonation and formed by disproportionation to provide a low-energy route for even-electron transfer required in ligand dehydrogenation processes.[75]

8.2.3 *Heterocyclic Complexes*

A wide range of mixed ligand Os^{II} and Os^{III} complexes incorporating py, substituted py, and related heterocyclic amines have been reported. These include $[OsCl_2(py)_2(CO)_2]$, $[Os(NH_3)_5py]^{2+/3+}$, $[OsX_2py_4]$ (X = Cl, Br), and $[OsCl_2py_3(PPh_3)]$. Mononuclear pyrazine, pyrimidine, and pyridazine (L) complexes of type $[Os(NH_3)_5(L)]^{2+}$ and the protonated forms $[Os(NH_3)_5(LH)]^{3+}$ have been reported, the pK_a of LH being higher in the complex than for the free protonated heterocycle.[76]

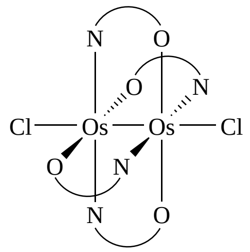
The formation of binuclear complexes using bifunctional ligands has been an important area in Os chemistry. The pyrazine bridged complexes $[(H_5N)_5Os(pz)Os(NH_3)_5]^{4+/5+/6+}$ represent the Os analogs of the famous Ru^{II}–Ru^{III} mixed valence Creutz–Taube ion $[(H_5N)_5Ru(pz)Ru(NH_3)_5]^{5+}$ (*see* ***Ruthenium: Inorganic & Coordination Chemistry***). $[(H_5N)_5Os(pz)Os(NH_3)_5]^{4+/5+/6+}$ can be readily prepared from the highly labile mononuclear precursor $[Os(NH_3)_5(OSO_2CF_3)]^{2+}$ (Scheme 1), $[(H_5N)_5Os(pz)Os(NH_3)_5]^{5+}$ (**36**) being categorized as a delocalized Class III mixed valence complex with formal oxidation state $Os^{II.5}Os^{II.5}$.[77]



(**36**)

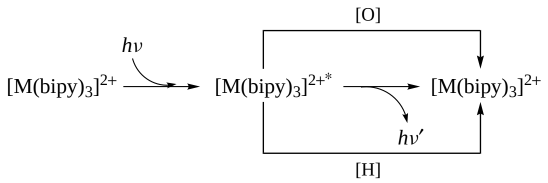
Another class of binuclear complexes are those incorporating bridging chelate ligands. For example, reaction of $OsCl_3$ with 2-hydroxypyridine (hp) gives a dinuclear species $[Os_2(hp)_4Cl_2]$ (**37**) (μ_{eff} = 1.44 BM) with hp bridging two Os centers, Os–Os = 2.344(2) Å; in the complex $[Os_2(hp)_4Cl_2(NCMe)_2]$ the Os–Os distance is elongated to 2.357(1) Å.[78]

Bidentate heterocyclic chelate ligands (*see Bidentate Ligand*) such as bipy, phen, and their substituted derivatives (LL) form tris-chelate complexes of the type $[Os(LL)_3]^{2+}$, the Os^{II} oxidation state being stabilized by these π-acceptor ligands. A wide variety of methods can be employed to



(**37**)

prepare these species, one of the best being the reaction of LL with $[OsCl_6]^{2-}$ at elevated temperatures. The main interest in these types of complex derives from the use of the Ru^{II} analogs $[Ru(LL)_3]^{2+}$ as photosensitizers, the excited state of $[Ru(bipy)_3]^{2+*}$ being relatively long lived ($t_{1/2}$ = 6.0 μs). The excited state complex can be assigned as a Ru^{III}–bipy radical anion species in which an electron has been excited via irradiation within the metal-to-ligand charge transfer manifold to form an oxidized metal and reduced ligand center (equation 6). This principle of 'charge separation' is the basis of potential solar traps and photochemical catalysts. As a result of this interest in Ru chemistry, there is an extensive literature based on the coordination chemistry, spectroscopy, and photophysics of tris-chelate Os^{II} complexes $[Os(LL)_2]^2$.



(6)

Although many tris-chelate complexes of Os^{II}, $[Os(LL)_3]^{2+}$, are luminescent, the lifetimes of the Metal to Ligand Charge Transfer (MLCT) excited state species $[Os(LL)_3]^{2+*}$ are, in general, substantially shorter than those of the Ru analogs. This reflects the efficient quenching of the third-row metal radical via spin–orbit coupling, leading to enhanced radiative and nonradiative decay rates for the triplet–singlet transitions.[79] Interestingly, the lifetimes of the excited state species $[Os(LL)_3]^{3+*}$ (LL = bipy, phen) are some 10^6 times less than for $[Ru(LL)_3]^{2+*}$. Quenching of this excited state species by a variety of electron transfer agents such as Fe^{III} and Co^{III} ions has been reported. The luminescent and redox properties of supramolecular polynuclear transition metal complexes have been comprehensively reviewed.[3,4,80]

The complex $\{\Lambda\text{-}[Ru(bpy)_3]\Delta\text{-}[Os(bpy)_3]\}(PF_6)_4$ exhibits alternating layers of $\Lambda\text{-}[Ru(bpy)_3]^{2+}$ and $\Delta\text{-}[Os(bpy)_3]^{2+}$. Interestingly, this novel hetero-racemic material is characterized by the specific property that the excitation energy is efficiently transferred to and accumulated at the site of lowest energy, that is, the $\Delta\text{-}[Os(bpy)_3]^{2+}$ complex and this is the

only site which emits. Furthermore, the emission spectrum is completely altered under the application of a magnetic field.[81]

The complexes $[Os(LL)_3]^{2+}$ can be oxidized chemically or electrochemically to $[Os(LL)_3]^{3+}$, the $Os^{II/III}$ couples being related to the photophysical behavior of the 2+ complexes. A substantial amount of work has been carried out on the outer-sphere electron transfer to $[Os(LL)_3]^{3+}$ (a good one-electron oxidant that is co-ordinatively stable) with a range of reductants such $[Fe(CN)_6]^{4-}$ (*see* ***Electron Transfer in Coordination Compounds***).

The substitution chemistry of Os–bipy complexes is illustrated in Scheme 2. A wide variety of mixed ligand Os^{II} and Os^{III} (and some Os^{IV}) bipy species can be prepared. Many of the complexes $[Os(bipy)_2X_2]^{x+}$ have *cis* geometries in order to minimize steric interactions (*see Steric Effect*) between the bipy ligands.

One of the more important aspects of complexes of the type *cis*-$[Os(bipy)_2(L_2)]^{2+}$ (L = vinylpyridine) is their use as derivatives to form electroactive polymer films. Thus polypyridine films containing redox-active $Os^{II/III}$ centers can be generated by electropolymerization of the coordinated vinylpyridine ligands of the parent complex from homogeneous solution.[82] Importantly, these polypyridyl films contain redox-active Os fragments at each unit.

The electrochemical reduction of CO_2 by *cis*-$[Os(bipy)_2(CO)Cl]^+$ has been the subject of much interest. Under anhydrous conditions CO is formed, while in the presence of H_2O formate ion is formed additionally.[83] The Os^{II} complex *cis*-$[Os(bipy)_2(H_2O)_2]^{2+}$ can be oxidized via a series of steps to the corresponding Os^{VI} species *cis*-$[Os(bipy)_2(O)_2]^{2+}$ (equation 7).[84]

$$[Os^{II}(bipy)_2(H_2O)_2]^{2+} \longrightarrow [Os^{III}(bipy)_2(OH)(H_2O)]^{2+} \longrightarrow [Os^{IV}(bipy)_2(O)(H_2O)]^{2+} \longrightarrow [Os^{V}(bipy)_2(O)(OH)]^{2+} \longrightarrow [Os^{VI}(bipy)_2(O)_2]^{2+} \quad (7)$$

A range of Os complexes of terpy has been prepared. Like bipy and phen, terpy tends to stabilize Os^{II}, and so reaction of $[OsCl_6]^{2-}$ with terpy at high temperature affords the highly stable complex $[Os(terpy)_2]^{2+}$. Aspects of the substitution chemistry of Os–terpy complexes are summarized in Scheme 3.

As for the bipy analogues, the interconversion of aqua to oxo ligand can occur on oxidation of $[Os(terpy)(bipy)(H_2O)]^{2+}$ (equation 8).[85] The formation of asymmetric complexes $[Os(LL)_2]^{2+}$ (LL = substituted terpy) has been accomplished; these species incorporate a donor substituent on one terpy and an acceptor substituent on the other, thus facilitating intramolecular electron transfer in MLCT excited state, $[Os(LL)_2]^{2+*}$.[86]

$$[Os^{II}(terpy)(bipy)(H_2O)]^{2+} \longrightarrow [Os^{III}(terpy)(bipy)(OH)]^{2+} \longrightarrow [Os^{IIV}(terpy)(bipy)(O)]^{2+} \quad (8)$$

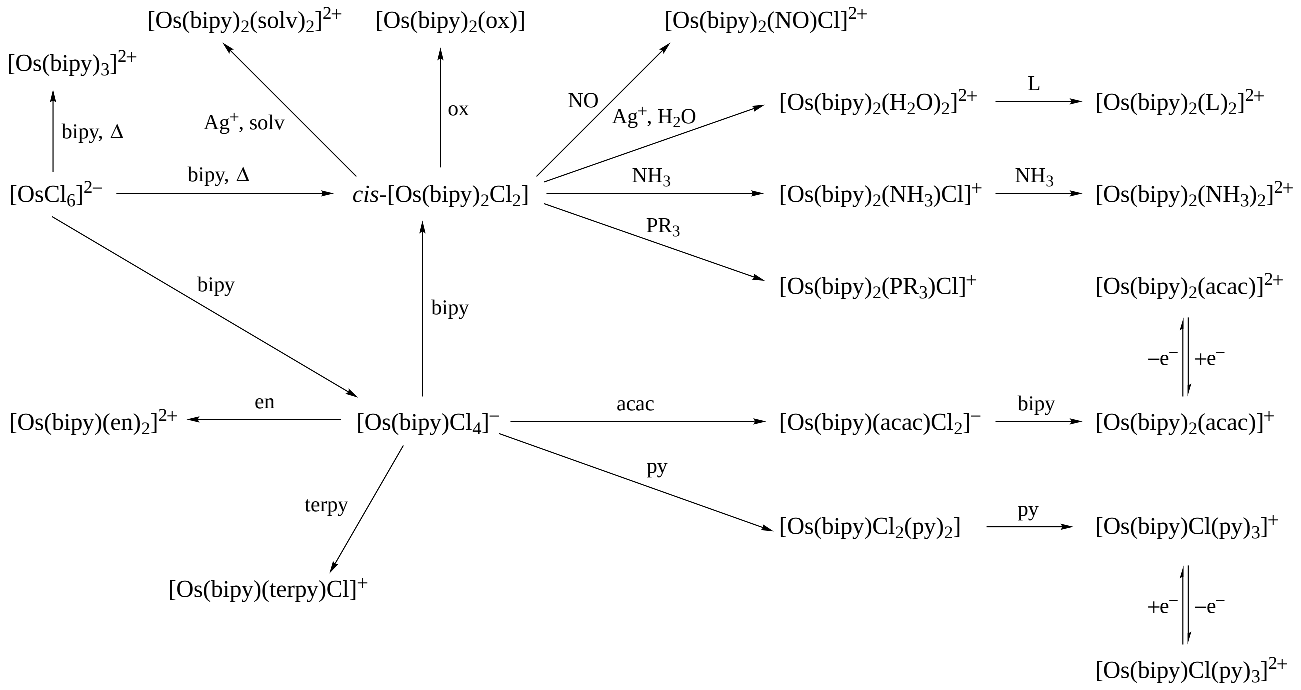
Heterobimetallic complexes of Os^{II} and Ru^{II} bipy have been covalently linked via peptide-bridges derived from L-proline and L-leucine. Efficient intramolecular quenching of the Ru^{II} excited state by the Os^{II} complex was observed.[87] Heterobimetallic complexes of Os^{II} and Ru^{II} have been prepared with 2,2′:3′,2″:6″,2‴-quaterpyridine where two bipy ligands are directly linked together, and efficient intramolecular photo-induced electron transfer observed (Figure 12). Attachment of nucleobases to bipy ligands has afforded heterobimetallic complexes of Os^{II} and Ru^{II} via Watson–Crick base pair formation, and efficient intramolecular electron transfer is observed across the hydrogen-bonded interface. Also, attachment of two bipyridyl ligands by poly(oxoethylene) chains yields complexes whose conformation is solvent dependent. Consequently, by control of the solvent polarity the Os-Ru distance can be modulated and correspondingly the Ru → Os energy transfer rate.[88]

In a related manner, bipyridyl units have been linked by a redox-active benzoquinone (bq) spacer, which acts as a redox switch in the Ru-bq-Os complex.[89]

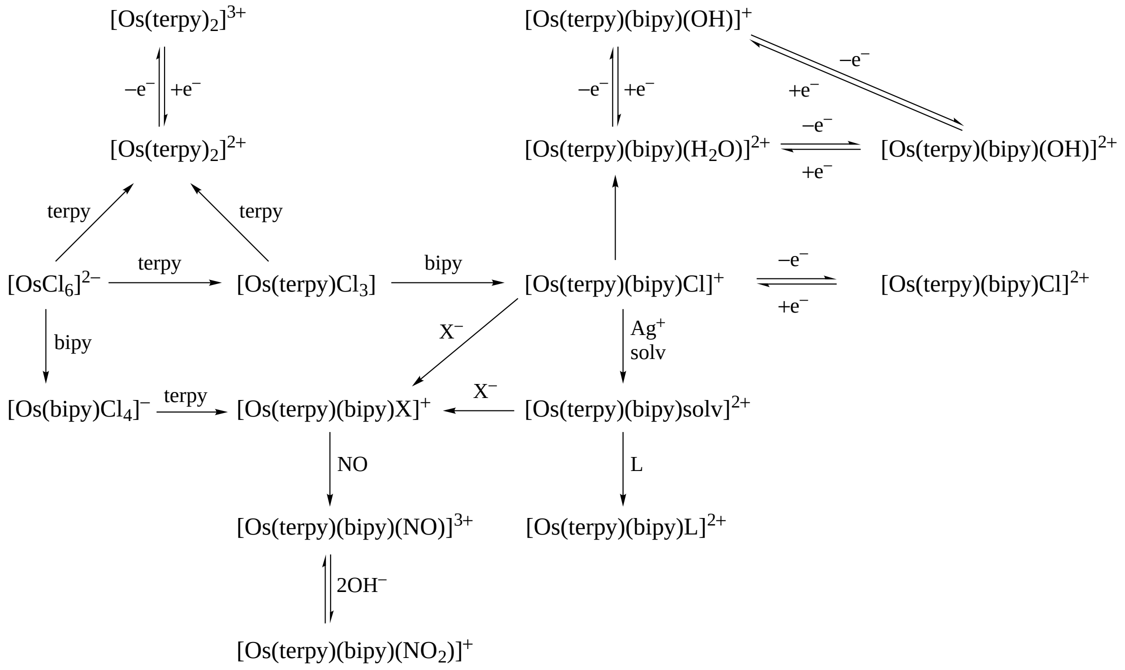
Os^{II} and Ru^{II} bis(terpyridine) complexes have been covalently linked (Figure 13) and their electrochemical, absorption spectra, photochemical and photophysical properties have been studied. The strong electronic interaction decreases as the one or two phenylene spacers are added but remains large enough to allow fast electron transfer.[90]

A series of Ru-Os terpy complexes have been reported with the terpy ligands separated by an a 1,4-diethynylene-2,5-dialkoxybenzene connector. Each additional 1,4-diethynylene-2,5-dialkoxybenzene unit in the bridge contributes about 8.1 Å to the length and decreases the rate of electron transfer by a factor of three.[91] An Os bis(terpyridine) complex has been designed where one terpy ligand incorporating a hydrophobic biphenylene tail inserts into a cyclodextrin which in turn is attached to a ruthenium terpyridine complex. It has been shown that this supramolecular complex displays fast electron transfer with a rate of $9.5 \times 10^9\ s^{-1}$.[92] Similarly, Os and Ru phenanthroline complexes have been linked by an adamantane spacer, the life-time of the Ru^{III}–Os^{II} intermediate being particularly long (130 µs) with the electron transfer rate from Ru^{II} to Os^{II} being faster than for Ru^{II} to Os^{III}.[93]

Two short reviews on the chemistry of mixed Ru^{II} and Os^{II} dendrimers $[M(L)_n(BL)_{3-n}]^{2+}$ (L = 2,2′-bipyridine or 2,2′-biquinoline; BL = 2,3- or 2,5-di-pyrindin-2-yl pyrazine; $n = 0$ or 2) have been published.[94,95] The energy transfer between units is very fast due to sufficiently strong electronic interaction; for the complexes of 2,3-dpp this takes place within 200 fs. Therefore, these dendrimers can be used to perform valuable functions such as light harvesting and the controlled storage or release of a given number of electrons at a certain potential.[94,95] This work has been further extended to include decanuclear dendrimers bearing three different metal ions for example, Os{(μ-2,3-dpp)Ru-[(μ-2,3-dpp)$PtCl_2]_2\}_3(PF_6)_8$. Also, tetranuclear dendrimers with Os^{II}



Scheme 2



Scheme 3

at the core and three external Ru^{II} complexes associated with six pyrenyl chromophores attached to the periphery have been described. The aim here is to harvest light and promote a periphery to core energy transfer.[96]

The intercalation of several Os^{II} complexes such as $[Os(Phen)_2(dppz)]^{2+}$ dppz = dypyrido[3,2-a:2′,3′-c]phenazine and charge transfer through the DNA base stack has been reviewed.[97] Os^{II} complexes have also been tethered

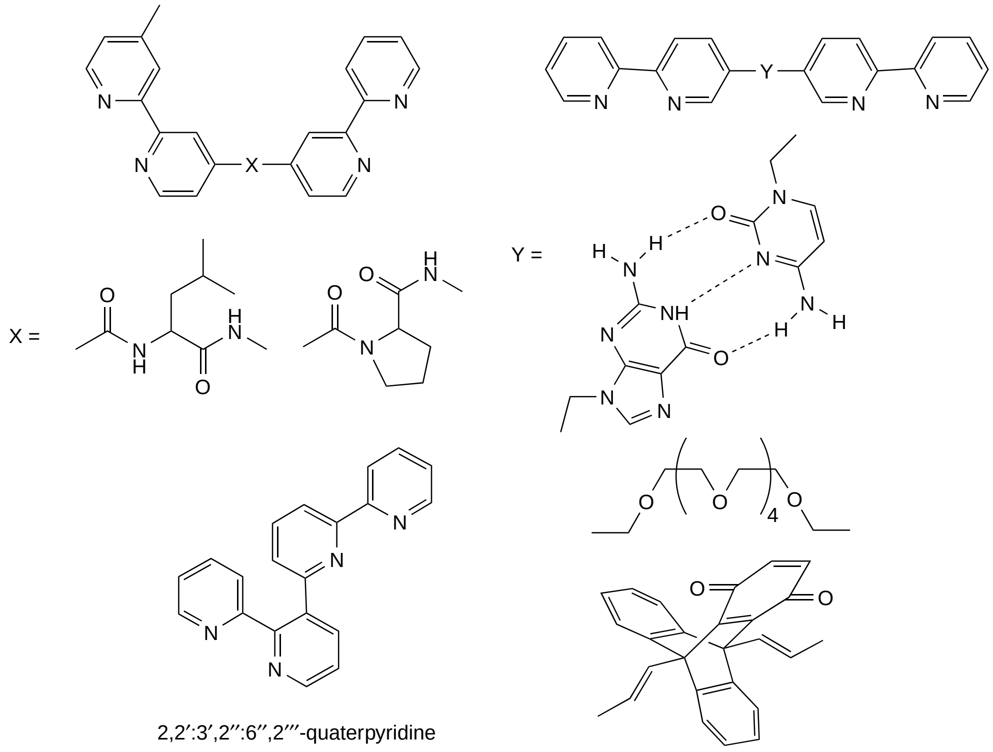


Figure 12 Bipyridyl ligands used to form heterobimetallic complexes of Os^{II} and Ru^{II}

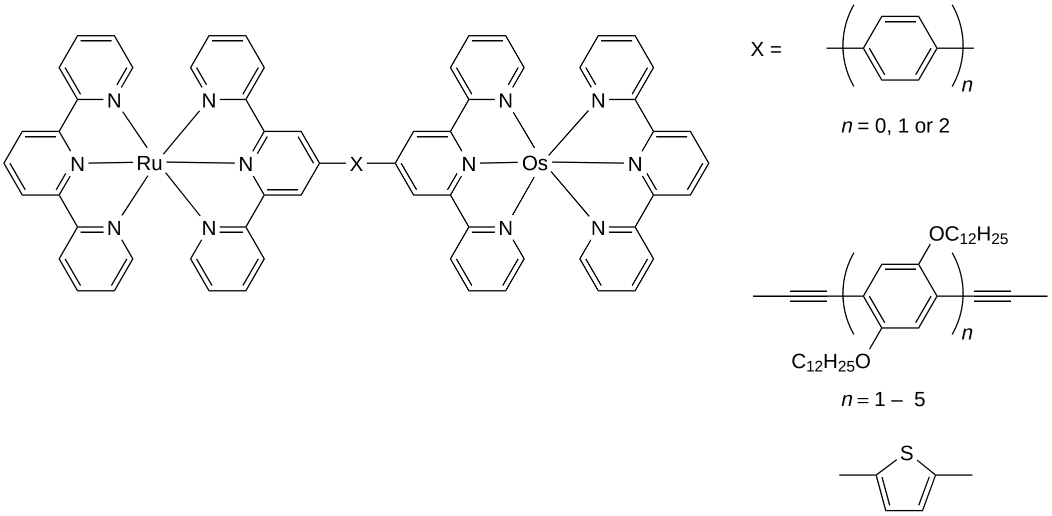

Figure 13 Terpyridyl heterobimetallic complexes of Os^{II} and Ru^{II}

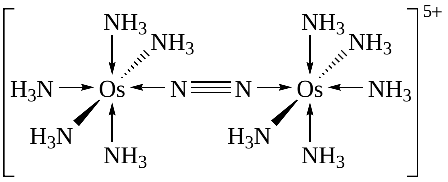
to DNA to study the triplet energy transfer between metallointercalators.[98]

8.2.4 N_2 Complexes

Coordination of the π-acceptor N_2 ligand is most often found for Os^{II}, although some dinitrogen complexes of Os^{III} are known (*see Dinitrogen & Dinitrogen Complexes*). These complexes are generally prepared by substitution reaction at Os^{II} with N_2, or by controlled oxidation of coordinated NH_3 ligands with KNO_2 under acidic conditions. In the complex $[Os(NH_3)_5(N_2)]^{2+}$ (Figure 14), the N_2 ligand is bound terminally, Os–N = 1.842(13) Å, with Os–N(NH_3) = 2.144(15), 2.151(15) Å,[99] the shorter bond to N(N_2), reflecting the strong π-back donation (*see Back Bonding*) from Os^{II} to N_2. Other N_2 complexes include $[Os(NH_3)_4(N_2)(CO)]^{2+}$,

$[Os(NH_3)_4(N_2)_2]^{2+}$, $[OsCl(N_2)(PMe_2Ph)_3(SC_6F_5)]$ (Figure 15),[100] and $[Os(H)_2(N_2)(PEtPh_2)_3]$.



(**38**)

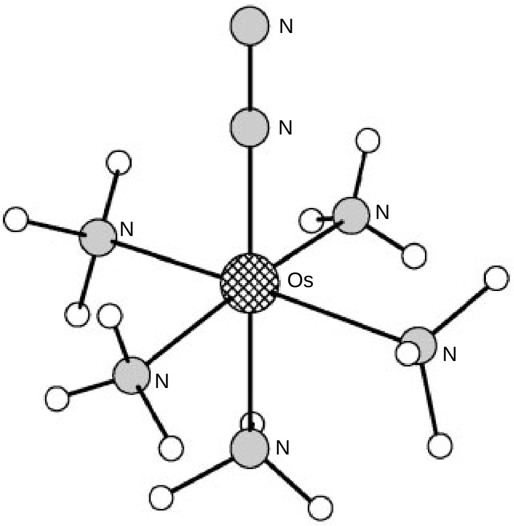


Figure 14 The structure of $[Os(NH_3)_5(N_2)]^{2+}$

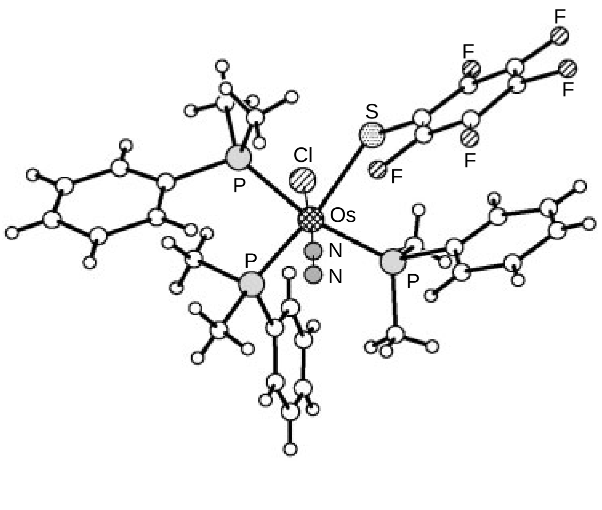

Figure 15 The structure of $[OsCl(N_2)(Pme_2Ph)_3(SC_6F_5)]$

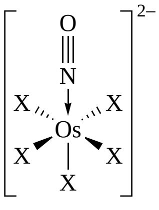
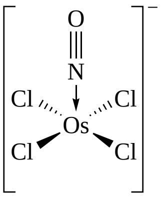
Bridging N_2 complexes can also be prepared. Thus reaction of $[Os(NH_3)_5(N_2)]^{3+}$ with $[Os(NH_3)_5(H_2O)]^{2+}$ affords the mixed valence Os^{II}–Os^{III} dimer $[(H_3N)_5Os(\mu^2\text{-}N_2)Os(NH_3)_5]^{5+}$ (**38**), which can be reduced to the 4+ and oxidized to the 6+ ions.[101] Other μ^2-N_2 complexes include $[(H_3N)_4(OC)Os(\mu^2\text{-}N_2)Os(CO)(NH_3)_4]^{4+}$ and $[(H_3N)_4ClOs(\mu^2\text{-}N_2)OsCl(NH_3)_4]^{3+}$.

8.2.5 Nitrosyl Complexes

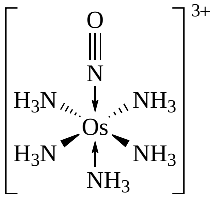
The chemistry of metal nitrosyls has been reviewed.[102] Most NO complexes of Os are regarded as formally NO^+ complexes with terminal, linear coordination of the ligand (*see Nitrosyl Complexes*). Most of the complexes are of d^6 Os^{II}, although there are examples of d^5, d^7, d^8, d^9, and d^{10} Os centers with NO^+ and related ligands. The stabilization of low oxidation state Os species reflects the very strong π-acceptor properties of NO^+, NO^+ being isoelectronic with CO and one of the strongest π-acceptor ligands known. The coordination chemistry of NO^+ with Ru is much better developed than that with Os, but there are clear similarities and parallels between them. Coordinated NO^+ can be readily characterized by IR spectroscopy, the $\nu_{N\equiv O}$ stretching vibration occurring in the range 1900–1800 cm^{-1}. Most of the Os–NO^+ complexes incorporate other ligands and are commonly prepared either by substitution reactions with NO or by reactions with NO_2^-, NH_2OH, or N_2H_4, or by oxidative reactions (*see Oxidative Addition*) of substrates to formal Os^0 and Os^{-II} species such as $[OsCl(NO)(PR_3)_2]$ and $[Os(NO)_2(PPh_3)_2]$ (see Section 9). Common examples of Os–NO^+ complexes include $[Os(NO)X_5]^{2-}$ (**39**) (X = F, Cl, Br, I), $[Os(NO)Cl_4]^-$ (**40**), $[Os(NH_3)_5NO]^{3+}$ (**41**), and $[OsX_2(OH)(NH_3)_2(NO)]$ (**42**).



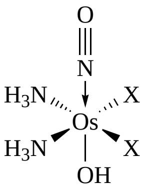
(**39**)



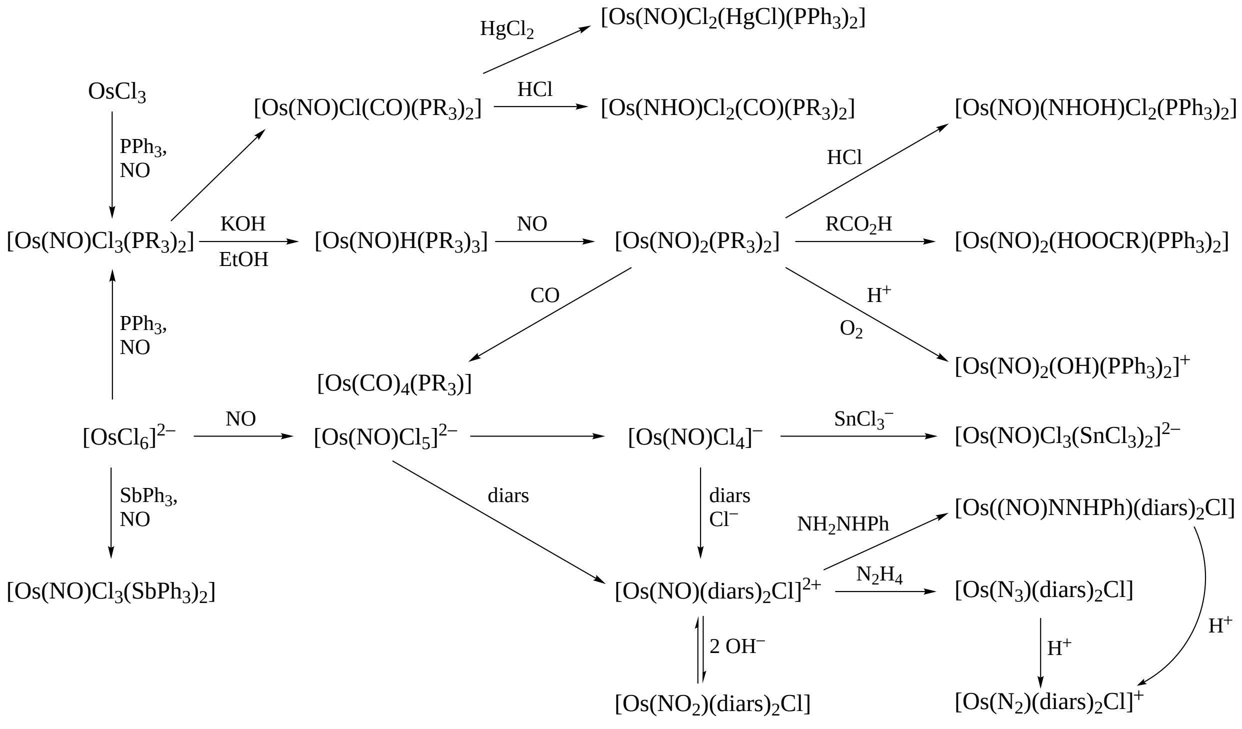
(**40**)



(**41**)



(**42**)



Scheme 4

A complication in NO^+ coordination chemistry is that reactions can occur at the metal center or at the NO^+ center to afford other N-containing ligands such N_2, $NO_2{}^-$, or NH_2OH. Some of the reactions of coordinated NO^+ are illustrated in Scheme 4.

Examples of complexes incorporating hydrazine (NH_2NH_2), HNO, RN_2, NS, and NSCl have also been reported.

8.2.6 *Macrocyclic Complexes*

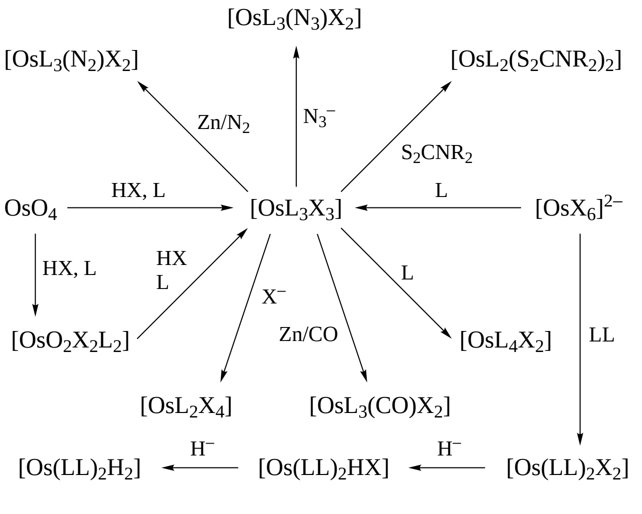
The chemistry of Os with macrocycles (*see Macrocycle*) is dominated by complexes of OEP, tetraphenylporphyrin (TPP), and related porphyrins. Insertion of Os into these ligands occurs under vigorous conditions (typically using Os_3CO_{12} or related CO containing low-valent Os starting material, *see Metal Carbonyls*) in the presence of py to give [Os(OEP)(CO)(py)] and [Os(TPP)(CO)(py)]. These complexes can be converted to $[Os(porph)(L)_2]$ (L = py, PR_3, tetrahydrofuran (THF), imid, MeCN) by photolytic removal of CO. Thermolysis of $[Os(OEP)py_2]$ affords the highly novel Os=Os bonded dimer $[Os(OEP)]_2$ (equation 9).[103] The complex $[Os(OEP)(\eta^2\text{-}H_2)]$ has been reported[104] as have binucleating porphyrins which insert H_2 into the Os=Os bond (equation 10).[105] Complexes of octaethylporphyrin complexes with Os^{II} have been dimerised to form homometallic and heterobimetallic (the latter with Ru porphyrins) complexes. The electrochemical and magnetic properties have been studied to illustrate the bonding in various oxidation states, particularly relating to the formation of δ-bonds.[106]

By comparison, the chemistry of Os phthalocyanins (Pc) is less well developed, mainly because of their much lower solubility. Reaction of $OsCl_3$ with *o*-cyanobenzamide in naphthalene at 290 °C followed by extended extraction affords '[OsPc]'. Reaction with ligands L affords the complexes $[Os(Pc)(L)_2]$ (L = py, pz, tz). Addition of one equivalent of L affords the polymers $[Os(Pc)(L)]_n$ (L = pz, tz).[107] Examples of Os complexes with saturated polyaza macrocycles have been reported.

$$[Os(OEP)(CO)py] \xrightarrow[py]{h\nu} [Os(OEP)py_2] \xrightarrow{\Delta} (OEP)Os{=}Os(OEP) \quad (9)$$

$$(L)(porph)Os{=}Os(porph)(L) \xrightarrow{H_2} (L)(porph)Os{-}H_2{-}Os(porph)(L) \quad (10)$$

A novel Os^{II} and Ru^{II} bis(bipyridyl) containing an amide macrocyclic receptor has been shown to detect the presence of anions by both electrochemical and optical methodologies. Photophysical studies have clearly shown that the rate constants of the energy transfer process responsible for the quenching of the luminescent ruthenium excited state significantly decreases in the presence of chloride ions.[108]



Scheme 5

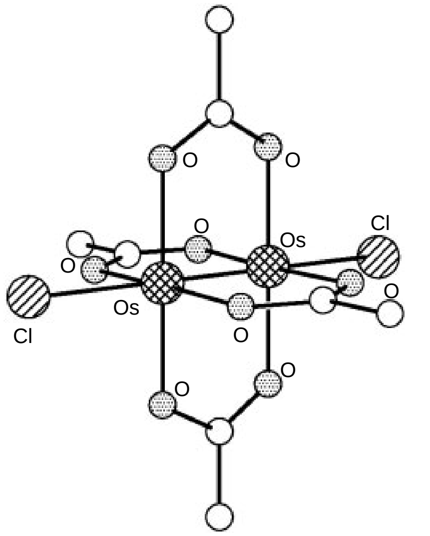


Figure 16 The structure of $[Os_2(OCOMe)_4Cl_2]$

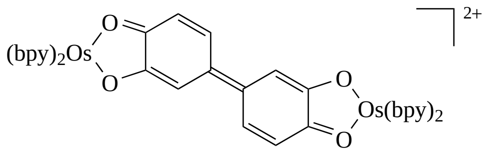
8.3 P-, As-, and Sb-donor Complexes

The chemistry of Os with PR_3, AsR_3, and SbR_3 ligands is very extensive and rich, and is based largely about the substitution chemistry of octahedral, mixed ligand Os^{II} complexes, although there are examples extending from Os^{-II}, for example, $[Os(NO)_2(PPh_3)_2]$, to Os^{VI}, for example, $[OsO_2(en)(PR_3)_2]^{2+}$.[3,4] Scheme 5, in which reactivity depends upon L (= tertiary phosphine) and LL (= chelate phosphine), illustrates aspects of the substitution chemistry of Os–phosphine complexes.

An interesting series of Os–phosphine hydride and polyhydride complexes spanning formal oxidation states of Os^{II} to Os^{VI} has been prepared. Scheme 6, in which reactivity depends upon L (= tertiary phosphine), illustrates the synthesis of some of the more important polyhydrides including complexes of type $[Os(L)_2(dppe)H_2]$, $[Os(L)H_4]$, $[Os(L)_4H_3]^+$, and $[Os(L)_3H_6]$ ($L = PR_3$). The question of whether these complexes should be regarded as genuine η^1-polyhydrido (H^-) or η^2-dihydrogen (H_2) complex has caused controversy, the precise formulation being very sensitive to the types of ligand present.[109] *Trans*-$[Os(H\cdots H)(H)(depe)_2]^+$ is a fascinating case of an η^2-dihydrogen ligand with a long $H\cdots H$ distance on the brink of homolytic cleavage,[110] the corresponding dppe complex being assigned as *trans*-$[Os(H_2)(H)(dppe)_2]^+$ with a short H–H bond. $[OsH_6\{P(i\text{-}Pr)_3\}_2]$ shows relatively short but nonbonding $H\cdots H$ distances as determined by neutron diffraction, and is assigned as a hexahydride.[111]

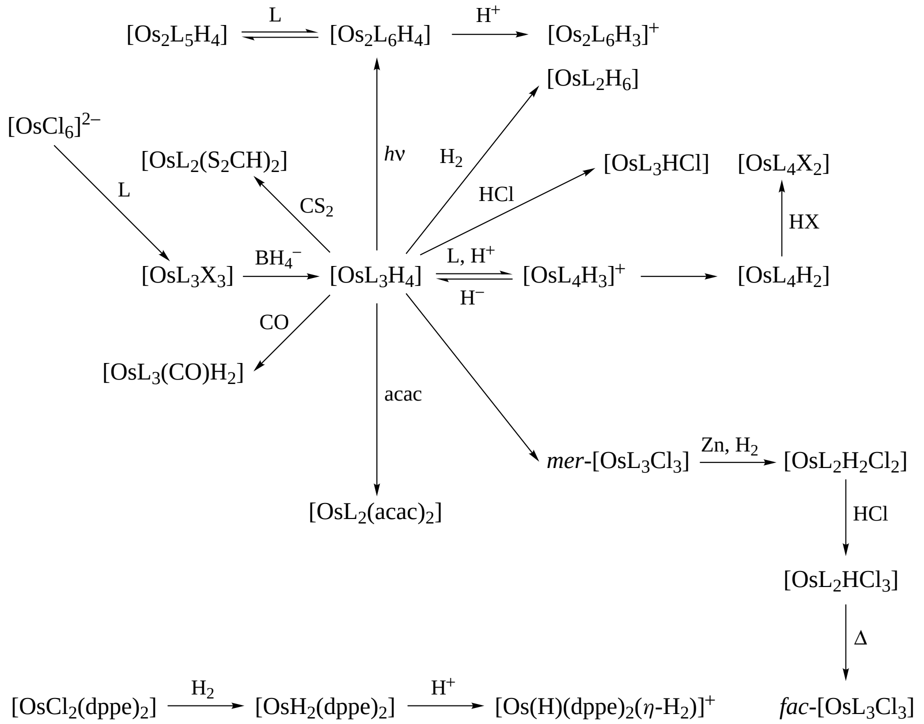
8.4 O-donor Complexes

The chemistry of Os with O-donors (*see* ***Water & O-donor Ligands***) is dominated by high-valent Os^{VI}–Os^{VIII} oxo complexes incorporating the Os=O and osmyl O=Os=O units. Although H_2O ligation occurs readily in mixed ligand complexes of Os^{III} and Os^{II}, the chemistry of $[Os(H_2O)_6]^{3+}$ is ill-defined with the formation of oxo–Os^{IV} species being prevalent. Surprisingly few alkoxide, diketonate, oxalate, nitro, sulfato, and carboxylate complexes have been well characterized. An interesting peroxo complex, $[Os(O_2)(CO)_2(PPh_3)_2]$ (*see Peroxo Complexes*), has been reported as the product of the reaction of O_2 with $[Os(CO)_2(PPh_3)_2]$.[112] An important series of binuclear complexes incorporating bridging carboxylates and other bifunctional ligands has been characterized. Thus reaction of $[OsCl_6]^{2-}$ with acetic anhydride and acetic acid affords the Os^{III}–Os^{III} complex $[Os_2(OCOMe)_4Cl_2]$ in good yield; reaction of $[Os_2(OCOMe)_4Cl_2]$ with other acids, RCOOH, yields $[Os_2(OCOR)_4Cl_2]$ (R = typically Pr, Bu). The structure of $[Os_2(OCOMe)_4Cl_2]$ (Figure 16) confirms an Os–Os distance of 2.316(2) Å[113]. The complexes $[Os_2(OCOR)_4Cl_2]$ are paramagnetic at room temperature (μ_{eff} = approx 1.2 BM per Os). Diosmium tetracarboxylates have been the subject of a recent review discussing their synthesis, physical properties and applications. Such complexes have been isolated as $Os^{II}Os^{II}$, $Os^{III}Os^{III}$ and mixed valence $Os^{II}Os^{III}$ dimers.[114]



(43)

The redox noninnocence of Os^{II} and Ru^{II} dioxolene complexes and of their nitrogen donor analogues has



Scheme 6

recently been discussed in a short review. The complex (**43**) is best described as a Os^{III}(catecholate−catecholate)Os^{III} species with cyclic voltammetry displaying two metal based reduction peaks and two ligand based oxidation peaks. In contrast, the Ru analogue is best described as a Ru^{II}(semiquinone−semiquinone)Ru^{II} complex.[115]

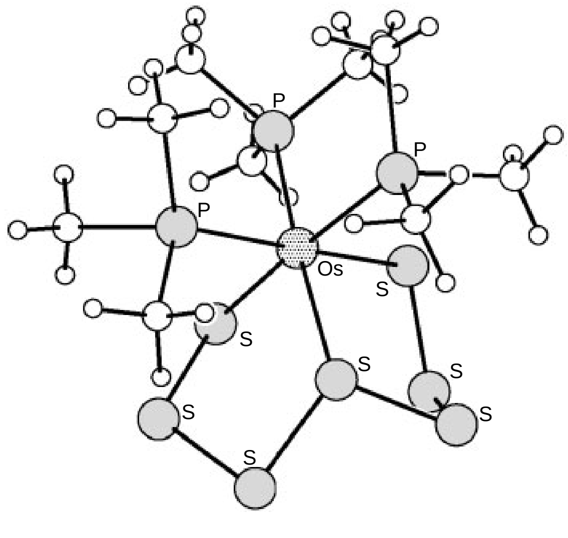


Figure 17 The structure of $[Os(PMe_3)_3(S_2)]$

8.5 S-donor Complexes

The chemistry of Os with S-donors is not well established. This is surprising, considering the expected match between soft Os^{II} and soft S-thioether and thiolate donors. Reaction of $[Os(PMe_3)_3(H)(CH_2PMe_2)]$ with elemental S (S_8) (*see* ***S-donor Ligands***; ***Sulfur: Inorganic Chemistry***) affords two products, $[Os(PMe_3)_3(S_6)]$ and $[Os(PMe_3)_3(S_7)]$ (Figure 17), the latter incorporating a tridentate S_7^{2-} ligand.[116] The homoleptic thioether complex $[Os([9]aneS_3)_2]^{2+}$ (Figure 18) has been prepared and shows Os–S = 2.3313(18)−2.3408(20) Å.[71] Furthermore, a mixed sandwich complex Os(4-$MeC_6H_4Pr^i$)([9]aneS_3) has been structurally characterised.

Trans-$[OsCl_2(Me_2SO)_4]$ reacts with excess hydrazine hydrochloride to form *mer*-$[OsCl_3(NH_3)_4(Me_2S)]$ in a concerted reaction. Overall this reaction involves oxidation of Os, deoxygenation of dimethylsulfoxide (DMSO), disproportion of hydrazine, and substitution by ammonia. In contrast, *cis*-$[RuCl_2(Me_2SO)_4]$ reacts to give *mer*-$[RuCl_3(N_2H_5)_4(Me_2SO)_2]$.[117]

A range of *Dithiocarbamate* complexes including the tris-chelate species $[Os(S_2CNR_2)_3]$ has been prepared by reaction of $[OsCl_6]^{2-}$ with the corresponding ligand. Additionally, an unusual dimeric species $[Os_2(S_2CNR_2)_3(S_3CNR_2)_2]^+$ (Figure 19) has been isolated from the above reaction, while reaction of $[Os(S_2CNR_2)_3]$ with elemental S_8 affords $[Os_2(S_5)(S_3CNR_2)(S_2CNR_2)_5]$ (Figure 20).[118] Various, mostly ill-defined, complexes of

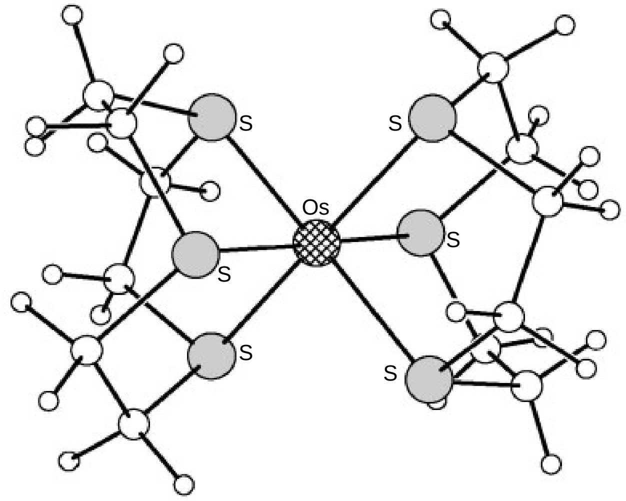

Figure 18 The structure of $[Os([9]aneS_3)_2]^{2+}$

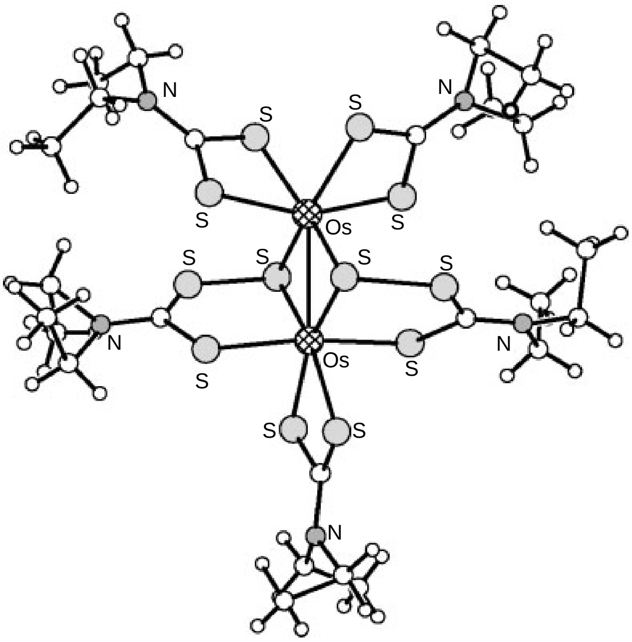

Figure 19 The structure of $[Os_2(S_2CNR_2)_3(S_3CNR_2)_2]^{+}$

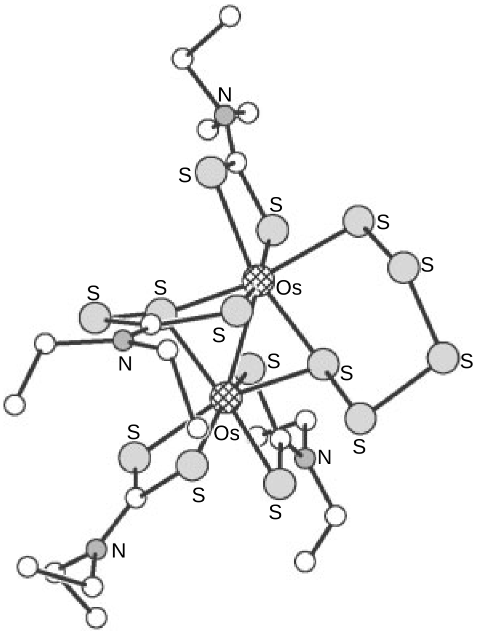

Figure 20 The structure of $[Os_2(S_5)(S_3CNR_2)_3(S_2CNR_2)_5]$

thiones, dithiolenes, thioketonates, and thiourea derivatives have been reported.

8.6 Halogen Complexes

Halides tend to stabilize the higher valent states of Os and so their chemistry has been described in previous sections. The interconversion of $Os^{V/IV/III/II}$ oxidation states in a series of halo–pyridine complexes $[OsX_n py_{6-n}]^{x+}$ ($n = 0–6$) has been assessed. It was found that py tends to stabilize Os^{II}, with Cl^- stabilizing the higher oxidation states Os^{IV} and Os^{V}.[119] Reduction of $[Os_2X_9]^{2-}$ affords the Os^{III} anion $[Os_2X_9]^{3-}$, which loses X^- to give $[Os_2X_8]^{2-}$. Interestingly, the Os–Os distance in staggered $[Os_2X_8]^{2-}$ increases on going from X = Cl (2.182), Br (2.196), I (2.217 Å), while the Os–Os distance of 2.209(1) Å is observed in eclipsed $[Os_2Cl_8]^{2-}$.[120]

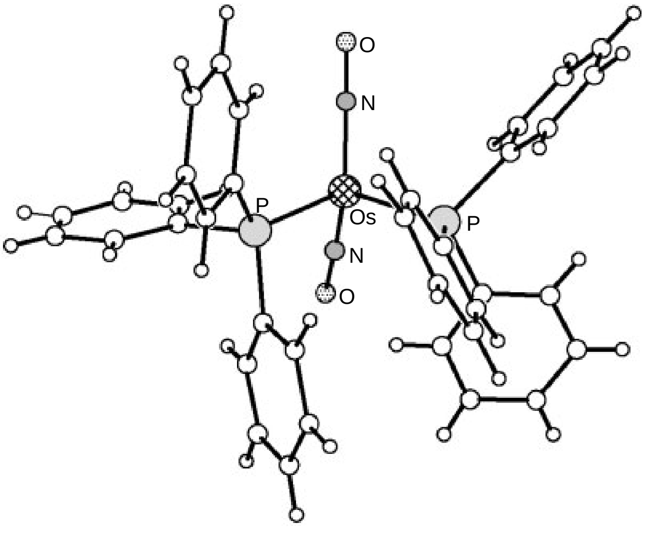

Figure 21 The structure of $[Os^{-II}(NO)_2(PPh_3)_2]$

9 LOW OXIDATION STATES

Coordination compounds of Os^{I} and Os^{-I} are very rare,[4] and when detected are often intermediates in redox reaction. Os^{0} and Os^{-II} complexes have d^8 and d^{10} electron configurations respectively, and are often associated with organometallic clusters.

The d^8 complex $[Os^{0}(NO)H(PR_3)_3]$ can be prepared from $[Os^{II}(NO)Cl_3(PR_3)_2]$ in KOH, and can be reduced further to the d^{10} nitrosyl complexes $[Os^{-II}(NO)_2(PPh_3)_2]$ by reaction with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide. The structure of $[Os^{-II}(NO)_2(PPh_3)_2]$ (Figure 21) is tetrahedral, with linear Os–N–O linkages.[121] The $\nu_{N\equiv O}$ stretching vibration occurs near $1600\,cm^{-1}$ consistent with very strong π-back donation to NO^+ from the highly electron rich Os^{-II} center (*see Electron Rich Compound*). $[Os^{0}(NO)Cl(PPh_3)_3]$ can be prepared from $[Os^{0}(NO)(CO)Cl(PPh_3)_2]$.[122] Ligand substitution occurs in $[OsCl(NO)(PPh_3)_3]$ to afford $[OsCl(NO)(PPh_3)_2(L)]$ (L = alkene, PR_3, SO_2). Further, $[Os^{0}(NO)Cl(PPh_3)_3]$ reacts with $P(i\text{-}Pr)_3$ to give *trans*-$[Os^{0}(NO)Cl\{P(i\text{-}Pr)_3\}_2]$ (Figure 22), which shows a square planar stereochemistry.[123] Since $[Os^{0}(NO)Cl\{P(i\text{-}Pr)_3\}_2]$ is a 16-electron species and is also co-ordinatively unsaturated, it undergoes a range of oxidative addition reactions to give the octahedral Os^{II} products illustrated in Scheme 7.

Oxidation of $[Os(NO)_2(PPh_3)_2]$ by O_2 in the presence of H^+ affords $[Os^{0}(NO)_2(OH)(PPh_3)_2]^+$ (Figure 23), which shows a square based pyramid (SQPY) structure with one linear and one bent Os–N–O linkage.[124]

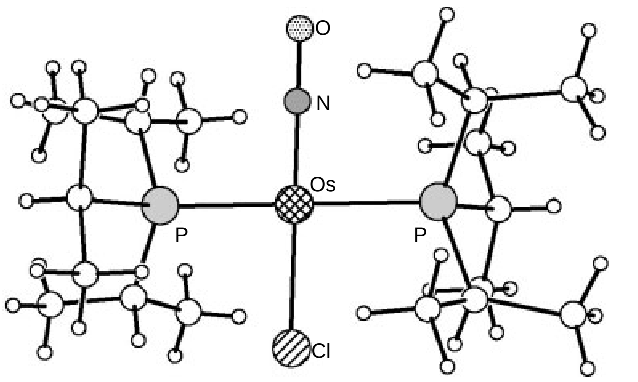

Figure 22 The structure of *trans*-$[Os^{0}(NO)Cl\{P(i\text{-}Pr)_3\}_2]$

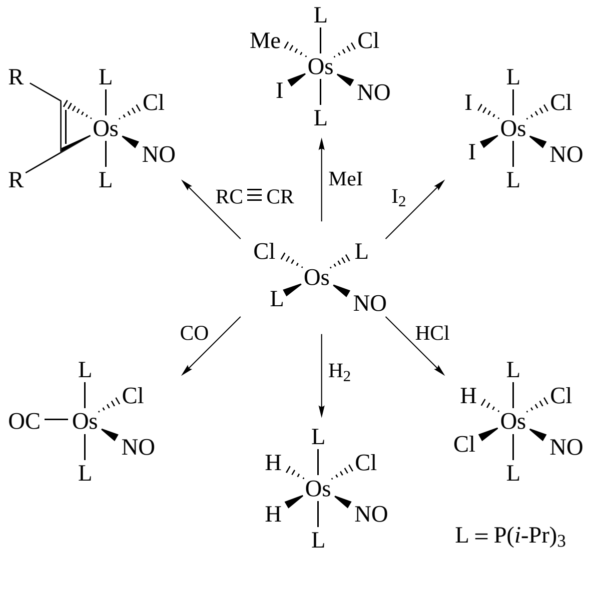

Scheme 7

1 INTRODUCTION

Organometallic complexes consist of a metal bonded to one or more carbon atoms of an organic molecule. The bond can be a sigma bond, as with metal–alkyl complexes (*see Alkyl Complexes*), or a π bond, as with metal–alkene (*see Alkene Complexes*) complexes. This section covers representative organometallic complexes of osmium along with a discussion of carbonyl complexes. It does not include cyanide complexes (*see* ***Cyanide Complexes of the Transition Metals***) or complexes of organic ligands, such as amines or alkoxides, bonded to osmium through an element other than carbon. General reviews of the organometallic chemistry of osmium can be found in annual surveys of the *Journal of Organometallic Chemistry* or *Coordination Chemistry Reviews*. Textbooks on aspects of organometallic chemistry such as 'The Organometallic Chemistry of the Transition Elements' or 'Metal–Ligand Multiple Bonds' typically include the organometallic chemistry of osmium.[1,2]

Osmium and ruthenium frequently form analogous complexes (*see* ***Ruthenium: Organometallic Chemistry***). The chemistry of iron is quite different (*see* ***Iron: Organometallic Chemistry***). Osmium forms stronger metal–metal bonds and stronger metal–carbon bonds than either iron or ruthenium. Osmium, like other third row transition elements, is more stable in its higher oxidation states. It is much less 'oxophilic' than the early transition metals so oxygen and nitrogen ligands bind reversibly to this metal. Unlike metals in the nickel and copper triads, osmium forms many complexes with terminal oxo, imido, and nitrido ligands.

Because it forms stronger bonds with ligands, osmium complexes are generally less active catalysts than analogous ruthenium complexes. The exception is in oxidation chemistry where certain osmium complexes are better and more selective catalysts. Because of this, osmium tetroxide and other osmium oxo complexes are widely used in the synthesis of complex organic molecules.

A variety of techniques are used to characterize organometallic osmium complexes. Particularly important are X-ray crystallography, for a three-dimensional picture of the placement of atoms within a molecule, NMR spectroscopy (^1H, ^{13}C, ^{31}P, and ^{183}Os), for information on the structure and symmetry of ligands in diamagnetic complexes, and IR spectroscopy, for the identification of multiple bonds between osmium and a ligand or within a ligand. Electrochemical studies and photoelectron spectroscopy provide information on the oxidation state of osmium and the relative electron density of the complex.

2 ALKYL COMPLEXES AND RELATED SPECIES OF Os(II), Os(III), Os(IV)

Osmium forms a wide variety of alkyl and aryl complexes including homoleptic alkyl and aryl complexes and many complexes with ancillary carbonyl (*see* ***Carbonyl Complexes of the Transition Metals***), cyclopentadienyl (*see Cyclopentadienyl*), arene (*see Arene Complexes*), and alkene ligands (*see Alkene Complexes*). It forms stronger bonds to carbon and other ligands than do the lighter elements of the triad. Because of this, most reactions of alkyl and aryl osmium complexes are slower than the reactions of the corresponding ruthenium complexes. However, because osmium is more stable in higher oxidation states, the oxidative addition (*see Oxidative Addition*) of C–H bonds is favored for osmium complexes. The rate of oxidative addition reactions decreases in the order Os > Ru ≫ Fe.

2.1 Simple Alkyl and Aryl Complexes

Alkyl and aryl carbonyl complexes of osmium result from the reactions of anionic carbonyl complexes with organic electrophiles. The reactions between $Na_2Os(CO)_4$ or $NaOsH(CO)_4$ and ROTf, or RI (R = Me, Et) produce

$OsR_2(CO)_4$ or $OsR(H)(CO)_4$. The alkyl hydrido complexes are prone to reductive elimination (*see Reductive Elimination*). A bimolecular reductive elimination of CH_4 from $OsMe(H)(CO)_4$ forms $Os_2(CO)_8Me(H)$. The reaction between $Os_2(CO)_8Me(H)$ and $OsMe(H)(CO)_4$ gives CH_4 and a linear trimetallic $\{Os(CO)_4Me\}\{Os(CO)_4\}\{Os(CO)_4Me\}$.

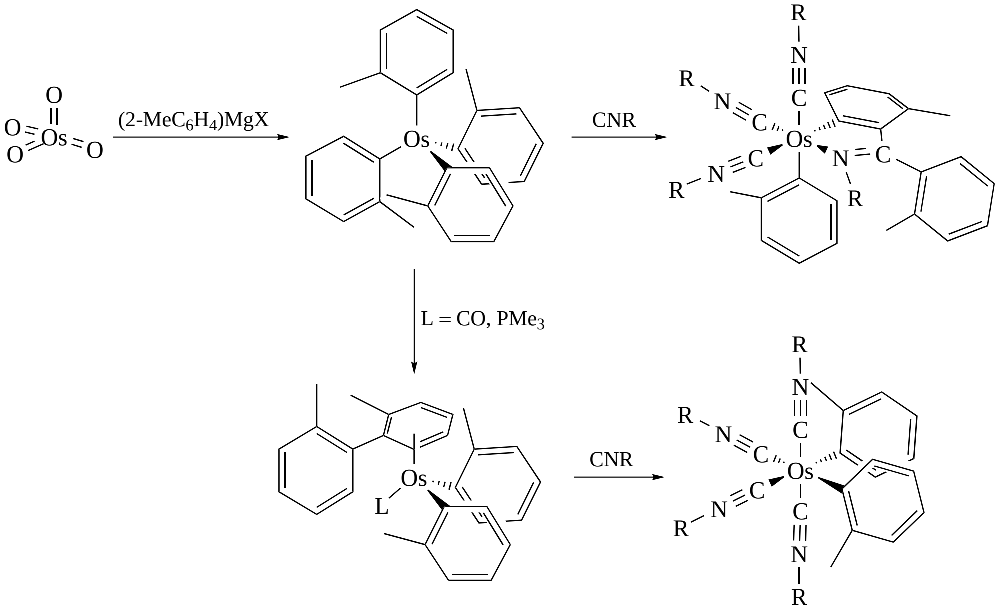
Other alkyl and aryl complexes are prepared by reactions between osmium halides and main group alkyl complexes. The reaction between $OsHCl(CO)(PPh_3)_3$ and $CH_2{=}C(CH_3)CH_2MgCl$ gives a sigma bonded allyl complex. Loss of PPh_3 causes isomerization to a π-allyl $OsH(\eta^3$-$CH_2CMeCH_2)(CO)(PPh_3)_2$.

The first homoleptic tetraalkyl and tetraaryl complexes of the platinum group metals, Os(*cyclo*-$C_6H_{11})_4$ and Os(*o*-$C_6H_4Me)_4$, were reported in 1985 (Scheme 1). These tetrahedral complexes were prepared by treatment of the appropriate Grignard reagents with OsO_4 or with $Os_2(\mu$-$O_2CMe)_4Cl_2$. Lewis bases CO, PMe_3, and Me_3CNC react with Os(*o*-$C_6H_4Me)_4$ to form Os(II) aryl complexes via reductive coupling (*see Reductive Coupling*) of the aryl ligands. Silver(I) salts oxidize Os(*o*-$C_6H_4Me)_4$ to [Os(*o*-$C_6H_4Me)_4]^+$ in dichloromethane.[3]

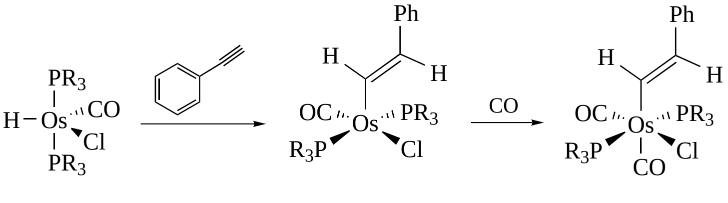
2.2 Alkenyl and Alkynyl Complexes

The insertion of alkynes into Os–H bonds produces vinyl complexes. For example, $OsH(O_2CCF_3)(CO)(PPh_3)_2$ reacts with PhC≡CR (R = Me, Ph) to give Os{C(Ph)=CHR}$(O_2CCF_3)(CO)(PPh_3)_2$. These complexes are catalysts for the oligomerization of phenyl acetylene. Terminal alkynes insert into the Os–H bond of $OsHCl(CO)(P^iPr_3)_2$ to give $Os(CH{=}CHR)Cl(CO)(P^iPr_3)_2$. This complex is coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) and can react with CO to form the six-coordinate complex $Os(CH{=}CHR)Cl(CO)_2(P^iPr_3)_2$ (Scheme 2).

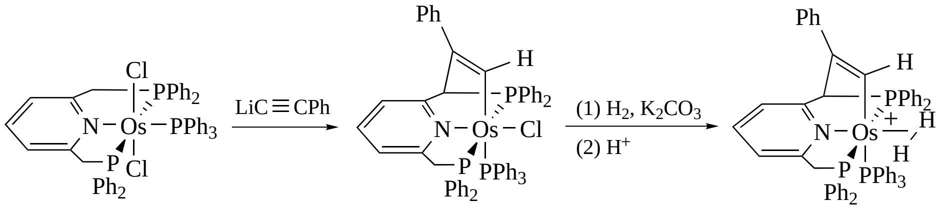
Alkynyl and alkenyl complexes can also be prepared by treating osmium halides with main group metal alkynyl or alkenyl complexes. However, the main group reagent can also act as a base. The reaction between $Os(PNP)Cl_2(PPh_3)$, where PNP is 2,6-$(CH_2PPh_2)C_5H_3N$, and lithium phenyl acetylide gives an alkenyl complex through an indirect route. The acetylide deprotonates an acidic C–H bond of the ligand. This forms an alkyne and a carbon nucleophile that combine. Successive addition of base, H_2 and acid results in the formation of a dihydrogen complex (*see* ***Hydrogen Bonding & Dihydrogen Bonding***) (Scheme 3).[4]



Scheme 1



Scheme 2



Scheme 3

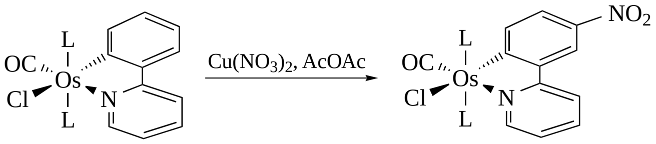
2.3 Reactions of Alkyl Complexes

In general, organometallic complexes with both hydrido and alkyl ligands are unstable due to facile reductive elimination. Because of the greater strength of the Os–C and Os–H and the greater stability of this metal in higher oxidations states, osmium alkyl hydrides eliminate alkane more slowly than ruthenium or iron complexes. The reaction of $[Os(CO)_3(PMe_3)_2(CH_3)][BPh_4]$ with borohydrides in acetonitrile gives $Os(CO)_2(PMe_3)_2(CH_3)H$ while the analogous iron complex reacts with borohydride to form $Fe(CO)_2(PMe_3)_2(NCMe)$ after reductive elimination of acetone.[5]

The rate of migratory insertion (*see Migratory Insertion*) reactions is usually lower for osmium complexes than for analogous ruthenium or iron complexes. In comparing CO insertion (*see CO Insertion*) into M–C bonds, the rate of insertion depends on metal according to Ru $>$ Fe $\gg$ Os or Fe $>$ Ru $\gg$ Os, depending on the ligand set.[6]

As a result of a stronger metal-iodide bond, the osmium complex of formula *trans*-$[MI(Me)(CO)_2(PMe_3)_2]$ does not spontaneously ionize in polar solvents. The ruthenium and iron complexes dissociate I^- in these solvents. Silver(I) salts are required to abstract the iodide from the osmium complex. When tris-pyrazoylmethane is added along with the silver salt, the methyl ligand migrates to a coordinated carbonyl ligand and $[Os(COMe)(pz_3CH)(CO)(PMe_3)_2]^+$ forms.

Typically, electrophiles react with osmium alkyl and aryl complexes at the metal–carbon bond. In a few cases, electrophiles add to the aromatic ligand instead. The aryl group in the osmium complexes $Os(Ar)Cl(CO)(PPh_3)_2$ undergoes electrophilic substitution reactions. The chelated 2-pyridylphenyl complex $Os(C_6H_4\text{-}2\text{-}C_5H_4N)Cl(CO)(PPh_3)_2$ is also activated toward electrophilic attack (*see Electrophilic Reaction*) at the phenyl ligand. Coordination of the pyridyl nitrogen stabilizes the complex and prevents attack at the Os–C bond even with reactive electrophiles (Scheme 4).[7]



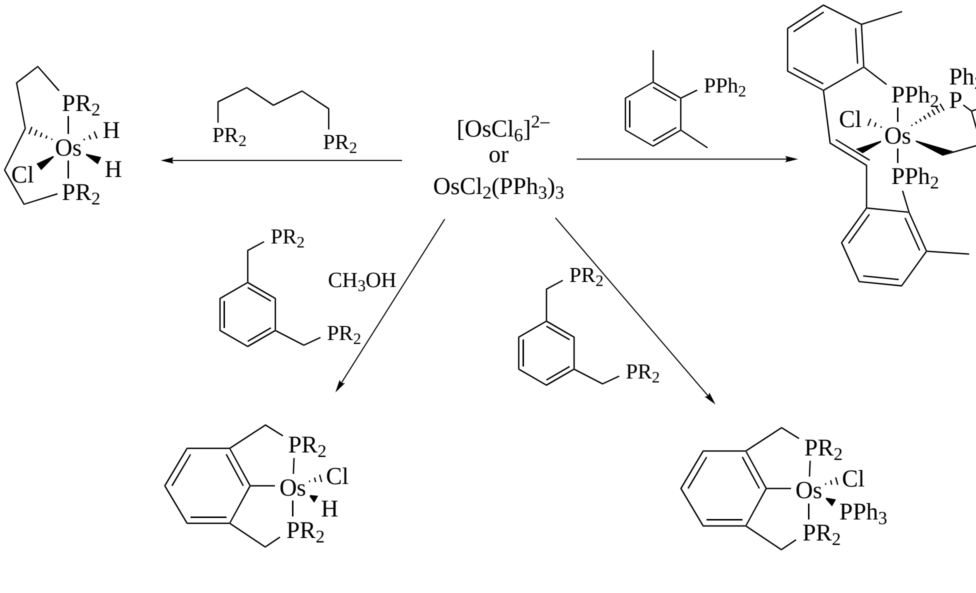
Scheme 4

2.4 Cyclometallation

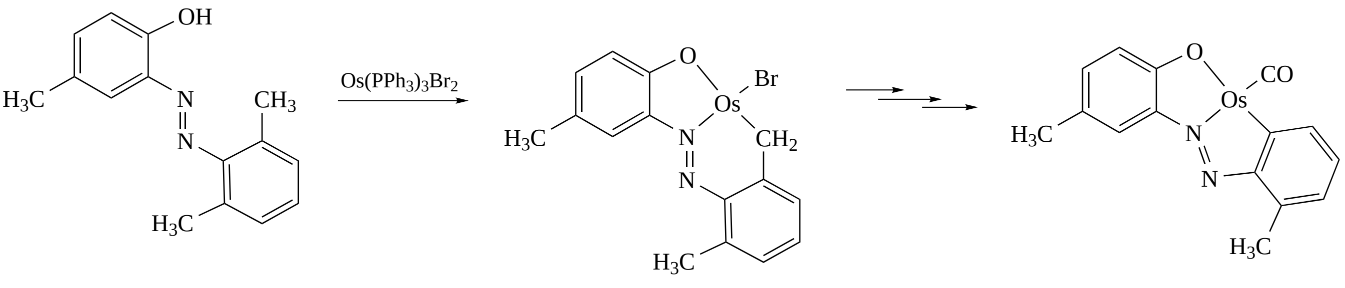
The oxidative addition of C–H bonds of ligands is very common and this reaction forms metal–alkyl or metal–aryl complexes. In osmium triarylphosphine complexes, orthometallation gives four-membered metallocycles. When the ortho positions are blocked with alkyl groups, oxidative addition can form five-membered osmacycles. For example, the reaction of $PPh_2(2,6\text{-}Me_2C_6H_3)$ with either $[OsCl_6]^{2-}$ or $OsCl_2(PPh_3)_3$ gives a cyclometallated products and couples two of the phosphine ligands. The reaction could occur either through a simple coupling reaction or through a carbene intermediate. A similar double C–H activation takes place between $[OsCl_6]^{2-}$ and $(Bu^t_2P)CH_2CH_2CH_2\ CH_2CH_2(PBu^t_2)$.[8] Metallation of the phenyl ring occurs when $1,3\text{-}(Pr^i_2PCH_2)_2C_6H_4$ coordinates to $OsCl_2(PPh_3)_3$ in the presence of a base.[9] The reaction between $1,3\text{-}(CH_2P^tBu_2)_2C_6H_4$ and $OsCl_2{}^{2-}$ gives the metallated product in methanol or 2-propanol solvent/reducing agent. The products react with borohydride to give hydrido and dihydrogen complexes (*see* ***Hydrogen Bonding & Dihydrogen Bonding***) (Scheme 5).

When *trans*-$OsCl_2(PMe_3)_4$ is reduced with Na/Hg it oxidatively adds a C–H bond of PMe_3 and forms $OsH(\eta^2\text{-}CH_2PMe_2)(PMe_3)_3$. Hydrolysis of $OsH(\eta^2\text{-}CH_2PMe_2)(PMe_3)_3$ yields $OsH(OH)(PMe_3)_4$. A related complex $OsH(R)(PMe_3)_4$ (where R = Me, CH_2CMe_3, CH_2SiMe_3) activates C–H bonds in benzene after dissociation of a phosphine ligand. There is a rapid γ-hydrogen activation with loss of H_2 in the neopentyl and (trimethylsilyl)methyl derivatives. Kinetic and isotopic labeling studies support an Os(IV) intermediate in the activation of benzene C–H bonds.

The C–H activation of nitrogen ligands such as pyridines, hydroxamates, and azido complexes results in the formation of osmium–carbon bonds. Cyclometallation of 2-phenylpyridine by $[Os(\eta^6\text{-benzene})Cl_2]_2$ gives $Os(\eta^6\text{-benzene})Cl(phpy)$ and HCl. Substitution by phenanthroline produces $[Os(phen)_2(phpy)]^+$. Both complexes show reversible electrochemical behavior (Os^{II}/Os^{III}) and can mediate electron transfer with glucose oxidase.[10] Cyclometallation of a hydroxamic acid to $Os(bpy)_2Cl_2$ gives an osmium(III) organometallic complex with N–C coordination to the hydroxamate ligand, $[Os(bpy)_2\{N(Ar)C(O)C_6H_3R\}]^+$.



Scheme 5



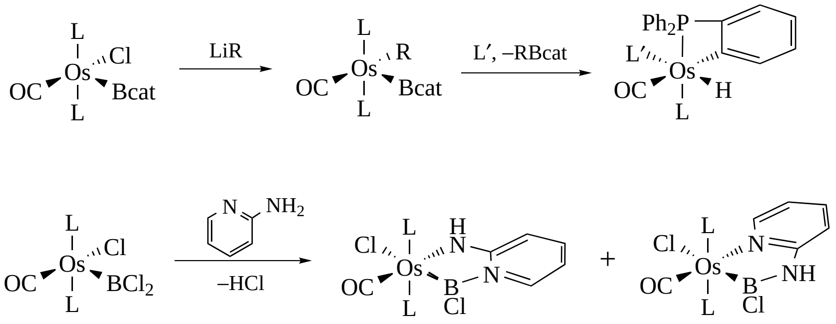
Scheme 6

Simple C–H activation of several arylazaphenols produces osmium complexes with tridentate O–N–C coordination to the arylazaphenolate ligand, $[Os^{II}(PPh_3)_2(CO)(L)]$. One electron oxidation of these complexes produces stable osmium(III) complexes that can function as mild, 1 electron oxidants. An internal C–C activation takes place with a phenylazido ligand, 2-(2′,6′-dimethylphenylazo)-4-methylphenol, and $Os(PPh_3)_3Br_2$. The carbonyl ligand in the product is derived from one methyl group on the ligand (Scheme 6).[11]

The hexahydride complex $OsH_6(PPr^i_3)_2$ reacts with ketones to give products resulting from C–H activation in the position adjacent to the carbonyl group of the ketone. The reaction with cyclohexylmethyl ketone to gives $OsH_3(PPr^i_3)_2(C_6H_8C(O)Me)$ and 3 equivalents of H_2. This probably results from metallation of the cyclohexyl ring at the 2 position followed by beta-hydride elimination (*see β-Hydride Elimination*), and metallation of the alkene. This means that three hydrogen atoms are removed from the ketone.[12] This same hydrido osmium complex reacts with aromatic ketones to give orthometallated (*see Orthometalation*) products $OsH_3(PPr^i_3)_2(C_6H_4C(O)R)$. When the aromatic group is fluorinated in both ortho positions, there is C–F activation to give $OsH_3(PPr^i_3)_2(C_6H_xF_yC(O)R)$, $2H_2$, and HF. When only one ortho position is fluorinated, C–H bond activation is preferred over C–F bond activation.

2.5 Boryl and Stannyl Complexes

Boryl and stannyl complexes are similar in some ways to alkyl complexes. Both are important because of their relationship to intermediates in the catalytic borylation and stannylation of alkenes. The reaction of catecholborane complex of osmium, $Os(Bcat)Cl(CO)(PPh_3)_3$ with tolyllithium gives a molecule with both Os–B and Os–C sigma bonds. This reductively eliminates when the borane and aryl ligand are cis to one another to give (tolyl)Bcat and an orthometallated product. A B–Cl bond in the simple borane complex $Os(BCl_2)Cl(CO)(PPh_3)_2$ reacts with 2-hydroxypyridine to give a bidentate pyridylborane complex $Os\{–B(Cl)OC_5H_4N–\}Cl(CO)(PPh_3)_2$. With 2-aminopyridine in ethanol, $Os(BCl_2)Cl(CO)(PPh_3)_2$ reacts to give either $Os\{–B(Cl)NHC_5H_4N–\}Cl(CO)(PPh_3)_2$, with the amino group



Scheme 7

bonded to boron, or Os{–B(OEt)NC$_5$H$_4$–hNH–}Cl(CO)(PPh$_3$)$_2$, with the pyridine nitrogen bonded to boron (Scheme 7).[13]

The coordinatively unsaturated stannyl complexes Os(SnR$_3$)Cl(CO)(PPh$_3$)$_2$ reacts with Na[Me$_2$NCS$_2$] to give the dithiocarbamate complex Os(SnR$_3$)(S$_2$CNMe$_2$)(CO)(PPh$_3$)$_2$. This reacts with I$_2$ at the Sn–C bonds.[14]

3 PI COMPLEXES

3.1 Alkene and Alkyne Complexes

Alkenes and alkynes add to coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) osmium complexes to form η^2-alkene and alkyne complexes. Ethene accelerates the reductive elimination of methane from OsH(CO)$_4$Me and forms Os(η^2-CH$_2$=CH$_2$)(CO)$_4$. Photochemical displacement of a phosphine ligand in Os(CO)$_2$(PPh$_3$)$_3$ gives an unsaturated complex that is trapped by ethene to give Os(η^2-CH$_2$=CH$_2$)(CO)$_2$(PPh$_3$)$_2$. An unsaturated species results from abstraction of chloride by Ag(I) in OsCl(NO)(CO)(PPh$_3$)$_2$. Either ethene or a number of different alkynes can add to form [Os(η^2-CH$_2$=CH$_2$)(NO)(CO)(PPh$_3$)$_2$]$^+$ or [Os(η^2-RC≡CR′)(NO)(CO)(PPh$_3$)$_2$]$^+$. Diphenyl acetylene displaces two ligands in Os(CS)(CO)(PPh$_3$)$_3$ to give Os(CS)(PhC≡CPh)(PPh$_3$)$_2$.

Photolysis of Os$_3$(CO)$_{12}$ in the presence of a diene (1,3-butadiene, 1,3-pentadiene, 1,3-cyclooctadiene, or 1,3-cyclohexadiene) gives the mononuclear diene complexes Os(CO)$_3$(η^4-diene). The 1,3-cyclooctadiene complex OsCl$_2$(COD)(PEtPh$_2$)$_2$ was prepared by the reduction of [OsCl$_6$]$^{2-}$ in the presence of the diene followed by treatment with PEtPh$_2$.

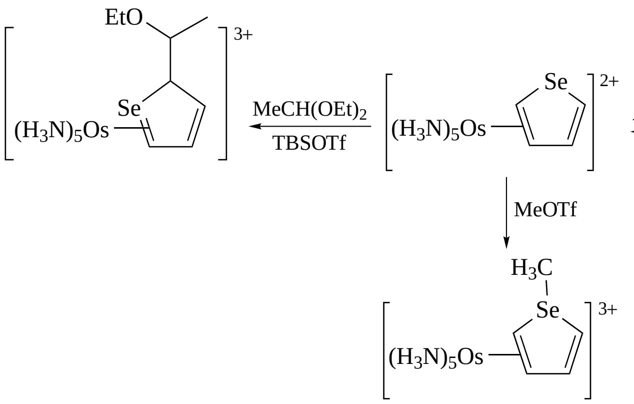
Alkene and η^2-ketone complexes can be prepared by reduction of [Os(NH$_3$)$_5$(OSO$_2$CF$_3$)]$^{2+}$ in the presence of substrate. The acetone complex [Os(NH$_3$)$_5$(η^2-O=CMe$_2$)]$^{2+}$ undergoes substitution reactions only very slowly at room temperature. the acetone is not labile. Upon thermolysis, it decomposes to a carbonyl complex [Os(NH$_3$)$_5$(CO)]$^{2+}$. The propenoic acid ligand in [Os(NH$_3$)$_4$(CH$_2$=CHCO$_2$H)]$^{2+}$ coordinates to the metal through the double bond and through one oxygen atom of the acid moiety. The pK_a of the coordinated propenoic acid is 3.20, demonstrating that the coordinated alkene substituent is electron withdrawing. The complex can be reversibly oxidized to the Os(III) state. Selenophene, *cyclo*-C$_4$H$_4$Se, coordinates to osmium(II) through one C=C in the complex [Os(NH$_3$)$_5$(η^2-selenophene)][OSO$_2$CF$_3$]$_2$. Electrophilic addition to the unsaturated ligand is dramatically affected by coordination to osmium (Scheme 8).[15]

Substitution reactions at Os(CO)$_4$(η^2-alkene) or Os(CO)$_4$(η^2-alkyne) take place through initial dissociation of a ligand. The complexes Os(CO)$_4$(η^2-alkyne), where the alkyne is CF$_3$C≡CCF$_3$ or HC≡CH, compounds are more reactive than Os(CO)$_5$ in substitution and insertion reactions. The acetylene complex is 10 times more reactive than the hexafluoro-2-butyne complex. This is probably due to the ability of the alkyne to act as a four electron donor and stabilize electron-deficient intermediates. The reaction of Os(CO)$_4$(η^2-HC≡CH) with excess PMe$_3$ gives a CO insertion product Os(CO)$_2$(PMe$_3$)$_2${C(H)=C(H)-C(O)} while reaction with the bulkier phosphine PBu$^t_3$ gives a double insertion product, Os(CO)$_3$(PBu$^t_3$){C(O)–C(H)=C(H)–C(O)} (Scheme 9).[16]

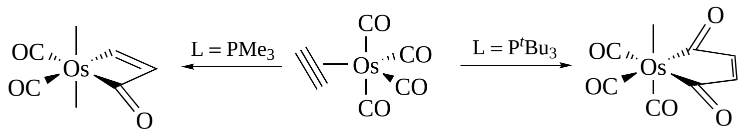
3.2 Arene Complexes

Arene complexes of osmium(0) or osmium(II) can be prepared by co-condensation of osmium atoms with arenes at low temperature or by the reduction of osmium halides in the presence of the arene. An osmium complex with a tetrahapto- and hexahapto-benzene, Os(η^6-C$_6$H$_6$)(η^4-C$_6$H$_6$), results when osmium atoms are condensed with benzene at low temperature. NMR studies show that this molecule is fluxional (*see Fluxional Molecule* and ***Structure & Property Maps for Inorganic Solids***) and the two arene rings interconvert. Acids protonate one arene ring in Os(η^6-C$_6$H$_6$)(η^4-C$_6$H$_6$) and form the cyclohexadienyl cation [Os(η^6-C$_6$H$_6$)(η^5-C$_6$H$_7$)]$^+$, while addition of trimethylphosphine gives an arene C–H addition product Os(η^6-C$_6$H$_6$)Ph(H)(PMe$_3$).

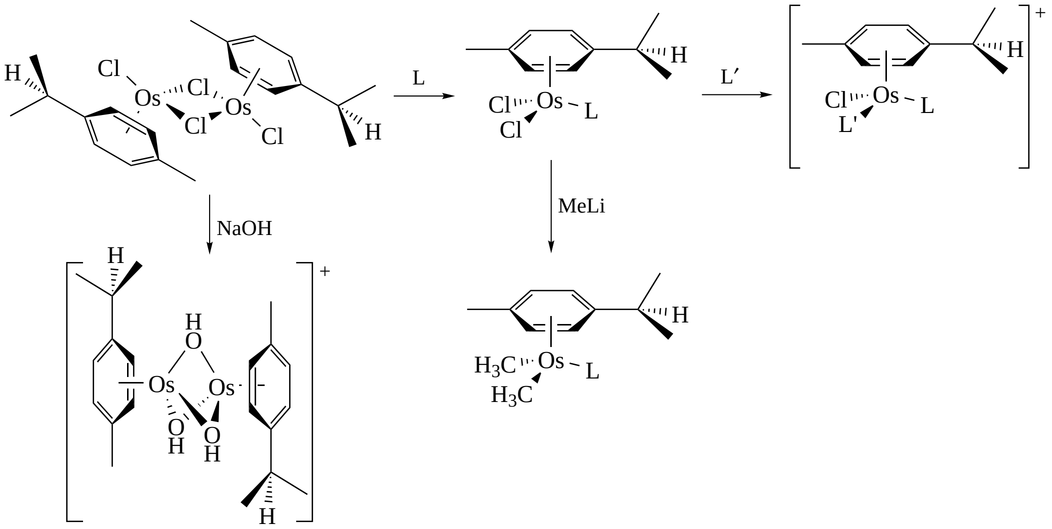
The benzene complex [OsCl$_2$(η^6-C$_6$H$_6$)]$_x$ is polymeric. Similar complexes of *p*-cymene (*p*-MeC$_6$H$_4$Pr^i)



Scheme 8



Scheme 9



Scheme 10

and mesitylene (1,3,5-$Me_3C_6H_3$) are dimeric complexes $[OsCl_2(\eta^6\text{-arene})]_2$. The osmium arene unit is relatively inert in the *p*-cymene and mesitylene complexes. The reaction between $[OsCl_2(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)]_2$ and NaOH gives the bridging hydroxide complex $[\{Os(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)\}_2(\mu\text{-}OH)_3]^+$. This complex is catalytically active for the oxidation of acetaldehyde and propionaldehyde to the carboxylic acids in water. The reactions of $[OsCl_2(\eta^6\text{-arene})]_2$ with CO, nitriles, isonitriles, trialkylphosphines, triarylphosphines, or phosphites yields complexes with the formula $OsCl_2(\eta^6\text{-arene})L$. The *p*-cymene complexes add a second donor ($L'{=}CO$, $CH_2{=}CH_2$, $CH_2{=}CHCH_3$) to form cationic complexes $[OsCl_2(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)LL']^+$ (Scheme 10). One or both of the chloride ligands in $OsCl_2(\eta^6\text{-arene})L$ can exchange for alkyl (or aryl) groups by reaction with alkyllithium or alkylmagnesium halide compounds.

The synthesis of chiral-at-metal complexes may lead to the development of more selective asymmetric catalysts (*see*

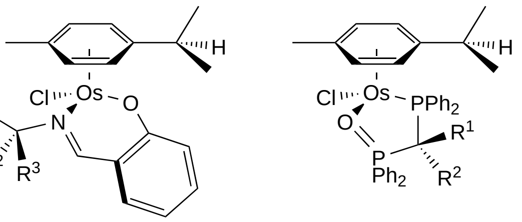


Figure 1 Chiral, half-sandwich complexes of osmium(II)

Asymmetric Synthesis by Homogeneous Catalysis). Two chiral-at-metal osmium complexes, (η^6-cymene)OsCl(κ^2-(S))–($R^1R^2R^3$)N=CH(o-C_6H_4(OH)-N,O), were prepared from [$OsCl_2$(η^6-p-cymene)]$_2$ and Schiff bases as mixtures of diastereomers (Figure 1). The complexes are configurationally stable in the solid state but isomerize in solution.[17] The reaction of [$OsCl_2$(η^6-p-cymene)]$_2$ with a diphenylphosphine monooxide and $AgSbF_6$ ligand gave [(η^6-p-cymene)OsCl(κ^2-Ph_2PCH(Me)P(O)Ph_2-P,O)][SbF_6].[18]

The triphenylmethyl carbocation, [CPh_3][PF_6], abstracts a hydride from a methyl group in $OsMe_2$(η^6-C_6H_6)(PR_3) and Os(H)Me(η^6-C_6H_6)(P^iPr_3). With $OsMe_2$(η^6-C_6H_6)(PR_3), the intermediate methyl methylene complex forms a stable ethene complex Os(η^2-CH_2=CH_2)(η^6-C_6H_6)(PR_3) after loss of a proton. A deuterium labeling study indicates that a hydrido methylene complex is intermediate in hydride abstraction from Os(H)Me(η^6-C_6H_6)(P^iPr_3) but the final product OsMe(η^6-C_6H_6)(κ^2-CH_2CHMeP^iPr_2) is derived from C–H activation of the phosphine ligand. Cationic arene complexes such as [OsI(η^6-C_6H_6)(PMe_3)$_2$][PF_6] react with alkyllithium reagents or sodium borohydride at the arene ring to produce cyclohexadienyl complexes OsI(η^5-C_6H_6R)(PMe_3)$_2$ or OsI(η^5-C_6H_7)(PMe_3)$_2$.

Binuclear (*see* ***Dinuclear Organometallic Cluster Complexes***) and polynuclear (*see* ***Polynuclear Organometallic Cluster Complexes***) arene complexes can be prepared from [$OsCl_2$(η^6-arene)]$_2$. The reaction of [$OsCl_2$(η^6-p-cymene)]$_2$ with [PPh_4]$_2$[WS_4] forms a trimetallic [OsCl(η^6-p-cymene)]$_2$$WS_4$ with two pseudooctahedral osmium atoms bridged by a tetrahedral tetrathiotungstate.[19] An (arene)metal sulfido cluster [(η^6-p-cymene)$_3$$Os_3S_2$]$^{2+}$ results from the reaction of [$OsCl_2$(η^6-p-cymene)]$_2$ with S($SiMe_3$)$_2$, methanolic NaSH, or aqueous Na_2S. The 1:1 reaction between the arene complexes [$OsCl_2$(η^6-arene)]$_2$ and [NEt_2H_2][Pt(S_2CNEt_2)(Ph_2PS)$_2$] produced the heterobimetallic complexes (η^6-arene)ClOs($SPPh_2$)$_2$Pt(S_2CNEt_2). With additional quantities of the platinum complex, tri- and pentametallic complexes are produced.

3.3 Cyclopentadienyl Complexes

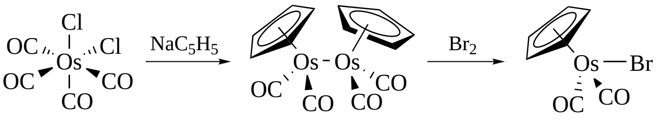
The cyclopentadienyl ligand is a good π-donor and π-acceptor ligand. Stable cyclopentadienylosmium complexes are known for the metal in oxidation states 0 through VI.

Osmacene, Os(η^5-C_5H_5)$_2$, is prepared in low yield from the reaction of $OsCl_4$ with sodium cyclopentadienide in refluxing THF and decamethylosmacene is prepared similarly from lithium pentamethylcyclopentadienide and [$OsCl_6$]$^{2+}$. The cyclopentadienyl rings in osmacene are eclipsed. The cyclopentadienyl rings can be monoacylated under Friedel–Crafts conditions and can be lithiated. Oxidation of osmacene gives a dimer with a metal–metal bond. The reaction with ferric ammonium sulfate produces [Cp_2Os(OH)]$^+$ while oxidation with I_2 in sulfuric acid gives [Cp_2OsI]$^+$.

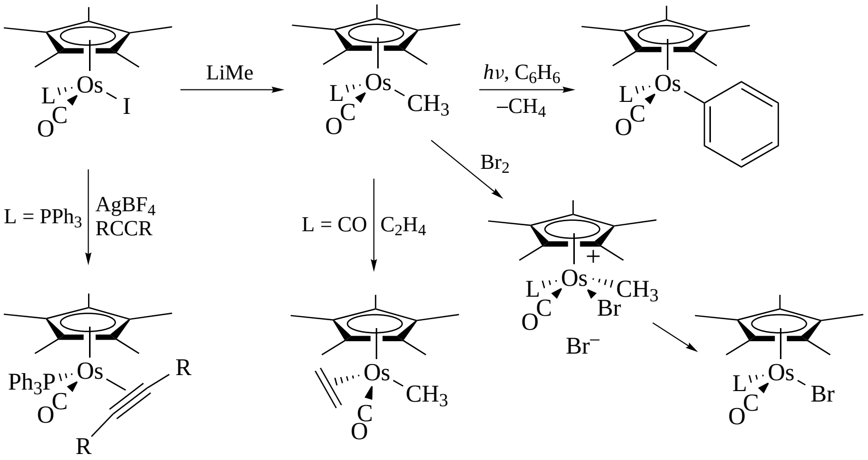
Due to the greater metal–metal bond strength of the third row metal, the carbonyl complex [CpOs(CO)$_2$]$_2$ has an osmium–osmium bond that is unbridged by carbonyl ligands. In the iron analog, the metal–metal interaction is very weak and the dimer owes its integrity mainly to the bridging carbonyl groups. The reaction between $OsCl_2$(CO)$_4$ and sodium cyclopentadienide produces [CpOs(CO)$_2$]$_2$. Oxidation of [CpOs(CO)$_2$]$_2$ with Br_2 gives CpOs(CO)$_2$Br (Scheme 11). The reaction of OsO_4 with cyclopentadiene in HBr, followed by the addition of PPh_3 gives CpOs(PPh_3)$_2$Br. The pentamethylcyclopentadienyl dimer [Cp*$OsBr_2$]$_2$ is prepared in a series of steps from OsO_4.[20]

The halide complexes CpOsL(CO)X and Cp*OsL(CO)X (L = CO, PMe_3, PPh_3; X = Cl, Br, I) are precursors to alkyl, aryl, alkene, and alkyne complexes. For example, The reaction of Cp*Os(CO)$_2$I with LiMe give a methyl complex, Cp*Os(CO)$_2$(CH_3). Photolysis results in the loss of methane, probably thorough intermediate oxidative addition of a C–H bond from the Cp* group, and activation of benzene to give Cp*Os(CO)$_2$Ph. Ethene displaces a carbonyl ligand in Cp*Os(CO)$_2$(CH_3) to give Cp*Os(CO)(η^2-CH_2=CH_2)(CH_3). Oxidation of Cp*Os(PMe_2Ph)(CO)(CH_3) with Br_2 gives the osmium(VI) methyl complex [Cp*Os(PMe_2Ph)(CO)Br(CH_3)][Br], which eliminates CH_3Br. Silver(I) salts abstract I^- from Cp*Os (PPh_3)(CO)I in the presence of internal alkynes to give the alkyne complexes [Cp*Os(PPh_3)(CO)(η^2-RC≡CR)]$^+$ (Scheme 12).

Certain metalloboranes are structurally and electronically related to osmium cyclopentadienyl complexes. Metalloboranes (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***) with arachno, nido, and closo type geometries with four, five, six, ten, and eleven vertices have been synthesized from [$OsCl_2$(η^6-C_6H_6)]$_2$ or from $OsCl_3$($PPhMe_2$)$_3$.



Scheme 11



Scheme 12

4 OSMIUM CARBENE AND CARBYNE COMPLEXES

Carbene ligands can be classified as singlet carbenes (Fischer carbenes, *see Fischer-type Carbene Complexes*) or triplet carbenes (Schrock carbenes or alkylidene, *see Schrock-type Carbene Complexes*). Singlet carbenes bond to osmium, usually in low oxidation states, in a way that is very similar to bonding between the metal and CO. Typically, there is a heteroatom or phenyl substituent to the carbene carbon and the degree of multiple bonding between the metal and carbene carbon is low. The bond between a triplet carbene and osmium is similar to the double bond between carbon atoms in ethene. There are only hydrogen or carbon substituents on the carbene carbon and the osmium center is usually in higher oxidation states.

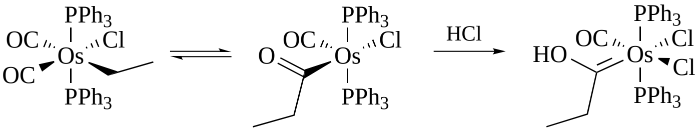
Osmium carbyne (*see Carbyne Complexes*) or alkylidyne complexes have a triple bond between the metal and the carbon atom of the ligand. Carbyne complexes are related to singlet carbenes. They are analogous to linear nitrosyl (*see Nitrosyl Complexes*) complexes and the osmium is usually in a lower oxidation state. Alkylidyne complexes are related to triplet carbenes and the bonding between the osmium and the carbon atom is similar to the C–C bond in an alkyne.

The chemistry of osmium carbene and carbyne complexes is rich owing to the high Os–C bond strength that stabilizes these species. Alkyl and vinyl complexes can convert to carbene and vinylidene complexes. They can interconvert with carbyne complexes. In similar systems, the osmium(VI) carbyne $OsHCl_2(CR)L_2$ and the ruthenium(IV) carbene $RuCl_2(CHR)L_2$ form. This demonstrates the tendency for osmium to react to form higher oxidation state species. Osmium carbyne complexes are usually more stable than ruthenium carbyne complexes. Other π-acceptor ligands, such as CO, favor the conversion of the carbyne–hydrido complex to a carbene complex.[21]

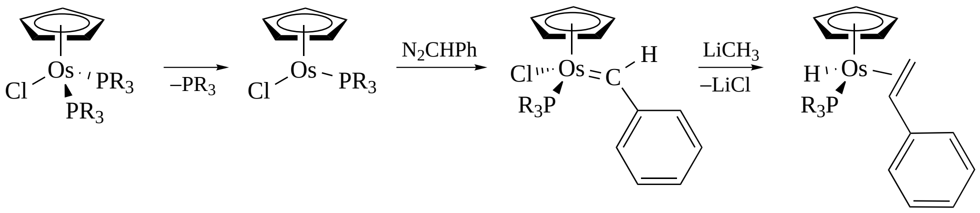
4.1 Carbenes

Carbene complexes with heteroatom substituents can be prepared by adding electrophiles to coordinated imidoyl, acyl, thioacyl, dithioester, or diselenoester ligands. Protonating the nitrogen atom of $Os(CH{=}NMe)Cl(CO)_2(PPh_3)_2$ gives the cationic carbene complex $[Os({=}CHNHMe)Cl(CO)_2(PPh_3)_2]^+$. The addition of HCl to $OsEtCl(CO)_2(PPh_3)_2$ promotes migration of the ethyl group to CO. The acyl ligand is protonated to give the hydroxycarbene $Os\{{=}C(OH)Et\}Cl_2(CO)(PPh_3)_2$ (Scheme 13). Alkylation of the thioformyl complex $Os(CHS)Cl(CO)_2(PPh_2)_2$ with $CH_3OSO_2CF_3$ gives $[Os\{{=}C(SCH_3)H\}Cl(CO)_2(PPh_3)_2][SO_3CF_3]$.

There are several other methods for the synthesis of carbene complexes of osmium. The reaction of a nucleophile with isocyanide complexes can result in the formation of osmium carbene complexes. Certain electron-rich alkenes add to osmium to form carbene complexes. For example,



Scheme 13



Scheme 14

the reaction of {(*cyclo*-$CH_2NMe)_2C$}={C(NMeCH$_2$-)$_2$} with $OsCl_2(PBu_2Ph)_4$ gives the tetracarbene complex $OsCl_2$(*cyclo*-$CNMeCH_2CH_2NMe)_4$. The elimination of halide from the haloalkyl complex $OsCl(CCl_3)(CO)(PPh_3)_3$ gives $OsCl_2(CCl_2)(CO)(PPh_3)_2$. Nitrogen, oxygen, and sulfur-containing nucleophiles react with halocarbenes to give substituted carbene complexes. Dimethylamine reacts with $OsCl_2(CCl_2)(CO)(PPh_3)_2$ to produce $OsCl_2\{C(Cl)NMe_2\}(CO)(PPh_3)_2$.

A common method for the preparation of carbene complexes without heteroatom substituents is the reaction of a coordinatively unsaturated metal complex with a diazoalkane. This method is effective for the preparation of CpOsCl(P^{i}Pr$_3$)(=CHPh) from CpOsCl(P^{i}Pr$_3$)$_2$. The carbene in this complex is electrophilic and reacts with alkyl and aryl lithium compounds and with Grignard reagents (*see Grignard Reagents*) (Scheme 14).[22]

The reaction between diphenyldiazomethane and the osmium porphyrin complexes Os(por)(CO) in air produces oxo-bridged carbene complexes [Os(por)(=CPh$_2$)]$_2$(μ-O). When the porphyrin is highly electron deficient, a bis-carbene complex Os(por)(=CPh$_2$)$_2$ is formed instead. The oxo carbene complexes catalyze the cyclopropanation of styrene and cyclohexane with ethyl diazoacetate.[23] Diphenyldiazomethane also reacts with (η^6-arene)Osκ^1{-OC(O)CF$_3$}κ^2{-O$_2$CCF$_3$} to give diphenylcarbene complexes (η^6-arene)Osκ^1{-OC(O)CF$_3$}$_2$(=CPh$_2$). Coupling products result when the carbene complex is treated with vinylmagnesium bromide or with ethylvinyl ether in the presence of a proton-acceptor.[24]

Carbene complexes can also form via the abstraction of an alpha hydrogen atom from an alkyl ligand. The abstraction of a methylimido ligand on an osmium(VI) complex $[CpOs(NCH_3)(CH_2SiMe_3)_2]^+$ with PPh_3 leads to the formation of Ph_3PNMe, alpha elimination of $SiMe_4$, and trapping of the resulting alkylidene complex with additional PPh_3 to give $[CpOs\{CH(SiMe_3)PPh_3\}]^+$. Cyclometallation of the ylide (*see Ylide*) gives the isolated product.

4.2 Carbynes

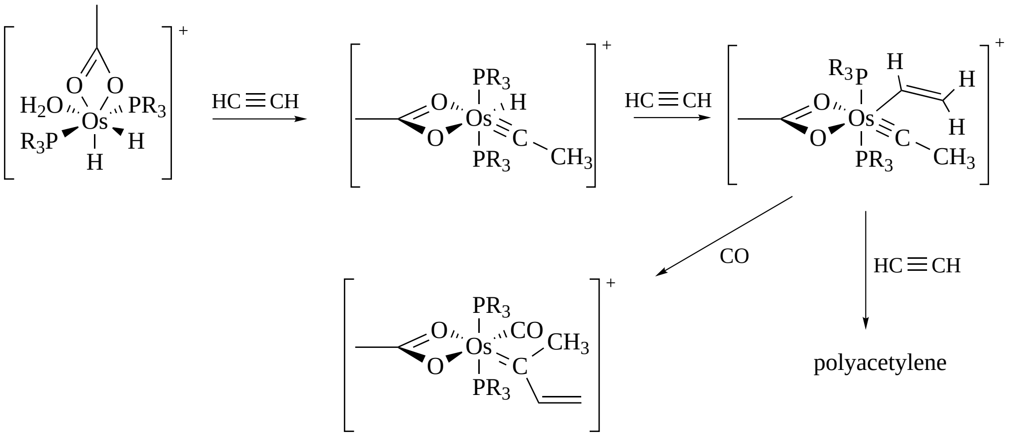
There are two principle methods for the synthesis of osmium carbyne complexes: (1) modification of a halocarbene, or (2) reaction of a hydride with a terminal alkyne. The reaction of $OsCl_2(CCl_2)(CO)(PPh_3)_2$ with *p*-tolyllithium produces $OsCl(\equiv CC_6H_4CH_3)(CO)(PPh_3)_2$. The alpha carbon of the carbyne ligand is nucleophilic. Electrophiles such as HCl and Cl_2 add to this carbon to form carbene complexes.

Osmium hydrido and dihydrogen complexes (*see **Hydrogen Bonding & Dihydrogen Bonding***) react with terminal alkynes to form carbene, vinylidene, and carbyne complexes. The simple dihydride OsH$_2$Cl$_2$(P^{i}Pr$_3$)$_2$ reacts with certain terminal alkynes, HC≡CR, to give the carbyne complex OsHCl$_2$(≡CCH$_2$R)(P^{i}Pr$_3$)$_2$. The dihydrogen complex Os(H$_2$)(CO)Cl$_2$(P^{i}Pr$_3$)$_2$ reacts with phenyl acetylene to give the carbene complex OsCl$_2$(=CHCH$_2$Ph)(CO)(P^{i}Pr$_3$)$_2$. Carbene complexes also results from the addition of CO to OsHCl$_2$(≡CCH$_2$R)(P^{i}Pr$_3$)$_2$. The π-acid ligand induces migration of the hydride to the unsaturated hydrocarbon ligand in an intramolecular reductive elimination.

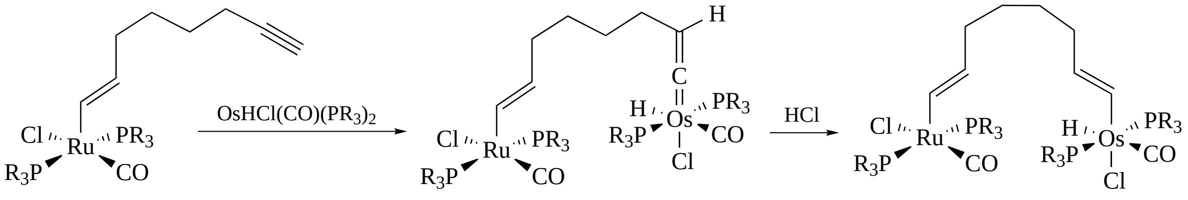
The acetate derivative, OsH$_2$(OAc)$_2$(P^{i}Pr$_3$)$_2$ reacts with HC≡CCMe=CH$_2$ to give a vinylidene OsH(OAc)(=C=CHCMe=CH$_2$). The monoacetate cation [OsH$_2$(OAc)(H$_2$O)(P^{i}Pr$_3$)$_2$][BF$_4$] reacts with HC≡CR to give either the osmacylopropene [OsH(OAc)(=CR–CH$_2$–)(P^{i}Pr$_3$)$_2$][BF$_4$] or the carbyne complex [OsH(OAc)(≡C–CH$_2$R)(P^{i}Pr$_3$)$_2$][BF$_4$] depending on the nature of R. The reaction of [OsH$_2$(OAc)(H$_2$O)(P^{i}Pr$_3$)$_2$][BF$_4$] with acetylene gives [Os(CH=CH$_2$)(OAc)(≡C–CH$_3$)(P^{i}Pr$_3$)$_2$][BF$_4$]. The complex catalytically polymerizes acetylene (Scheme 15). The aquo dihydrido complex [OsH$_2$(OAc)(H$_2$O)(P^{i}Pr$_3$)$_2$][BF$_4$] reacts with ethene to form a bimetallic complex, [{(P^{i}Pr$_3$)(η^2-C$_2$H$_4$)$_2$Os}$_2$(μ-OH)$_2$(μ-O$_2$CCH$_3$)][BF$_4$], with bridging hydroxides along with ethane.

A dihydrido osmium(IV) complex of a P–C–P chelating ligand {2,6-(CH$_2$PBu$^t_2$)$_2$C$_6$H$_5$}OsH$_2$Cl reacts with terminal alkynes to give vinylidenes {2,6-(CH$_2$PBu$^t_2$)$_2$C$_6$H$_5$}OsCl(=C=CHR). The reaction of HC≡CCMe$_3$ with OsCl$_2$(PPh$_3$)$_3$ gives a mixture of carbyne and vinylidene complexes. The products result from a series of steps beginning with the oxidative addition of the terminal alkyne to the Os(II) center, forming OsCl$_2$H(PPh$_3$)$_3$(C≡CCMe$_3$) followed by either reductive elimination of HCl or by rearrangement to the vinylidene OsCl$_2$ (PPh$_3$)$_2$(=C=CHCMe$_3$).

Protonation of the oximate complexes OsHCl$_2$(ON=CR$_2$)(P^{i}Pr$_3$)$_2$ produces OsHCl$_2$(=N=CR$_2$)(P^{i}Pr$_3$)$_2$. An X-ray crystal structure of one derivative shows that it has a short osmium–nitrogen bond distance. This complex reacts with



Scheme 15



Scheme 16

terminal alkynes to give carbyne complexes. Studies of reaction intermediates show that the transformation involves a series of hydrogen transfer reactions among the metal center, the acetylene, and the coordinated nitrogen atom.[25]

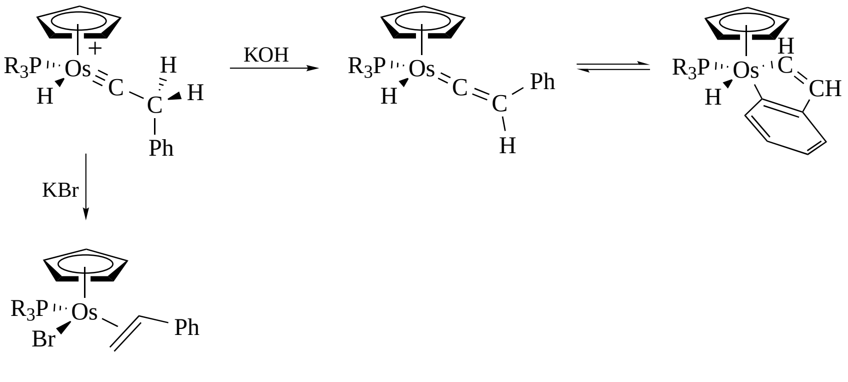
The reactivity of osmium with terminal alkynes can be used to prepare bimetallic complexes. When an osmium hydride reacts with a terminal alkyne that is part of a ruthenium complex, the product is a Ru–Os bimetallic complex with a hydrocarbon bridge (Scheme 16). Another bimetallic complex, $[Cp(PPh_3)_2Os{=}C{=}C{=}CH{-}C{\equiv}C{-}Os(PPh_3)_2Cp]^+$, resulted from the reaction between $[CpOs(PPh_3)_2]^+$ with $HC{\equiv}CCH(OH)C{\equiv}CH$ followed by alumina. The unsaturated C_5 bridging group is V-shaped.

Several groups have completed computational studies on the relative stabilities of osmium carbyne, carbene, and vinylidene species. DFT calculations on the relative thermodynamic stability of the possible products from the reaction of $OsH_3Cl(P^iPr_3)_2$ with a vinyl ether $CH_2{=}CH(OR)$ showed that the carbyne was favored.[26] Ab initio calculations indicate that the vinylidene complex $[CpOs({=}C{=}CHR)L]^+$ is more stable than the acetylide, $CpOs({-}C{\equiv}CR)L$, or acetylene, $[CpOs(\eta^2\text{-}HC{\equiv}CR)L]^+$, complexes but it doesn't form from these complexes spontaneously. The unsaturated osmium center in $[CpOsL]^+$ oxidatively adds terminal alkynes to give $[CpOsH({-}C{\equiv}CR)L]^+$. Deprotonation of the metal followed by protonation of the acetylide ligand gives the vinylidene product.

Carbynes and vinylidenes interconvert. Deprotonation of $OsHCl_2({\equiv}CCH_2Ph)(P^iPr_3)_2$ converts the carbyne to a vinylidene ligand. In the presence of pyrazole, the vinylidene complex $OsH(pz)(Hpz)({=}C{=}CHPh)(P^iPr_3)_2$ can be isolated. A related complex, $OsH_3Cl(PPh_3)_2$, reacted with an internal alkyne, $CH_3C{\equiv}CPh$, to give the allenyl–vinyl complex $OsCl(CMe{=}CHPh)(CH_2{=}C{=}CHPh)(PPh_3)_2$. Deprotonation of one of the methylene protons on the carbyne ligand of $[CpOs(H)({\equiv}CCH_2Ph)(P^iPr_3)][BF_4]$ converts it to a vinylidene complex that is in equilibrium with an orthometallated metallocycle. Trimethylphosphite traps a vinyl complex and reprotonation of this gives a carbene. The reaction of $[CpOs(H)({\equiv}CCH_2Ph)(P^iPr_3)][BF_4]$ with KBr results in the formation of an alkene complex $CpOsBr(\eta^2\text{-}CH_2{=}CHPh)(P^iPr_3)$ rather than a vinylidene complex (Scheme 17). Labeling studies indicate that bromide induces hydride migration in an intermediate vinylidene hydride complex.[27]

4.3 Phosphinidene and Silylene Complexes

An aminophosphinidene complex $Cp^*Os(CO)_2\{PCl(N\text{-}^iPr_2)\}$ was prepared by reaction of $[Cp^*Os(CO)_2]^-$ with $^iPr_2NPCl_2$. As with Fischer carbenes (*see Fischer-type Carbene Complexes*), the nitrogen group stabilizes the electron-deficient phosphorus atom of the phosphinidene ligand. Based on a crystal structure of the ruthenium analog, there is likely



Scheme 17

an osmium–phosphorus single bond in this complex.[28] An unstabilized silylene complex $(C_5Me_5)Os(PMe_3)_2(=SiMe_2)$ results from the reaction of $Cp^*Os(PMe_3)_2(SiMe_2X)$, where X = Cl, OTf, with $LiB(C_6F_5)_4$ in fluorobenzene solution. The product is unstable in dichloromethane, probably owing to Cl abstraction by the silicon center.[29]

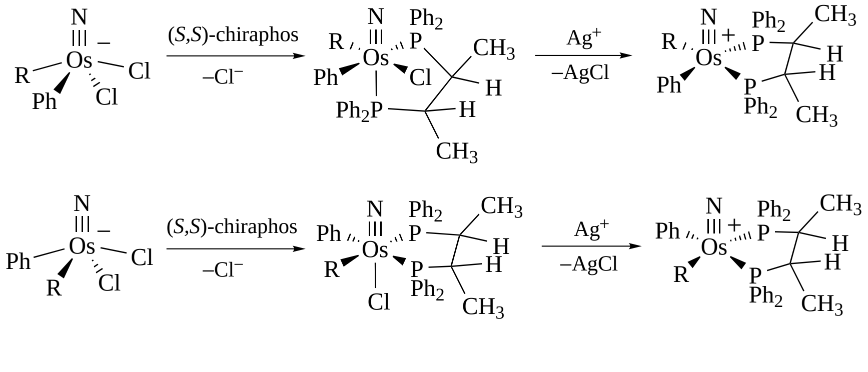
5 HIGH OXIDATION STATE COMPLEXES

While inorganic complexes of osmium in oxidation states +4 through +8 have been known for many years, the study of high-valent alkyl and aryl complexes of osmium is much more recent. The organometallic complexes include homoleptic (*see Homoleptic Compound*) alkyls and aryls, oxo alkyls and aryls, nitrido/imido alkyls and aryls, and cyclopentadienyl (*see Cyclopentadienyl*) alkyls and aryls. The majority of these are complexes of osmium(VI).

Organometallic osmium(IV) complexes are readily characterized by NMR spectroscopy because they are either diamagnetic or, depending on their symmetry, paramagnetic but with sharp NMR signals. Unlike most Os(IV), six-coordinate porphyrin complexes, the dialkylporphyrin complex of osmium(IV) $Os(TPP)(CH_2SiMe_4)_2$ is diamagnetic and has a distorted geometry with a C–Os–C angle of 140°. Calculations indicate that this distortion in the environment removes the degeneracy of the d_{xz} and d_{yz} orbitals on osmium and is responsible for the diamagnetism.[30]

5.1 Nitrido and Imido Complexes

The nitrido osmium(VI) alkyl and aryl complexes constitute the largest group of high oxidation state organometallic complexes of this metal. Five-coordinate complexes are square pyramidal with an apical nitrido ligand. Examples include anionic complexes $[N(n\text{-Bu})_4][Os(N)Ph_4]$, cationic complexes $[Os(N)(CH_2SiMe_3)_2(NCMe)_2][BF_4]$, and neutral species $Os(N)(CH_3)_3(PMe_3)_2$. The acetylide complexes $[N(n\text{-Bu})_4][Os(N)(C{\equiv}CR)_4]$ are similar to the alkyl and aryl derivatives but somewhat less sensitive to moisture. The chiral-at-metal osmium complex $[N(n\text{-Bu})_4][cis\text{-}Os(N)(CH_2SiMe_3)PhCl_2]$ results from series of alkylation and protonation reactions from $[N(n\text{-Bu})_4][Os(N)Cl_4]$. (*S*,*S*)-Chiraphos displaces a chloride from this complex to produce two isomers of $Os(N)(CH_2SiMe_3)PhCl((S,S)\text{-chiraphos})$ with different configurations at osmium (Scheme 18). One isomer reversibly loses an additional chloride ion and can be separated from the isomer with the opposite configuration by the careful addition of $AgSbF_6$. The diastereomers



Scheme 18

[(*S*)-Os(N)(CH_2SiMe_3)Ph((*S*,*S*)-chiraphos)][SbF_6] and [(*R*)-Os(N)(CH_2SiMe_3)Ph((*S*,*S*)-chiraphos)] [SbF_6] can be isolated separately.

Nitridoosmium complexes with sulfur-containing ligands are electron rich because of the strong π donation from the ligands to the metal. Metal–alkyl complexes with thiolate or dithiolate ligands show a lowered Os≡N stretching vibration in the IR spectrum.[31] The nitridoosmium(VI) complex with four coordinated sulfur atoms in Os(N)Cl(κ^2-$SPPh_2NPPh_2S)_2$ reacts with $(CF_3CO)_2O$, and other acylating agents gave a product resulting from chloride substitution Os(N)($OCOCF_3$)(κ^2-$SPPh_2NPPh_2S)_2$ rather than rather than acylation of the nitrido group.

Simple alkyl and arylimido complexes of osmium(VI), such as $Os(NAr)_2R_2$ or $Os(NMe)R_4$, can be prepared by reacting oxo complexes with primary amines or arylcyanates, or by alkylating nitrido ligands. In general, the imido ligands are weaker π -donors than nitrido or oxo ligands.

5.2 Cyclopentadienyl, Indenyl, and Poly(pyrazolyl)borato Complexes

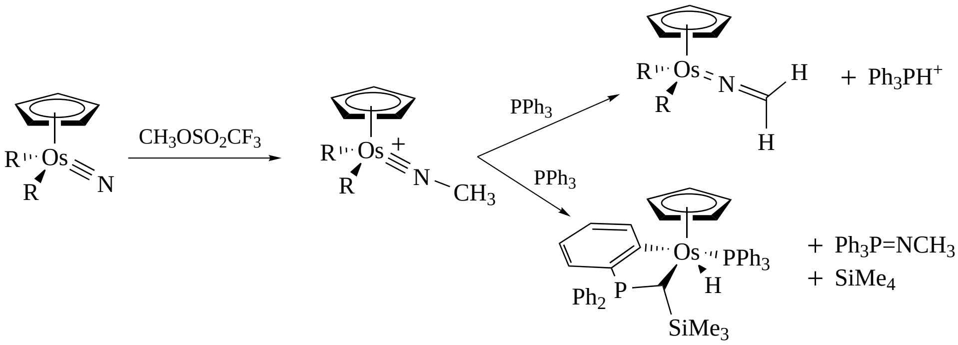
Cyclopentadienyl (*see Cyclopentadienyl*) and pentaalkylcyclopentadienyl osmium complexes have a very rich reaction chemistry and there has been a recent increase in reports of high oxidation state osmium cyclopentadienyl complexes. Poly(pyrazolyl)borates (*see Tris(pyrazolyl)borates*) and alkyl-substituted poly(pyrazolyl)borates are often used as cyclopentadienyl ligand analogues because of the facial coordination that each ligand type usually exhibits, the number of electrons it donates to the metal, and its charge. The bimetallic complex $Cp^*_2Os_2Br_4$ is a precursor for osmium(IV) allyls such as Cp*Os(η^3-allyl)Br_2.[32] The carbyne complex CpOs(≡$CCMe_3$)($CH_2CMe_3)_2$ results from the reaction of Os(≡$CCMe_3$)($CH_2CMe_3)_2(py)_2(O_3SCF_3)$ with NaCp.

As with $[Os(N)R_4]^-$, the nitrido ligand in CpOs(N)($CH_2SiMe_3)_2$ is nucleophilic. This complex reacts with BF_3 to form an adduct, CpOs(NBF_3)($CH_2SiMe_3)_2$, with $AgBF_4$ to form a silver(I)-bridged adduct, {[CpOs($CH_2SiMe_3)_2]_2$(μ-N–Ag–N)}[BF_4] and with [Me_3O][BF_4] or $MeOSO_2CF_3$ to yield cationic methyl imido complexes [CpOs(NMe)($CH_2SiMe_3)_2$][X]. The isoelectronic indenyl and hydrotris(3,5-dimethylpyrazolyl)borate complexes are less reactive with electrophiles. A study of the electrochemistry of isoelectronic oxo, imido, and nitrido complexes Tp*M(E)(X)(Y) [M = Re, Os; Tp* = HB(3,5-$Me_2pz)_3$; Tp = HB$(pz)_3$] shows that the osmium nitrido complexes are the most electron poor. The oxidation potentials follow simple trends, Os(N) > Re(O) > Re(Ntolyl) and Tp > Tp*. Within each series, the oxidation potential trend correlates with the Hammett parameters of the ligands X and Y.

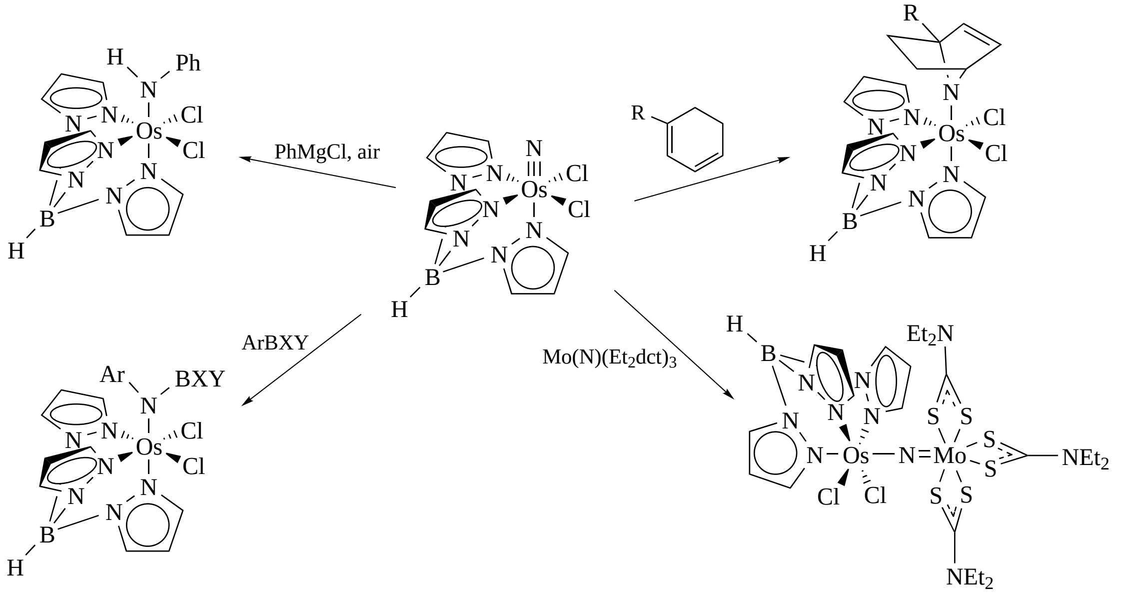
The osmium methylimido complex [CpOs(NCH_3)($CH_2SiMe_3)_2$][SO_3CF_3] reacts with PPh_3 to give both a methyleneamido complex CpOs(NCH_2)($CH_2SiMe_3)_2$ and the unique osmium(IV) metallocycle [CpOs(H)(PPh_3){$CHSiMe_3PPh_2$(C_6H_4)}][SO_3CF_3]. The imido group transfers to PPh_3 to produce Ph_2P=NMe. The imido complex reacts with ethylene to give oligomers of [–N(Me)CH_2CH_2–] (Scheme 19).

The nitrido ligands in nitridoosmium(VI) complexes that lack strongly electron-donating alkyl ligands are electrophilic. The nitrido complexes *cis*- and *trans*-[(tpy)OsNCl_2]$^+$ react with 1,3-diphenylisobenzofuran to form azavinylidene complexes. The *trans* terpyridyl complex also reacts with secondary amines, such as morpholine, to give azido complexes *trans*-[Os(tpy)Cl_2(NNR_2)][PF_6] along with a reduced, μ-dinitrogen complex [(tpy)$Cl_2Os]_2$(μ-N_2). Trialkyl and triarylphosphines also react at the electrophilic nitrido ligand in [Os(tpy)Cl_2(N)][PF_6]. The reaction with triphenylphosphine is first order in both phosphine and metal complex and gives [Os(tpy)Cl_2($NPPh_3$)][PF_6]. Related nitridoosmium(VI) complexes of Schiff-base ligands also form phosphoranimato complexes by attack of PPh_3 on the electrophilic nitrido group.

Grignard reagents (*see Grignard Reagents*), organoboranes (*see* ***Boron: Organoboranes***), and other nucleophilic reagents add to the electrophilic nitrido ligand in the hydrotris(1-pyrazolyl)borate (*see Tris(pyrazolyl)borates*) complex TpOs(N)Cl_2. The reactions with phenylmagnesium chloride or phenyllithium give the anilino complex after workup. Other aryl Grignard reagents react similarly. Boranes, such as BPh_3, also add to the nitrido group. Water, in the absence



Scheme 19



Scheme 20

of O_2, reacts with the addition product to form an anilino derivative of osmium(IV). It reacts with 1,3-cyclohexadienes at the nitride to form a azanorbornene derivatives. With a nucleophilic molybdenum nitrido complex, $(Et_2NCS_2)_3MoN$, $TpOs(N)Cl_2$ produces dinitrogen along with a bridging nitrido complex $(Et_2NCS_2)_3Mo(\mu\text{-}N)OsCl_2Tp$ and an osmium thionitrosyl complex $TpOsCl_2(NS)$ (Scheme 20). Labeling studies show that the dinitrogen results from the mixed-metal coupling reaction.[33] Derivatives of $TpOs(N)X_2$, where X is a halide, nitrato, or carboxylate ligand, react with PPh_3 to give reduced complexes $TpOs(NPPh_3)X_2$ and with BPh_3 to give $TpOs\{(NPh)BPh_2\}X_2$. The rate of reactions with phosphine correlates with the reduction potential of the nitrido complexes (*see Nitride Complexes*).[34] The nitrido ligand in $TpOs(N)Cl_2$ abstracts an oxygen from nitric oxide to form N_2O and $TpOs(NO)Cl_2$. A similar reaction occurs between $TpOs(N)Cl_2$ and $ONMe_3$.

Several new trimetallic complexes containing osmium in high oxidation state have been reported. The thermolysis of $Os(N)Cl_3L_2$, where L is a substituted pyridine ligand, produces linear triosmium complexes with bridging nitrido groups $Os_3(N)_2Cl_8L_6$.[35] The polynuclear osmium sulfido complexes $[N(n\text{-}Bu)_4][\{Os(N)(CH_2SiMe_3)_2\}_3(\mu_3\text{-}S)_2]$ and $\{Os(N)(CH_2SiMe_3)_2\}_2(\mu_3\text{-}S)_2(Pt)(dppe)$ were prepared by the reaction of $[N(n\text{-}Bu)_4][Os(N)(CH_2SiMe_3)_2Cl_2]$ with LiS or with $Pt(SSiMe_3)_2(dppe)$.[36]

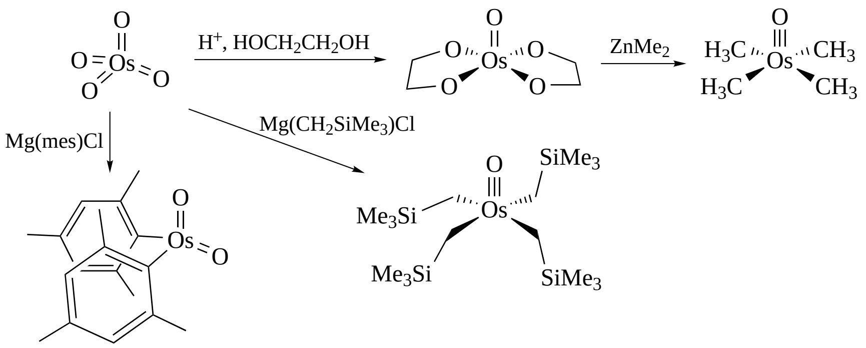
5.3 Oxo Complexes and O_2 Activation

Oxo ligands help to stabilize high oxidation state alkyl complexes. Some oxo alkyl and aryl complexes of osmium(VI) can be prepared from OsO_4. A mesityl complex, $OsO_2(2,3,5\text{-}C_6H_2Me_3)_2$, and a (trimethylsilyl)methyl complex, $OsO(CH_2SiMe_3)_4$, each result from the direct reaction of the Grignard reagent and OsO_4. The methyl complex $OsO(CH_3)_4$ can be prepared by alkylation of OsO_4 with $ZnMe_2$ or with $MeTi(OCHMe_2)_3$, or by methylation of $OsO(OCH_2CH_2O)_2$ (Scheme 21). Similar reactions result in $Os(O)Et_4$ and $Os(O)Me_2(CH_2SiMe_3)_2$. The reaction between $Os(O)_2(py)_2(OCH_2CH_2O)$ and dialkylzinc compounds produces $Os(O)_2(py)_2R_2$ (R = CH_3, CH_2SiMe_3). Except for $Os(O)Et_4$ which decomposes by ß-hydrogen elimination (*see β-Hydride Elimination*), the oxoalkyl complexes are remarkably stable to air and water.

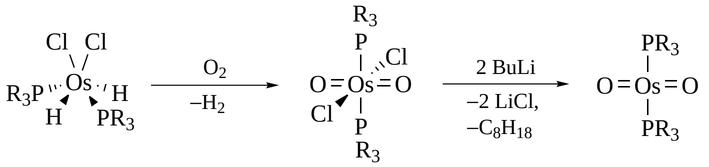
The reaction of molecular oxygen with osmium complexes is significant because of the importance of osmium-containing selective oxidation catalysts. Dioxygen adds to $OsCl_2H_2(P^iPr_3)_2$ to give an osmium(VI) dioxo complex *trans*-$Os(O)_2Cl_2(P^iPr_3)_2$. Reduction of this complex with n-butyllithium produces a unique square-planar d^4 complex *trans*-$OsO_2(P^iPr_3)_2$ (Scheme 22).[37] The osmium(II) complexes of chelating diphosphines $[OsCl(P\text{–}P)_2][PF_6]$ react quantitatively with O_2 to give peroxide complexes, $[OsCl(P\text{–}P)_2(\eta^2\text{-}O_2)][PF_6]$. The peroxo complex oxidizes iodide to I_3^- and PPh_3 to $OPPh_3$ in the presence of acid. The osmium-containing product is an osmium(IV) oxo complex.

6 CARBONYL COMPLEXES (*See Carbonyl Complexes of the Transition Metals*)

Carbon monoxide is a relatively poor Lewis base. The strength of the Os–CO bond depends on both the overlap



Scheme 21



Scheme 22

of the CO orbital containing the lone pair of electrons with an empty osmium orbital and the back donation of electron density from a filled osmium d orbital to the empty CO π^* orbital. This and the other π-acid ligands CS, CNR, NO, and PF_3 bond most strongly with electron rich, low oxidation state transition metals.

6.1 Simple Carbonyl Complexes

Osmium pentacarbonyl, a volatile, colorless liquid, has a trigonal bipyramidal structure. It loses CO to form the air stable yellow solid $Os_3(CO)_{12}$ (Figure 2). Photolysis of $Os(CO)_5$ at low temperature produces $Os_2(CO)_9$. Thermolysis of osmium carbonyl produces $Os_5(CO)_{16}$, $Os_6(CO)_{18}$, $Os_7(CO)_{21}$, and $Os_8(CO)_{23}$. At higher temperatures, the carbido clusters $Os_5C(CO)_{15}$ and $Os_8C(CO)_{21}$ are formed from $Os_3(CO)_{12}$. Reduction of either $Os(CO)_5$ or $Os_3(CO)_{12}$ with sodium produces the anionic carbonyl complex $Na_2Os(CO)_4$. This reacts with CO_2 to give the dimer $Na_2Os_2(CO)_8$. A cationic carbonyl complex $[Os(CO)_6][AlCl_4]$ has been characterized spectroscopically.

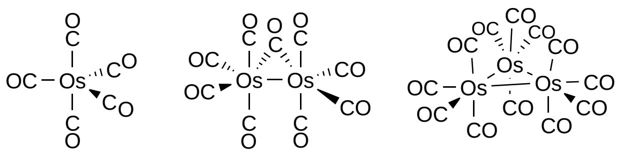


Figure 2 Osmium carbonyl complexes

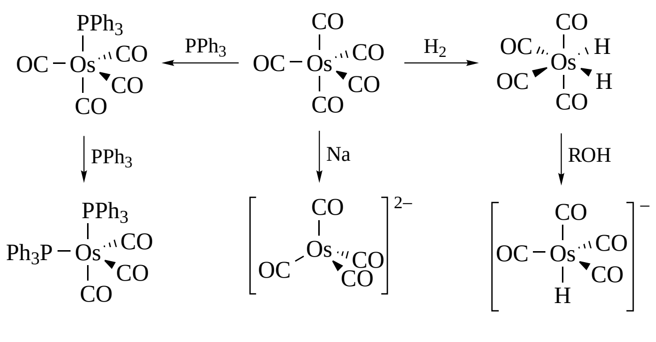
Osmium pentacarbonyl is a convenient precursor to other osmium carbonyl complexes. Hydrogenation gives the dihydride $OsH_2(CO)_4$. This hydride is not acidic with a pK_a of 18.5 but it can be deprotonated by strong bases to give $[OsH(CO)_4]^-$ and reduced by sodium (Scheme 23). Substitution of CO on $Os(CO)_5$ by trialkyl or triarylphosphines, arsines, or stibenes gives $Os(CO)_4L$ or $Os(CO)_3L_2$. Other carbonyl phosphine complexes result from the reduction of osmium halides by alcohols in the presence of the tertiary phosphine.

Neutral carbonyl halides $Os(CO)_4X_2$, $[Os(CO)_3X_2]_2$, $[Os(CO)_2X_2]_n$, and $[Os(CO)_4X]_2$ can be prepared from $Os(CO)_5$ or from $OsH_2(CO)_4$. The anionic carbonyl halides *trans*-$[OsX_4(CO)_2]^-$, *cis*-$[OsX_4(CO)_2]^-$, and *mer*-$[OsX_3(CO)_3]^-$ result from carbonylation of Na_2OsX_6 (X = Cl, Br) under different conditions. The reaction between $NaOsBr_4(CO)_2$ and HX (X = Cl, Br, I) produces $[OsX_5(CO)]^{2-}$.



Scheme 23

6.2 Complexes of Other Pi Acid Ligands

Isonitriles are isoelectronic with carbon monoxide but homoleptic (*see Homoleptic Compound*) isonitrile complexes are more difficult to prepare than carbonyl complexes. The reduction of OsX_6^{2-} with ethanol in the presence of methylisonitrile gives $OsX_2(CNMe)_4$. The osmium(II) isonitrile complex $[Os(CNMe)_6]^{2+}$ results from the alkylation of $[Os(CN)_6]^{4-}$ with $MeOSO_2CF_3$. More generally, $[Os(CNR)_6]^{2+}$ can be prepared by reaction of $Os_2(O_2CMe)_4Cl_2$ with alkyl isonitriles.

The reaction between osmium carbonyl complexes and $NO_{(g)}$ produces nitrosyl complexes. Photolysis of $Os(CO)_5$ with NO in an inert gas matrix at low temperature generates $Os(CO)_2(NO)_2$ but this complex is thermally unstable. The phosphine complex $Os(PPh_3)_2(NO)_2$ results from the reaction of $Os(PPh_3)_2(CO)_2Cl_2$ with $NaNO_2$. The reaction of $Os(PPh_3)_2(NO)_2$ with perfluoroacetic acid produces a hydroximate $Os\{ON{=}C(O)CF_3\}(O_2CCF_3)(NO)(PPh_3)_2$ and a hydride $OsH(O_2CCF_3)(NO)(PPh_3)_2$.

Substitution reactions of CS_2 for alkene, carbonyl, or phosphine ligands gives either carbon disulfide complexes or thiocarbonyl complexes. The reaction of $Os(CO)_2(\eta^2\text{-}C_2H_4)(PPh_3)_2$ with CS_2 forms $Os(CO)_2(\eta^2\text{-}CS_2)(PPh_3)_2$. This reacts with PPh_3 to give the thiocarbonyl complex $Os(CO)(CS)(PPh_3)_3$ and $S{=}PPh_3$. The reaction between $OsCl_2(PPh_3)_3$ with CS_2 gives $OsCl_2(CS)(PPh_3)_2$ and $S{=}PPh_3$ directly. The carbon disulfide complex $Os(CO)_2(\eta^2\text{-}CS_2)(PPh_3)_2$ reacts with methyl iodide to give a dithiocarbene complex and with sodium borohydride to give a thioester (Scheme 24).

6.3 Carbonyl Clusters

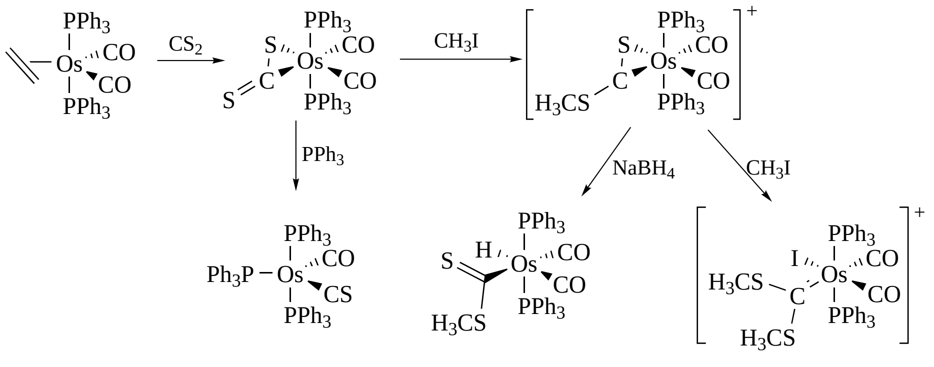
Osmium forms stronger metal–metal bonds than either iron or ruthenium; consequently, there are a large number of osmium carbonyl clusters (*see Cluster*) and these complexes have a large body of reaction chemistry. The triosmium cluster are prepared from $Os_3(CO)_{12}$. Most are diamagnetic and air-stable materials. Additional information can be found in a review by Deeming.[38]

The triosmium carbonyl $Os_3(CO)_{12}$ is a saturated complex in that all of the osmium centers achieve an 18 electron count and the molecule is relatively unreactive. By heating to temperatures over 120 °C or photolysis, various two-electron donor molecules can substitute for carbonyl ligands and form mixtures of $Os_3(CO)_{11}L$, $Os_3(CO)_{10}L_2$, $Os_3(CO)_9L_3$ and other complexes. Bulky phosphine and phosphite ligands usually take equatorial positions in the cluster while less sterically demanding isonitrile ligands can bond in axial positions. More selective carbonyl substitution reactions occur when the cluster is treated with amine-N-oxides or phosphine oxides. Nucleophilic attack by $ONMe_3$, for example, on one carbonyl ligand of $Os_3(CO)_{12}$ results in the formation of CO_2 and $Os_3(CO)_{11}(NMe_3)$. The amine is weakly bonded and can be displaced by a variety of other donors.

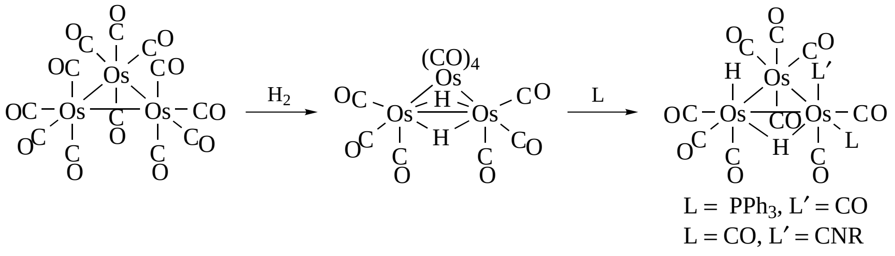
The acetonitrile complexes $Os_3(CO)_{11}(NCMe)$ and $Os_3(CO)_{10}(NCMe)_2$ are particularly reactive species and are useful precursors to other triosmium cluster complexes. Aldehydes react with $Os_3(CO)_{11}(NCMe)$ to give $Os_3(CO)_{10}(\mu\text{-H})(COR)$. Phosphines, phosphites, and arsines cleanly substitute for the acetonitrile ligands.

Alkenes and alkynes can substitute for carbonyl ligands on $Os_3(CO)_{12}$. Carbon monoxide slowly dissociates from $Os_3(CO)_{11}(\eta^2\text{-PhC}{\equiv}\text{CPh})$ and a cluster with a bridging alkyne ligand forms, $Os_3(CO)_{10}(\mu\text{-PhC}{\equiv}\text{CPh})$. The addition of ethene to the cluster gives a bridging vinylidene complex, $Os_3(CO)_9(\mu\text{-H})_2(\mu\text{-C}{=}CH_2)$. The oxidative addition of terminal alkynes to $Os_3(CO)_{12}$ gives $Os_3(CO)_9(\mu\text{-H})(\mu_3\text{-CCR})$. Nucleophiles add to the bridging alkyne unit.

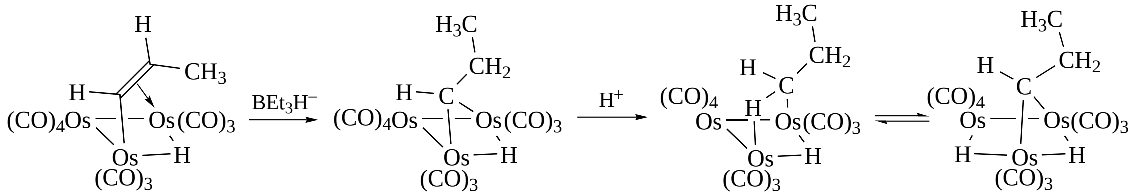
The reaction of $Os_3(CO)_{12}$ with H_2 at 110 °C. produces a reactive, unsaturated hydrido cluster $Os_3(\mu\text{-H})_2(CO)_{10}$. This dark purple complex is analogous to diborane and has the two hydrides bridging a very short Os–Os bond. It can add phosphines, phosphites, arsines, pyridine, and isocyanides to form $Os_3H_2(CO)_{10}L$ (Scheme 25). The hydrido cluster adds alkenes and alkynes. Initially, an addition complex with a π-bonded alkene or alkyne is formed. Hydride addition to the unsaturated ligand follows.



Scheme 24



Scheme 25



Scheme 26

While much of the efforts in osmium cluster chemistry are on synthesis and structural characterization, there have been a number of important studies on reactions in solution, particularly on isomerization reactions. The reaction between diazomethane and $Os_3(\mu\text{-}H)_2(CO)_{10}$ produces a mixture of a methyl complex $Os_3(\mu\text{-}H)(CH_3)(CO)_{10}$ and a methylene complex $Os_3(\mu\text{-}H)_2(\mu\text{-}CH_2)(CO)_{10}$. Variable-temperature NMR studies showed that these two isomers are in equilibrium and that the methyl group interacts with a second osmium center through a C–H–Os bridge.[39] Two isomers of the substituted vinyl compound $Os_3(CO)_9L(\mu\text{-}H)(\mu\text{-}CH{=}CH_2)$ are in equilibrium in solution. The position of the equilibrium depends on the size of the phosphine ligand, L. There is a similar steric effect in the equilibration of methyl and methylene tautomers of $Os_3(\mu\text{-}H)_2(\mu\text{-}CH_2)(CO)_9L$ and $Os_3(\mu\text{-}H)(CH_3)(CO)_9L$ with larger ligands favoring the methylene complex.

The propyl compound $Os_3(\mu\text{-}H)_2(\mu\text{-}CHCH_2CH_3)(CO)_{10}$ equilibrates with a propylidene tautomer $Os_3(\mu\text{-}H)(CH_2CH_2CH_3)(CO)_{10}$ at −25 °C (Scheme 26). It decomposes to propene and $Os_3(\mu\text{-}H)_2(CO)_{10}$ near room temperature. Information from this and other studies shows that the alkyl/alkylidene equilibrium shifts toward the alkylidene form with greater chain length of the alkyl. The rate of β-hydride elimination (*see β-Hydride Elimination*) is four times greater for the propyl compound versus the ethyl compound $Os_3(\mu\text{-}H)R(CO)_{10}$ at room temperature.[40]

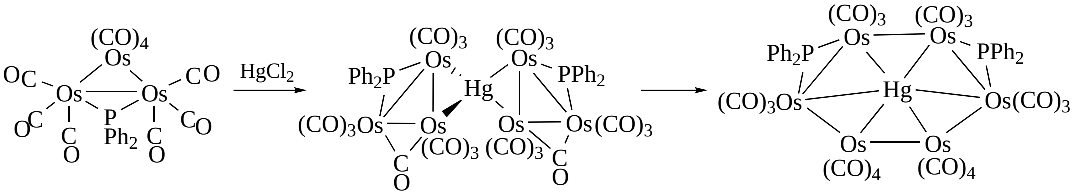
The monophosphine complexes $Os_3(\mu\text{-}H)_2(CO)_9L$ react with diazomethane to give N_2 and a wide range of homologous alkenes. The rates of diazomethane decomposition correlate well with the electronic nature of L rather than its size, with less donating ligands showing higher rates.

Roberto and coworkers have developed a high-yield synthesis of $Os_3(CO)_{10}(\mu\text{-}H)(\mu\text{-}OH)$ by hydrolysis of the silica supported intermediate $Os_3(CO)_{10}(\mu\text{-}H)$(OSi-silica) in a biphasic water/toluene mixture.[41] The hydroxy compound undergoes ready substitution by a variety of HOR compounds to give new $Os_3(CO)_{10}(\mu\text{-}H)(OR)$ derivatives. This suggests the use of the triosmium compound as a labeling agent for specific sites in biomolecules.

The face-bonded triosmium cluster of buckminsterfullerene $Os_3(CO)_9(\mu_3\text{-}\eta^2;\eta^2;\eta^2\text{-}C_{60})$ has been prepared and phosphine substituted derivatives were structurally characterized.

Larger osmium clusters result from the pyrolysis of $Os_3(CO)_{12}$ or by the addition of mononuclear fragments to unsaturated clusters. A by-product of the hydrogenation of $Os_3(CO)_{12}$ is $Os_4(CO)_{12}H_2$. The thermal reaction between $OsH_2(CO)_4$ and Os_3 clusters gives tetraosmium hydrido clusters. The addition of sulfur, selenium, or tellurium to $Os_3(CO)_{12}$ produces clusters with bridging chalogenide ligands such as $Os_4(CO)_{12}(\mu_3\text{-}S)$. The raft-like (*see Raft Clusters*) clusters $Os_6(CO)_{20}(NCMe)$ and $Os_6(CO)_{19}(NCMe)_2$ were formed by the coupling of $Os_3(CO)_{10}(NCMe)_2$ in the presence of $PdCl_2$. Mercury(II) induces the coupling of two triosmium clusters to $Os_6(\eta^6\text{-}Hg)(\mu\text{-}PR_2)_2(CO)_{20}$ (Scheme 27).[42]

Silica has been used as a reaction medium for improved syntheses of higher nuclearity clusters by reduction of supported $[Os(CO)_3Cl_2]_2$ in the presence of adsorbed sodium or potassium carbonate. In this manner $K_2[H_2Os_4(CO)_{12}]$ is prepared in yields greater than 85% by carbonylation at 200 °C, and $Na_2[Os_{10}C(CO)_{24}]$ is generated in 75% yield by reduction with H_2 at a similar temperature. Treatment of silica supported $[Os(CO)_3Cl_2]_2$ with Na_2CO_3 in ethylene glycol at



Scheme 27

160 °C. and 1 atmosphere H_2 gives $Na_2[H_4Os_{10}(CO)_{24}]$ in up to 80% yield.

7 CATALYSIS WITH OSMIUM COMPLEXES

Osmium complexes catalyze a large number of reaction of organic molecules including the reduction of alkenes, alkyne, carbon monoxide, aldehydes, and ketones with molecular hydrogen.[43] The osmium catalysts are used less often than corresponding ruthenium catalysts. Because the Os-ligand bonds are stronger than Ru-ligand bonds, catalytic reactions are usually slower with osmium. Also, the greater cost of osmium over ruthenium disfavors its use in most catalytic reactions.

In oxidation reactions, however, osmium is significantly more selective than catalysts derived from other transition metals. Osmium-based catalysts for the hydroxylation and amination of alkenes are very widely used in organic synthesis.[44] With alkaloid-derived ligands, the hydroxylation and amination reactions are highly enantioselective (*see Enantioselectivity*). The use of bleach, hydrogen peroxide, ferric cyanide, and oxygen have been reported as secondary oxidants for some of these reactions.

The heterobimetallic complexes $[N(n\text{-Bu})_4]$ $[Os(N)R_2(\mu\text{-}O)_2CrO_2]$ catalyze the selective oxidation of alcohols with molecular oxygen.[45] A mechanism in which alcohol coordinates to the osmium center and is oxidized by ß-hydrogen elimination (*see β-Hydride Elimination*) is consistent with the data. The hydroxide adduct of OsO_4, $[Os(OH)_2O_4]^{2-}$, with ferric cyanide and other co-oxidants catalyzes the oxidative dehydrogenation of primary aromatic and aliphatic amines to nitriles, the oxidation of primary alcohols to carboxylic acids, and of secondary alcohols to ketones. Osmium derivatives such as $OsCl_3$ catalyze the effective oxidation of saturated hydrocarbons in acetonitrile through a radical mechanism.[46]

Much of the current research focuses on improving the selectivity of the oxidation reactions while making them more atom efficient. Oxidation of single functional groups with high stereoselectivity (*see Stereoselectivity*) is important for applications of osmium catalysis in organic synthesis. The use of molecular oxygen or hydrogen peroxide as secondary oxidants improves the atom economy of the reactions, and the development of supported analogs of osmium catalysts will improve their ease of use.

1 INTRODUCTION

Oxidation catalysis[1–7] by transition metals holds a special place in chemistry. It forms a part of bioinorganic chemistry[1,2,5,6] in that biological oxidations are catalyzed by metalloenzymes. It relates to organic chemistry[3] in that organic reactions are the ones often catalyzed. It poses hard mechanistic problems, as shown by the sharp disagreements that have arisen on this issue over the years on matters such as the intermediacy of radical versus nonradical pathways. Oxidation is often also harder to control in terms of selectivity than most reductive pathways. A few highly selective catalysts like the Sharpless and Jacobsen oxidations have been developed, and they have proved so useful that they have been widely adopted as organic methods. Selective oxidation also has great importance for industrial applications.[7] Many potentially useful conversions, such as methane to methanol, remain elusive yet a broad spectrum of valuable catalytic transformations has been discovered, including the Wacker process and terephthalic acid syntheses. Suppression of oxidation catalysis by transition metals with sequestering agents such as sodium EDTA is also of practical importance, for example, in the food industry. Environmental applications[8] include oxidative environmental remediation, as in the Collins catalyst.

So vast and disparate is the range of topics involved that we can only touch on selected individual aspects. Severe selection is therefore necessary, and the reader interested in following up particular areas in greater detail is referred to the appropriate monographs.[1–6] In particular, Meunier's book[2] is good for mechanistic detail and biomimetic applications, and Comprehensive Organic Chemistry[3] has an extensive discussion of reagents, catalysts, and their reactions in the context of organic methods.

2 REAGENTS AND CONDITIONS

Some general points hold for all catalytic oxidations. In any catalytic reaction, we need a stoichiometric source of oxidizing power, the primary oxidant. In biology this is typically air, in large-scale commercial applications, air or oxygen, but in organic chemistry, a wide range of more sophisticated oxidants tends to be used, often *t*BuOOH, MCPBA or some other peroxy species. Commercially, only the cheaper oxidants are possible for large-scale work while higher value fine chemical products can justify more expensive oxidants.

Where O_2 or air is used as primary oxidant, both oxygen atoms may be introduced into substrate, in which case we have a dioxygenase (equation 1). This pathway tends to occur for substrates that are most readily oxidized. The harder substrates, notably unactivated CH bonds, require the presence of a 2e reductant to help activate the O_2. In this case one O atom of the O_2 molecule is reduced to H_2O while the other is incorporated into substrate, Q. This is the monooxygenase pathway.[1,2]

$$2Q + O_2 = 2Q{=}O \tag{1}$$

$$Q + 2e^- + 2H^+ + O_2 = Q{=}O + H_2O \tag{2}$$

Each major class of oxygenase and monooxygenase enzyme has a vast literature. A general pattern, however, is that most such enzymes have either Fe or Cu as active site metals, often in multinuclear cluster centers. For iron, the Fe(II)/(III) couple is often accessed with Fe(IV) present in certain cases. For copper, the typical states are Cu(I)/(II) with Cu(III) also present in some cases. Since O_2 is a 4e oxidant, while the low-valent metals are 1 or 2e reductants, a cluster site can help attain compatibility of oxidant and reductant by allowing the site to take up more than one electron.

The initial interaction of O_2 with a reduced metal in a metalloenzyme commonly goes with 1e or 2e metal-to-ligand electron transfer to give coordinated superoxide (O_2^-) as in hemoglobin or peroxide (O_2^{2-}) as in hemocyanin (Figure 1). Reversibility of O_2 binding is possible in this way as in oxygen transport proteins. In an oxygenase reaction the initial O_2^- or O_2^{2-} metal adduct can react directly with the substrate to go on to product. In the case of a monooxygenase, 2e reduction cleaves the O–O bond to form a highly reactive metal-oxo intermediate that is the active oxidant.

Typical examples of enzymes and their properties appear in the articles ***Copper Proteins: Oxidases***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***; ***Iron: Heme***

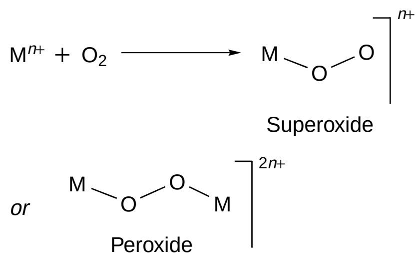

Figure 1 Two of the commonest ways in which O_2 can bind to a metal

Proteins, Mono- & Dioxygenases; oxygen as a ligand is discussed in ***Dioxygen & Related Ligands***.

Air and dioxygen are desirable primary oxidants where they are effective; a stoichiometric coreductant may have to be present for oxidation to occur if a monooxygenase pathway is adopted.

A very broad class of primary oxidants act as oxygen atom transfer agents, the most widely used oxidants in oxidation catalysis. These include peracids or their anion forms, such as MCPBA or oxone ($O\text{-}OSO_3^{2-}$) as well as *N*-oxides such as *N*-methyl morpholine *N*-oxide or hypochlorite ion. They all have general structure XO, where X is a good leaving group.

Peroxides, typically *t*BuOOH and H_2O_2 itself, form another very important class of oxidant. These can act as O transfer agents but more commonly undergo metal-catalyzed O–O homolysis to yield radicals. A typical reaction sequence is shown in (equation 3–4). These oxidants are favored because of their cheapness and, for H_2O_2, its benign character. Electron transfer oxidants, including Ce(IV) and $[FeCp_2]^+$, are less often involved in catalytic chemistry.

$$\text{Fe(II)} + H_2O_2 \Longrightarrow \bullet OH + \text{Fe(III)–OH} \quad (3)$$

$$\text{Fe(III)-OH} + H_2O_2 \Longrightarrow \bullet O_2H + \text{Fe(II)} + HOH \quad (4)$$

Mayer[9] has given the best discussion of thermodynamic issues at stake in oxidation. Primary oxidants differ greatly in their thermodynamic driving force given by the Mayer classification, for example: O_3/O_2, 25 kcal mol^{-1}; H_2O_2/H_2O, 34 kcal mol^{-1}; N_2O/N_2, 40 kcal mol^{-1}; $1/2O_2$, 60 kcal mol^{-1}; C_6H_5NO/C_6H_5N, 72 kcal mol^{-1}. Lower numbers are associated with more powerful oxidants. Ozone is so powerful an oxidant it does not need a catalyst, but all the others mentioned are commonly used with catalysis.

Likewise, substrates differ in their ease of oxidation. Mayer's figures are: Ph_3P/Ph_3PO, −135 kcal mol^{-1}; CO/CO_2, −127 kcal mol^{-1}; RH/ROH, −90 to −102 kcal mol^{-1}; Me_2S/Me_2SO, −87 kcal mol^{-1}; alkene/epoxide, −85 to −92 kcal mol^{-1}. PPh_3 is so easily oxidized, both thermodynamically and kinetically, that it is often used as a probe for minimal oxidation activity. If it is not oxidized then the catalytic system in question will probably be inactive for all substrates. Obviously, in order to catalyze a given oxidation, an oxidant with an adequate driving force needs to be chosen and the Meyer numbers provide a rational basis to make this choice.

A related problem is selectivity for partial oxidation. For example, in the oxidation of methane to methanol, one needs to avoid over-oxidation. This is hard because the intermediate oxidation products between CH_4 and CO_2 become progressively more kinetically reactive as the reaction proceeds, as suggested by Mayer's figures:

$$CH_4 + O \longrightarrow CH_3OH \qquad \Delta H^\circ = -89.8\ \text{kcal/mol} \quad (5)$$

$$CH_3OH + O \longrightarrow CH_2O + H_2O \qquad -95.3\ \text{kcal/mol} \quad (6)$$

$$CH_2O + O \longrightarrow HCOOH \qquad -124.1\ \text{kcal/mol} \quad (7)$$

$$HCOOH + O \longrightarrow CO_2 + H_2O \qquad -120.9\ \text{kcal/mol} \quad (8)$$

Of course, kinetics rather than thermodynamics is the key factor in selectivity so the Meyer figures only provide a rough guide.

In hydrogen atom transfer (HAT) oxidations, a common mechanistic type, a metal-oxo species abstracts an H atom from an X–H bond. In so doing the oxo acts as the base and takes the proton and the metal acts as the reductant and takes the electron. Thus HAT can be seen as the simultaneous transfer of H^+ and e^-. The main determinant of relative reactivity is the C–H (or X–H) bond energy. For example, tertiary CH bonds react before secondary and primary in line with the bond energies (CH_3–H, 105 kcal mol^{-1}; Et-H, 101 kcal mol^{-1}; *i*Pr-H, 98.6 kcal mol^{-1}). Once again, kinetic factors are relevant, for example, polar effects,[10] but where radical intermediates, X•, carry out a HAT, an important factor in understanding reactivity trends is the H–X bond energy of the corresponding product:

H–OH, 119 kcal mol^{-1}; RO–H, 105 kcal mol^{-1}; Cl–H, 103 kcal mol^{-1}; ROO–H, 89 kcal mol^{-1}; Br–H, 88 kcal mol^{-1}; I-H, 71 kcal mol^{-1}. Higher bond energies are associated with more reactive radicals.

Mayer[9] has also shown some of the best examples in which an effective HAT can occur by coupled transfer of a proton and an electron. For example, in the case of MnO_4^- as oxidant, a proton can be transferred to an oxo group while an electron reduces Mn(VII) to Mn(VI). Although it is diamagnetic, MnO_4^- acts as if it were an X• reagent with reactivity corresponding to an X–H bond energy of 80 kcal mol^{-1}. Phenol substrates are much more kinetically reactive than their PhO–H bond energy (87 kcal mol^{-1}) would suggest, presumably as the result of polar effects.

Alkyl hydroperoxides, very common primary oxidants, raise difficult mechanistic issues. Either free radical reactions can follow from peroxide homolysis, or metal-oxo chemistry can follow from O atom transfer to the metal. A peroxide that has proved useful in distinguishing the two cases is $PhCH_2CMe_2(OOH)$. If homolysis occurs, the resulting $PhCH_2CMe_2O\bullet$ radical fragments to $PhCH_2\bullet$ and Me_2CO at a rate of ca. 2×10^8 sec^{-1}, fast enough to avoid most

bimolecular traps. Likewise, the substrate may be chosen to rearrange rapidly: cyclopropylmethyl radical rearranges to homoalkyl radical at a rate of *ca*. 10^8 sec^{-1}. Ingold[11] has taken this analysis furthest and 'unmasked' several systems originally thought to involve metal-oxo chemistry but in fact going by a radical route.

Careful choice of solvent is usually required. Typical oxidation-resistant solvents include AcOH, MeCN, H_2O, $PhNO_2$, and $CHCl_3$.

The ligands also have to be oxidation resistant. This means that ligands, such as ethylenediamine, with weak, reactive CH bonds usually need to be avoided.

Strongly electron-donating ligands are often preferred as they stabilize high oxidation states. Deprotonated amides combine this feature with oxidation resistance and have seen numerous applications, such as the Collins catalyst.[12] In contrast, phosphines are not useful, being neither particularly strong donors, nor oxidation resistant. Most of the ligands that have proved useful in oxidation are chelates, no doubt to avoid ligand dissociation which would normally be followed by ligand oxidation.

3 AUTOXIDATION

Autoxidation, the oxidation of organic compounds by air, normally occurs via a radical chain mechanism. For example, cyclohexene undergoes allylic CH abstraction by an initiator, and the resulting cyclohexenyl radical reacts with O_2 to give the corresponding hydroperoxy radical that abstracts an H from cyclohexene. In this case the final product is the allylic hydroperoxide. Conversion of ethers to the hydroperoxides is another familiar example. The conversion of cumene to phenol and acetone is a commercial application of the reaction (equation 9).

$$\text{Ph-CHMe}_2 \Longrightarrow \text{Ph-C(OOH)Me}_2 \Longrightarrow \text{Ph-OH} + \text{Me}_2\text{CO} \quad (9)$$

$$\text{Q}\bullet + \text{RH} \longrightarrow \text{R}\bullet + \text{QH} \quad (10)$$

$$\text{R}\bullet + \text{O}_2 \longrightarrow \text{RO}_2\bullet \quad (11)$$

$$\text{RO}_2\bullet + \text{RH} \longrightarrow \text{R}\bullet + \text{RO}_2\text{H} \quad (12)$$

$$2\text{RO}_2\bullet \longrightarrow \text{RO}_4\text{R} \longrightarrow \text{products} + \text{O}_2 \quad (13)$$

A schematic autoxidation pathway involves initiation (equation 10), propagation (equation 11–12) and termination (equation 13). Since hydroperoxides easily undergo metal-catalyzed decomposition, the addition of a metal can both speed up an air oxidation and avoid the formation of a hydroperoxide, which is rarely the desired final product. This is perhaps the simplest type of metal catalysis. The metal is normally capable of 1e redox behavior, hence typically a 3d transition metal. As shown in equations (14–15), it can decompose the RO_2H to give the highly reactive RO• radical in a manner resembling equation (3–4). RO• radical can abstract H from RH and provide R• radical that in turn reacts with O_2 to form RO_2•; in this way, R plays the role of Q• in equation (10).

$$\text{RO}_2\text{H} + \text{M}^+ \longrightarrow \text{RO}\bullet + \text{M}^{2+} + \text{HO}^- \quad (14)$$

$$\text{RO}_2\text{H} + \text{M}^{2+} \longrightarrow \text{RO}_2\bullet + \text{M}^+ + \text{H}^+ \quad (15)$$

Fe(II)/(III) is the best known such redox couple, but numerous other catalysts are common, including Cu(I)/(II) and Co(II)/(III).

4 OXIDATION PATHWAYS

Metals that are capable of 2e redox changes, typically main group elements and 4d and 5d transition metals, can give heterolysis of a peroxide to form a diamagnetic oxidant that may avoid the radical pathways seen in the case of equation (14–15). O atom transfer to the substrate is possible in this way. Sharpless[13] epoxidation provides an excellent example. In this case *t*BuOOH is the primary oxidant, Ti(*i*-OPr)$_4$ is the catalyst precursor and a tartrate ester is the ligand that induces a high ee in the epoxy alcohol formed from an allylic alcohol. This reaction has been successfully developed on an industrial scale.

Meunier[14] has reviewed recent advances in asymmetric oxidation. Jacobsen's[15] asymmetric epoxidation catalysts are some of the most successful. These use Mn(III) in a chiral salen ligand with NaOCl as primary oxidant. The intermediacy of Mn(V) oxo species has been proposed as the active species formed after O atom transfer from the hypochlorite. Enantiomeric excesses of 97–98% are seen in the epoxide product on a consistent basis across a wide variety of alkene substrates.

Radical clock substrates,[12] such as methylcyclopropane, are also useful. Because the ring CH bonds are particularly strong, the methyl CH bonds are subject to H atom abstraction by radicals such as RO• or •OH. The resulting cyclopropyl methyl radical rearranges via ring opening with a rate of ca. $2 \times 10^8\ s^{-1}$. Seeing ring opened products can be a good test for a radical oxidation pathway. These tests refer to radicals that are genuinely free. If they are constrained in some way, anomalous results could be seen. It is not yet clear how constraints such as reversible trapping by metal species, or the presence of a constrained cavity such as an enzyme active site, could affect the outcome of such tests.

5 BIOINORGANIC MODEL OXIDATION CATALYSTS

The earliest homogeneous oxidation catalyst was Fenton's reagent[16] of 1898, which used H_2O_2 as primary oxidant and

Fe salts as the catalyst for alkane oxidation. These and many related later systems are believed to go by metal-catalyzed decomposition of H_2O_2 generating reactive radicals such as •OH in the process. A typical cycle of reactions often proposed is shown as (3)–(4). Once •OH is formed, it can abstract an H atom from an alkane C–H bond and lead to a hydroxylated product (equation 10–14).

Of the monooxygenase type of model, some use O_2 and a reducing agent, much like the enzymes themselves, some use H_2O_2, which can be regarded as prereduced O_2, and some use oxo-transfer agents such as PhIO. Porphyrins of Fe and Mn have been studied most extensively as catalysts.[17] The presumption has been that all these classes go through metal-oxo intermediates, although in reality, the mechanisms may be more complicated. The H_2O_2 type have their enzyme analogue in peroxidases, and the oxo-transfer type has its enzyme analogue in the fact that several monooxygenases accept oxo-transfer agents as viable primary oxidants *in vitro*.

A feature of many monooxygenases that hydroxylate arenes is the 1,2-migration of an H (D) atom during the oxidation, denoted the NIH shift.[18] This may be a result of the presence of an intermediate carbocation at the 2-position, following epoxidation of the 1,2-C=C multiple bond of the ring and subsequent ring opening.[19]

The Udenfriend[20] system of 1954 was perhaps the first to be specifically presented as a model of a biological process. In this system, Fe(II) is the catalyst, EDTA the ligand, air is the primary oxidant and ascorbic acid provides the reducing equivalents called for in this 'monooxygenase' system. Arenes can be hydroxylated to phenols, alkanes to alcohols, and alkenes to epoxides, although with modest efficiency. The NIH shift was not observed in the model, however.

Groves[21] has shown how a variety of model complexes, notably iron porphyrins, can catalyze a series of oxidation reactions of the monooxygenase type with oxo donors such as PhIO as primary oxidants. The intermediacy of metal-oxo species is indicated.

Meunier[22] has developed model chemistry for peroxidases such as ligninase with $KHSO_5$ as oxo-transfer oxidant and Fe or Mn-tetrasulfoporphyrin in aq. MeCN. These catalysts oxidize lignin models such as veratryl alcohol (3,4-methoxybenzyl alcohol) to give biologically relevant products such as quinones.

Another biologically inspired problem is water oxidation to dioxygen,[23] modeling Photosystem II (PSII) of green plants. The oxygen evolving center of PSII consists of a Mn_4Ca oxo-cluster that stores up four oxidizing equivalents before using them to release O_2. These storage steps may well be Mn(III) to Mn(IV) oxidations but the final O_2 forming step is still somewhat mysterious. A model system is known that uses oxone as oxidant and [(terpy)(H_2O)Mn(III)(μ-O)$_2$Mn(IV)(H_2O)(terpy)] as catalyst. Isotope labeling shows that the oxygen that appears in the O_2 formed comes, at least in part, from water.[24]

6 OXIDATION CATALYSTS FOR ORGANIC SYNTHESIS

The main goal of recent research in this area has been to find efficient asymmetric versions of nonradical metal-catalyzed epoxidation and hydroxylation reactions. The Sharpless epoxidation[25] converts allyl alcohols to the epoxides with exceptionally high e.e.s. and with predictable absolute configuration. The catalyst dictates the configuration independent of the substitution pattern.

Sharpless also introduced the catalytic asymmetric dihydroxylation of cis-disubstituted olefins with osmium tetroxide.[26] Jacobsen's catalyst,[15] mentioned earlier, is also much used in synthesis.

7 OXIDATION CATALYSTS FOR GREEN CHEMISTRY

The rise of green chemistry[8,27] is likely to greatly modify the practice of chemical science in the twenty-first century, as climate change obliges governments to mandate a move to renewable resources. This will undoubtedly involve a reliance on catalysis to convert the available feedstock to useful chemical products.

One of the goals of green chemistry is the destruction of pollutants, an area in which oxidation chemistry can play a major role. Collins[12] has developed an extremely robust, efficient Fe-based catalyst that uses H_2O_2 as oxidant to oxidize a variety of pollutant materials. The ligand set features deprotonated amide, a very strong electron donor ligand, with extensive alkyl substitution to protect what would otherwise be sensitive CH bonds. The result is an extremely oxidation-resistant catalyst which has proved useful in commercial applications, such as oxidative degradation of dyes.

Another goal is to develop the use of benign primary oxidants such as hydrogen peroxide for commercial oxidations. Neumann and coworkers[28] have reported an H_2O_2-based oxidation of alcohols to aldehydes and ketones that involving a benign medium, H_2O, a nontoxic catalyst, an early transition-metal polyoxometalate, and green work-up conditions – separation of the aqueous phase containing the catalyst from the organic-solvent-free aldehyde/ketone phase. Hill has useful catalysts of a similar type.[29] Many related catalysts exist: Sheldon's review is a useful resource.[30]

Ideally, air or oxygen would be able to act as primary oxidant. Bäckvall *et al*.[31] used a RuCl(OAc)(PPh$_3$)$_3$/hydroquinone/ Co(salophen)(PPh$_3$) system, for aerobic oxidation of benzylic and allylic alcohols. A modified Ru/quinone/Co system catalyzed the aerobic oxidation of secondary aliphatic alcohols.[32] Quinone can be used as an intermediate carrier of the oxidizing equivalents from oxygen or air. The regeneration of the quinone being performed directly with molecular oxygen, without the need for an extra catalyst.[33]

A number of systems consist of a palladium salt, typically $PdCl_2$ or $Pd(OAc)_2$, with a base. For example, $PdCl_2$–NaOAc catalyzes the aerobic oxidation of secondary alcohols in ethylene carbonate under mild conditions.[34] Sheldon has carried out mechanistic investigations on a number of related Pd systems and shown that water-soluble complexes of Pd(II) with phenanthrolines are stable, recyclable catalysts for the selective aerobic oxidation of a wide range of alcohols to aldehydes, ketones, and carboxylic acids in a biphasic liquid–liquid system. The active catalyst is a dihydroxy-bridged palladium dimer.[35]

Sheldon[36] and Trost[37] have both emphasized the importance of atom efficiency and catalysis in organic synthesis.

8 ORGANOMETALLIC OXIDATION CATALYSTS

Several important nonradical catalytic oxidations go via organometallic mechanisms. The commercially useful Wacker process[38] converts ethylene to acetaldehyde with air as oxidant, using Pd(II) and Cu(II) catalysts. The Pd(II) binds to the ethylene to give an organometallic intermediate, the alkene complex. This complex subsequently uses water as the O source to oxidize the ethylene to acetaldehyde, the Pd being reduced in the process. The resulting Pd(0) is reoxidized to Pd(II) with two equivalents of Cu(II) and the Cu(I) so formed is then reoxidized by air to close the cycle.

Shilov chemistry,[39] developed from 1970, employs $[Pt(II)Cl_4]^{2-}$ salts to oxidize alkanes RH to ROH or RCl with modest efficiency. Pt(IV) is an efficient (but economically impractical) primary oxidant that makes the process catalytic. This discovery strongly contributed to the continuing activity in CH activation. Periana developed a related and much more efficient system for methane oxidation to methanol using 2,2′-bipyrimidine ligands and sulfuric acid as solvent. In this case, the sulfuric acid is the primary oxidant and the methanol formed is protected by being converted in situ to $MeOSO_3H$, an ester that strongly resists further oxidation. This area is more fully described under the entry ***Alkane Carbon–Hydrogen Bond Activation***.

9 CONCLUSION

Oxidation is still less well developed than other metal-catalyzed reactions but the application is a very important one practically, so efforts are continuing. The mechanisms are hard to decipher, often being radical in character, but selective nonradical oxidations are becoming much more common. Asymmetric versions of oxidation catalysts have now appeared that have become very useful in organic synthetic and commercial applications.

1 INTRODUCTION

Metal oxides containing single metallic elements (binary oxides) and more than two metallic elements (double oxides and salts of oxoacids) are commonly used as catalysts in a variety of chemical reactions.[1] Oxide and metallic catalysts are two major groups of industrial catalysts. In practice, most catalysts are produced from mixtures of more than two phases; the phase primarily responsible for the catalysis is called the active component.

The components, which are added to enhance or modify catalytic functions, are called promoters or additives. In general, the active components are dispersed on the surface of materials, called supports or carriers, to increase the surface area and/or stability of the active components. Typical supports include metal oxides, such as alumina, silica, and titania, and zeolites that possess micropores. The categorization of catalyst materials into three components – active, additive, and support – is a convenient classification method.

Metal oxide catalysts can be classified as oxides of transition elements or as oxides of other typical metals. Typical transition elements include Cr, Fe, Co, Mo, and V, whose oxides catalyze oxidation and reduction reactions by changing the oxidation state of the metal ion. For selective oxidation of hydrocarbons, mixed oxides containing Mo and V are widely used. Oxides of other metals (acidic oxides such as silica and silica-alumina, basic oxides such as CaO and MgO, and amphoteric oxides such as alumina) catalyze acid or base reactions such as alkylation, isomerization, and hydration-dehydration.

Table 1 classifies catalysts according to reaction type, and shows typical oxide catalysts used in practical processes.

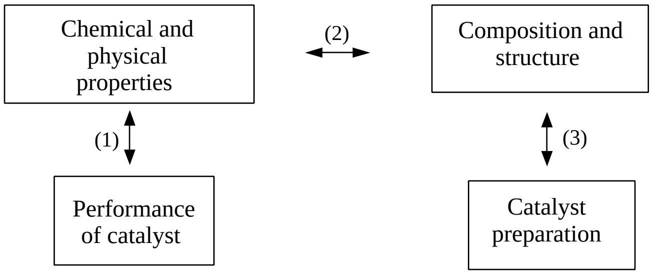
2 GENERAL ASPECTS PERTINENT TO CATALYSIS

Catalyst design involves both chemical and reaction engineering aspects in a rational and efficient methodology for the development of practical catalysts. Catalytic activity, selectivity, and durability are the main gauges of catalyst performance, while redox capability and acid-base properties are the most important chemical properties. The first two relationships shown in Scheme 1 for oxide catalysts will be described briefly. The factors controlling catalyst performance may be categorized into geometric (crystal plane and surface defects) and material-intrinsic factors that are intrinsic to the oxide material constituting the catalyst. The bulk structure is more closely reflected in the surface for oxide catalysts than for metal catalysts, as in the case of zeolites, heteropoly compounds, and perovskites.[2,3]

2.1 Geometric Factors

Even for the oxide catalysts consisting of the same elements and composition, the activity and selectivity vary depending on surface geometry. For example, the basal (010) plane of MoO_3 crystal (dispersed on graphite) is not selective, whereas the side (100) planes are highly selective for the oxidation of propene to acrolein (Table 2).[4] Another example is the anisotropic oxidation of n-butane to maleic anhydride over microcrystallites of $(VO)_2P_2O_7$.[5] The basal plane on which the $V^{4+}(=O)–O–V^{4+}$ sites are located are highly selective, but the side planes are less selective.

Vacancies in solid bulk influence oxidation activity in several ways. Allylic oxidation over multicomponent Bi–Mo oxide catalysts[6] is accelerated by cation vacancies by the rapid supply of oxygen from inside the bulk to active surface sites. Rapid oxygen diffusion in the bulk[7] as well as its correlation with catalytic activity[8] has been reported for Bi–Mo oxide (the oxygen diffusion becomes significant only in the presence of reductant). The redox cycle (see below) is accelerated by diffusion of metal ions in the case of iron oxide, $Fe_3O_4 \longleftrightarrow \gamma\text{-}Fe_2O_3$, in which the oxide ion packing remains unchanged during the reduction-oxidation process.[9]



Scheme 1 Useful relations for catalyst design

Table 1 Typical reactions catalyzed by oxide catalysts

Reaction	Catalyst
Oxidation	
Selective oxidation	
Propene → acrolein (acrylonitrile)	Mo–Bi–O, Fe–Sb–O
Propane → acrylic acid (acrylonitrile)	Mo–V–Te(Sb)–Nb–O
n-Butane → maleic anhydride	$(VO)_2P_2O_7$
Naphthalene → phthalic anhydride	V_2O_5/TiO_2
Isobutene → methacrylic acid	Mo–V–O(1st stage) + heteropolyacids (2nd stage)
Complete oxidation	
Catalytic combustion	Mn–Ba–Al_2O_3, La(Ce,Sr)CoO_3, Co_2MnO_4
Hydrogenation	
Ph–COOH → Ph–CHO	ZrO_2–Cr, In, etc.
$CO + H_2 \rightarrow CH_3OH$	Cu–ZnO, CuO–Cr_2O_3
Dehydrogenation	
Oxidative dehydrogenation	
Ethylbenzene → styrene	Fe_2O_3 – (K–Cr or –Ce, –Mo)
Simple dehydrogenation	
2-butanol → methyl ethyl ketone	Cu–ZnO
Acid catalysis	
Cracking (FCC)	Zeolite (USY)+ amorphous silica-alumina
Alkylation, isomerization	Zeolite, silica – alumina, Pt–SO_4^{2-}/ZrO_2, etc.
Methanol → gasoline	Zeolite (H-ZSM-5)
Hydration	$H_3PW_{12}O_{40}$, H-ZSM-5
Esterifiation	$H_4SiW_{12}O_{40}/SiO_2$
Ethylene + $H_2O + O_2$ → acetic acid + H_2O	Pd(–Te)–$H_4SiW_{12}O_{40}/SiO_2$
Base catalysis	
Isomerization(e.g. double bond shift)	Na/NaOH/alumina
Polymerization of alkene	CrO_2/Al_2O_3
Metathesis of alkene	WO_3/SiO_2
Denitrification	
$NO + NH_3 + (1/4)O_2 \rightarrow N_2 + (3/2)H_2O$	V_2O_5/TiO_2
Other reactions	
Anode of solid-state fuel cell	La(Sr)Co(Mn)O_3

Table 2 Oxidation of propene over different crystal planes of MoO_3 crystal dispersed on graphite

	Rate of oxidation		
	Basal plane (010)	Side plane (100)	Apical plane (101), etc.
To acrolein	0.06	2.26	0.73
To CO_x	1.00	0	0
Total	1.06	2.26	0.73

For valency-controlled perovskite-type mixed oxides, such as $La_{1-x}Sr_xCoO_3$, the ease with which they form oxide vacancies increases the catalytic activity for hydrocarbon oxidation.[2]

2.2 Material-Intrinsic Factors

General trends exist between the catalytic activity (or selectivity) and the intrinsic nature of the metallic components, which depend on the type of catalysis. General correlations for three typical cases and the promotion effects of mixing more than two metal oxides are described below.

Most oxidation reactions over oxide catalysts are well understood in terms of the redox mechanism, for example, repeated reduction and oxidation of the surface layer or bulk of the oxide catalyst. In the first step, a metal oxide catalyst oxidizes reactant molecules, such as carbon monoxide to carbon dioxide (equation 1; reduction of catalyst). In the second step, the reduced catalyst is oxidized back to its initial state by oxygen molecules supplied by the gas phase (equation 2; reoxidation of catalyst). The catalytic oxidation (equation 3) proceeds by repetition of this redox cycle.

$$CO + MO \longrightarrow CO_2 + M \quad (1)$$

$$M + \tfrac{1}{2}O_2 \longrightarrow MO \quad (2)$$

$$CO + \tfrac{1}{2}O_2 \longrightarrow CO_2 \quad (3)$$

During selective oxidation of alkenes, hydrogen abstraction and oxygen-addition reactions are usually key steps, in which different oxygen species participate. The rate of hydrogen abstraction increases, in general, with an increase in the basicity of oxide ion, whereas oxygen addition is facilitated by oxygen bonded to high-valence metal ions as in $Mo^{VI}{=}O$ and $V^{V}{=}O$. For the selective oxidation of alkanes, the Lewis

acid site or Lewis acid-base pair site on oxide catalysts are considered to play an important role for activation of alkane through dehydration from methylene group. Oxygen species on the surface are formed as expressed by equation (4); the formation and reactivity of these species have been reviewed.[10]

$$O_2(ads) \longrightarrow O_2^{-}(ads) \longrightarrow O_2^{2-}(ads) \longrightarrow O^{-}(ads) \longrightarrow O^{2-}(lattice) \quad (4)$$

In acid–base catalysis,[11] proton addition to or abstraction from reactant molecules (with Brønsted acids or bases), or formation of coordination bonds (with Lewis acids), and subsequent bond breaking and rearrangement are the key reaction processes. Most cases involve ionic reaction intermediates bound to the surface by electrostatic interactions.

In the case of binary oxides (single metallic elements), the surface tends to change from basic to acidic as the electronegativity of the metal ion increases (decrease in ionic radii and increase in the positive charge), for example, from BaO and CaO to SiO_2 and MoO_3. Thomas[12] and Tanabe[13] predicted the acidic properties of mixed oxides containing two kinds of cations, on the basis of differences in the coordination number and positive charge of the cation species introduced in the framework of the major component oxide. In the case of aluminosilicate zeolites, the isomorphic substitution of Si in the framework of Si^{IV} oxide by Al^{III} creates cation-exchange sites.

The acid strength of metallic salts of oxoacids in the solid state (and hence the catalytic activity by acid catalysis) increases with electronegativity of the metal ion.[14]

2.3 Promotion Effects of Mixed Oxides

As described above, most industrial catalysts are mixed oxides of at least two oxide phases, because catalyst performance is greatly improved by mixing different oxides, according to be following mechanisms: (i) stabilization, (ii) control of redox properties, (iii) creation of acidity and basicity, (iv) control of electronic and coordination state of the metal ion, and (v) combination of more than two functions to evolve acid-oxidation and acid–base bifunctional catalysts. Examples are provided in the following sections.

3 MIXED OXIDE CATALYSTS

3.1 Bi–Mo Oxides

Bismuth molybdates having a Bi/Mo ratio in the range of 0.67–2.0 catalyze the selective oxidation of propene to acrolein, and the ammoxidation of propene to acrylonitrile (equations 5 and 6). Both reactions proceed through an allylic intermediate. Three typical active phases – α-$Bi_2Mo_3O_{12}$, β-$Bi_2Mo_2O_9$, and γ-Bi_2MoO_6 – exist in this Mo/Bi ratio range. Their structural characteristics are summarized in Table 3.[15] The α-phase has a structure similar to that of scheelite (AMO_4).[16] The structure of the γ-phase is related to koechlinite with layers of $[Bi_2O_2]^{2+}$ and $[MoO_2]^{2+}$ connected by O^{2-} ions. The β-phase structure possesses Bi vacancies in addition to the two structures described above.

$$CH_2{=}CH\text{-}CH_3 + O_2 \longrightarrow CH_2{=}CH\text{-}CHO + H_2O \quad (5)$$

$$CH_2{=}CH\text{-}CH_3 + NH_3 + \tfrac{3}{2}O_2 \longrightarrow CH_2{=}CH\text{-}CN + 3H_2O \quad (6)$$

The catalytic activities of these phases for the oxidation of propene are α-$Bi_2Mo_3O_{12}$ (37), β-$Bi_2Mo_2O_9$ (16), and γ-Bi_2MoO_6 (8), where the figures in parentheses are measures of activity in units of 10^{-8} mol m^{-2} s^{-1} at 660 K.[17] The selective oxidation rate on bismuth molybdate is higher than that for iron molybdate by approximately two orders of magnitude, while these gave similar rates for complete oxidation.[17] Selectivity for acrolein over bismuth molybdates and other catalysts is given in Table 4.[18] The selectivity toward acrolein over these bismuth molybdates and bismuth iron molybdate is greater than 90%. When the partial pressure of oxygen is greater than that of propene, selectivity decreased.

The reaction proceeds via a redox mechanism. Evidence exists for involvement of bulk oxygen in the partial oxidation of propene over bismuth molybdates, suggested by the independence of the reaction rate from the partial pressure of oxygen in the feed gas over these catalysts. The percentage of oxygen atoms that can exchange with ^{18}O during the reaction of $^{18}O_2$ + propene are 9.4, 100, and 100 layers for α-$Bi_2Mo_3O_{12}$, β-Bi_2MoO_6, and γ-$Bi_3FeMo_2O_{12}$, respectively,

Table 3 Crystal structures of Bi–Mo oxides

Formula	Number of oxygen atoms bound only to Bi (per formula)	Number of Bi^{3+} vacancies	Degree of clustering of MoO_4
α–$Bi_2Mo_3O_{12}$	–	1	2
β–$Bi_2Mo_2O_9$	1	0.5	4
γ–Bi_2MoO_6	2	–	Infinite

Table 4 Acrolein selectivities in partial oxidation of propene

Catalyst	Selectivity (%)	Temp. (K)	Reaction feed (%) C_3H_6	O_2	Inert
α-$Bi_2(MoO_4)_3$	88–95	623–723	10	10	80
	88	703	50	50	0
β-$Bi_2Mo_2O_9$	85–93	623–743	30	30	40
	65	660	13	26	61
γ-Bi_2MoO_6	91	623–723	10	10	80
	66	660	12	26	61
$Bi_3FeMo_2O_{12}$	82–86	623–723	10	10	80
	83	703	50	50	0
Thermal oxidation	0	698	50	37	13

indicating that the partial oxidation involves lattice rather than gas-phase oxygen and that diffusion of oxygen in the bulk is rapid.[19] The roles of MoO_3 and Bi_2O_3 are assumed to be as follows. Initial α-hydrogen abstraction during the partial oxidation of propene over bismuth molybdates proceeds via oxygen atoms associated, at least partially, with bismuth molybdate catalysts acting as centers for the second abstraction of hydrogen and subsequent insertion of oxygen into acrolein.[18] A proposed mechanism for the partial oxidation of propene to acrolein is shown in Figure 1.[20]

A range of important multicomponent catalysts has the general formula $Bi_aMo_bM_c^{2+}\ M_d^{3+}\ O_n$, where M^{2+} is Ni, Co, Mg, or Mn, and M^{3+} is Fe, Cr, Al, or Ce. Proposed models of unsupported multicomponent catalysts are shown in Figure 2.[21,22] M^{2+} ions are essential and constitute the fundamental structure of the catalyst systems. Their catalytic activity is attributed to γ-Bi_2MoO_6 and α-$Bi_2Mo_3O_{12}$ phases on the surface.

More complex Bi–Mo oxide catalysts are claimed in patents, such as Bi–Mo–M^{2+}–M^{3+}–M^{+}–X–Y–O, where M^{+} is an alkali metal, X=Sb, W, and Y=P, B, and so on. In multicomponent catalysts, the metal molybdates $M^{2+}MoO_4$ and $M_2^{3+}(MoO_4)_3$ serve as supports for the active phase, α-$Bi_2Mo_3O_{12}$. Bulk migration of O^{2-} ions through lattice vacancies plays an important role in enhancing catalytic activity. In this complex system, the multifunctional nature promotes activation of oxygen, migration of oxygen species, and consecutive dehydrogenation and oxygenation. Tracer experiments using a model catalyst, α-$Bi_2Mo_3O_{12}$ supported on $Co_{11/12}Fe_{1/12}MoO_n$, whose lattice oxide was labeled by ^{18}O, led to the conclusion that the activation of molecular oxygen and oxidation of propene take place on different active sites; oxygen species activated by the support oxide involving iron and/or cobalt cations spill over through bulk diffusion to the reaction site of propene on bismuth molybdate.[23]

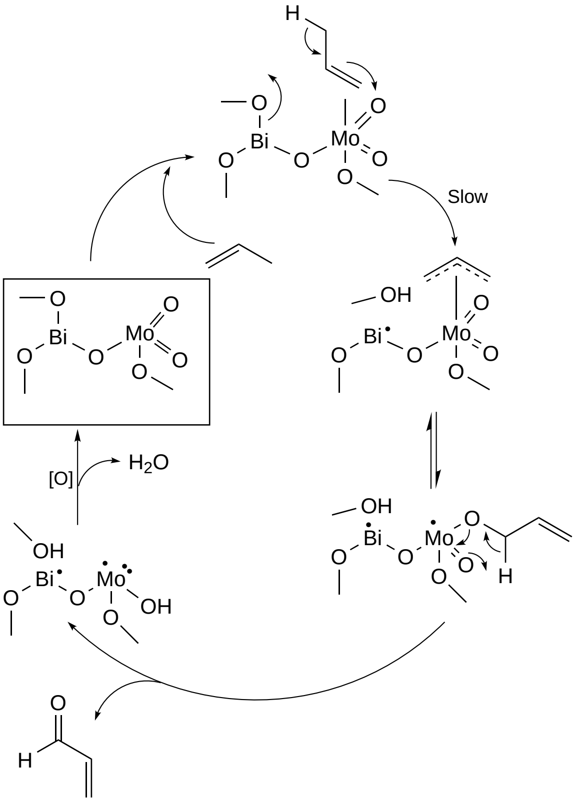


Figure 1 Mechanism for the selective oxidation of propene to acrolein over bismuth molybdate catalysts

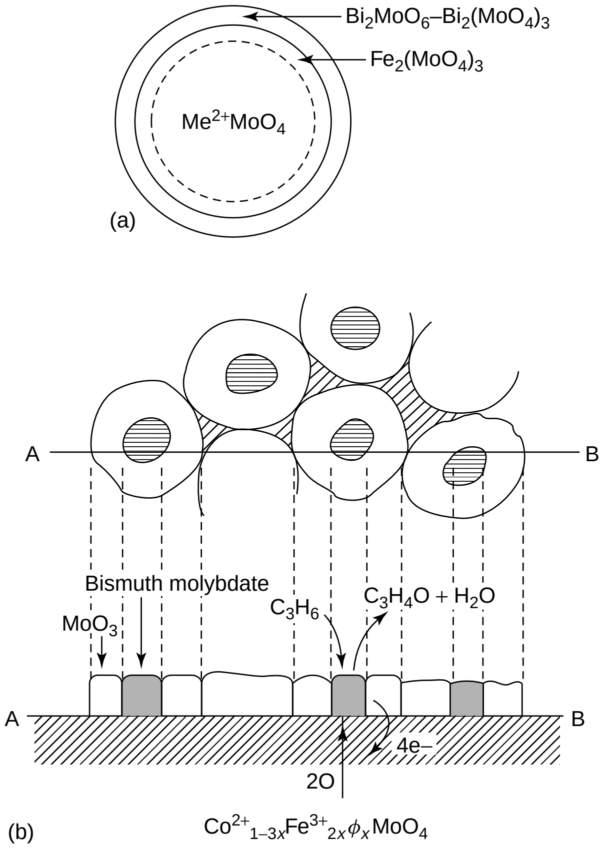

Figure 2 Model of multicomponent Bi–Mo oxide catalysts: (a) Wolf's model, and (b) Matsuura's model

Typical ammoxidation catalysts include $Bi_2O_3 + MoO_3$, $Fe_2O_3 + Sb_2O_4$ ($FeSbO_4$), $UO_3 + Sb_2O_4$ (USb_3O_{10}), and $SnO_2 + Sb_2O_4$.[15] In the UO_3–Sb_2O_4 catalyst, only USb_3O_{10} is the active and selective oxidation catalyst. Sb_2O_4 is inactive, and $USbO_5$ and UO_3 are active only for complete combustion. $FeSbO_4$ is also effective for ammoxidation and has been applied commercially.

3.2 Mo–V–Te–Nb Oxides

Among various mixed oxide catalysts supposedly active for the oxidation of propane to acrylic acid (equation 7) in patents and literature (Table 5),[24–29] Mo–V–Te–Nb oxides

Table 5 Mixed oxide catalysts for propane oxidation to acrylic acid

Catalyst	Conversion (%)	Selectivity (%)	Yield (%)	Temperature (K)	Feed
$MoSnO_n$	4	48	2	633	$C_3H_8/O_2/N_2$
$Mo_{1.51}Ni_1Te_{0.01}P_{0.02}O_n$	12	23	3	733	$C_3H_8/O_2/H_2O/He$
$Mo_1V_{0.4}Nb_{0.04}Bi_{0.08}Sb_{0.08}K_{0.08}O_n$	19	29	6	673	$C_3H_8/O_2/H_2O/N_2$
$Mo_1V_{0.3}Te_{0.23}Nb_{0.12}O_n$	80	60	48	653	$C_3H_8/air/H_2O$
$Mo_1V_{0.25}Te_{0.17}Nb_{0.20}O_n$	69	67	46	705	$C_3H_8/O_2/H_2O/N_2$
$Mo_1V_{0.3}Sb_{0.16}Nb_{0.05}O_n$	50	32	16	653	$C_3H_8/air/H_2O$
$Mo_1V_{0.3}Sb_{0.17}Nb_{0.07}O_n$	62	55	34	700	$C_3H_8/O_2/H_2O/N_2$

appear most promising. When Te of Mo–V–Te–Nb oxides is substituted with Sb, catalytic performance remains good, although these catalysts are less active and selective than the corresponding Te-containing catalysts.[28,29] As shown in Table 6, Mo–V–Te–Nb oxides are concurrently effective catalysts for the ammoxidation of propane to acrylonitrile (equation 8).[27,28,30] Two reactions, propane oxidation and ammoxidation, share fundamental reaction steps such as propane activation and propane dehydration, while ammonia activation and steps involving nitrile formation are present only for ammoxidation. Selective propane oxidation and ammoxidation are more difficult compared to propene oxidation and ammoxidation because the highly stable propane C–H bonds must be activated, and at the same time further oxidation of more reactive products to undesirable products or to carbon oxides must be suppressed. The highest yield of acrylic acid for propane oxidation over Mo–V–Te–Nb oxide catalysts (less than 60%) is much lower than that for propene oxidation followed by acrolein to acrylic acid (total yield greater than 90%).

$$CH_3\text{-}CH_2\text{-}CH_3 + 2O_2 \longrightarrow CH_2{=}CH\text{-}COOH + 2H_2O \quad (7)$$

$$CH_3\text{-}CH_2\text{-}CH_3 + NH_3 + 2O_2 \longrightarrow CH_2{=}CH\text{-}CN + 4H_2O \quad (8)$$

Mo is the essential element of effective catalysts for propene oxidation to acrolein and acrolein oxidation to acrylic acid, while V is an essential element for effective catalysis of acrolein oxidation to acrylic acid. Mo–V–Nb oxide catalysts are capable of activating propane even at 573 K, but yields products of acetic acid, acetaldehyde, and carbon oxides.[31] The addition of Te or Sb to Mo–V–Nb oxides induces certain structural changes leading to the formation of acrylic acid.[27,28]

The role of Nb in Mo–V–Te–Nb oxide catalysts has been clarified using model oxides, for example, mono-phasic crystalline Mo–V–Te oxide and Mo–V–Te–Nb oxide with the same orthorhombic layered structure.[32] Figure 3 shows a structural model of the orthorhombic phase of Mo–V–Te–(Nb) oxide in the *a-b* plane. Mo and V occupy octahedral sites and pentagonal bipyramidal sites, and Te is located in the hexagonal channels exclusively, but the heptagonal channels remain empty. Researchers have speculated that Nb is partially substituted with V.[32] As shown in Table 7, both catalysts show the same catalytic activity for propane oxidation and propene oxidation. However, selectivity for acrylic acid in both reactions increases by about 20% in the Nb-containing catalyst, while selectivities toward acetic acid and carbon oxides decrease. In addition, selectivity toward acrylic acid at low conversion for the propane oxidation is almost the same for both catalysts (Figure 4). These results indicate that the main role of Nb is not propane activation and formation of acrylic acid but is suppression of further oxidation of acrylic acid formed on the catalyst surface.

Few reports have discussed the structures of Mo–V–Te–Nb oxide catalysts in relation to propane oxidation and ammoxidation. Some reports indicate that not only the elemental composition but also preparative variables greatly affect the structure and performance of Mo–V–Te–Nb oxide catalysts. Among the preparative variables, methods for precursor preparation appear to be critical. One example is Mo–V–Te–Nb oxide, which when prepared by a solid-state method from corresponding oxides of each element is a mixture of MoO_3 and $(Mo{-}X)_5O_{14}$ (X is other cations) and is inactive for the propane ammoxidation. However, Mo–V–Te–Nb oxide prepared by a hydrothermal reaction method from the same oxide by the solid-state method is a mono-phasic oxide with an orthorhombic layered structure, which selectively catalyzes propane to acrylonitrile.[33]

Table 6 Catalytic results in propane oxidation and ammoxidation over Mo–V–Te–Nb oxide catalyst[a]

Reaction	Conversion (%)	Selectivity (%)	Yield (%)	Temperature (K)
Oxidation	80	60 (acrylic acid)	48 (acrylic acid)	653
Ammoxidation	89	64 (acrylonitrile)	58 (acrylonitrile)	693

[a]Composition of catalyst is $Mo_1V_{0.3}Te_{0.23}Nb_{0.12}O_n$.

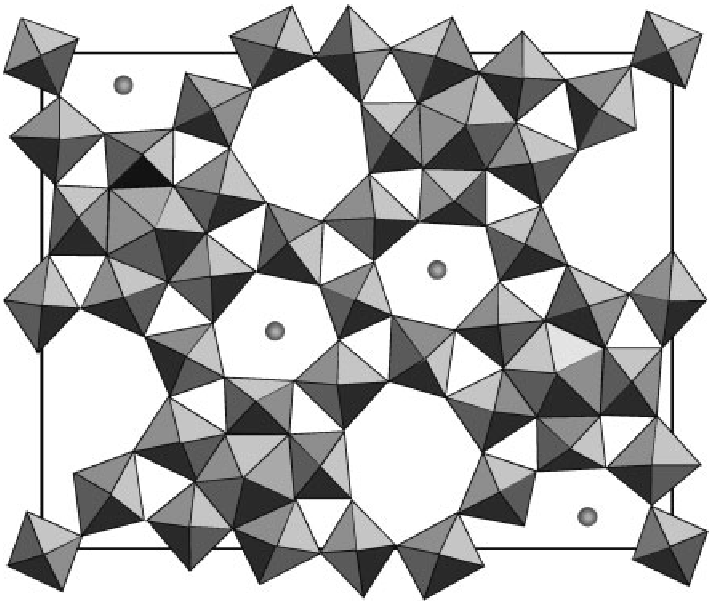

Figure 3 Structural model of the orthorhombic phase of Mo–V–Te–(Nb) oxide catalysts. Mo, V, and Nb are located in octahedral positions and in pentagonal channels. Te (•) is located in hexagonal channels

Table 7 Catalytic activity and selectivity for propane oxidation and propene oxidation over Mo–V–Te–(Nb) oxide catalysts

Catalyst	Temperature (K)	Conversion (%)		Selectivity (%)				
		C_3H_8	C_3H_6	acrylic acid	C_3H_6	acetone	acetic acid	CO_x
$Mo_1V_{0.44}Te_{0.10}O_n$	653	36.2	–	46.6	7.7	1.3	16.5	27.9
$Mo_1V_{0.25}Te_{0.11}Nb_{0.1}O_n$	653	33.4	–	62.4	8.7	0.4	7.3	21.2
$Mo_1V_{0.44}Te_{0.10}O_n$	615	–	56.5	55.6	–	17.3	14.2	12.9
$Mo_1V_{0.25}Te_{0.11}Nb_{0.1}O_n$	613	–	61.1	81.7	–	6.2	6.7	5.4

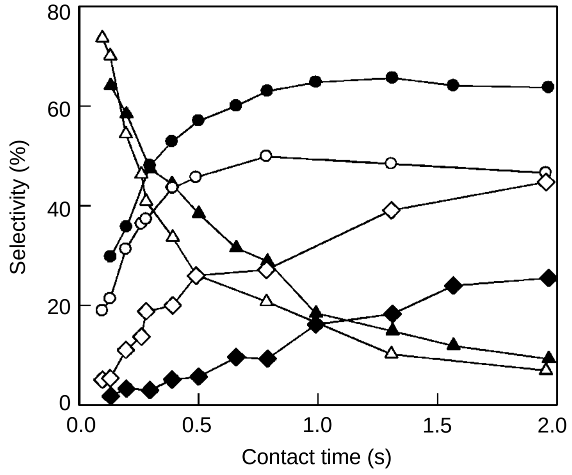

Figure 4 Selectivity changes of acrylic acid (circle), propene (triangle), and further oxidation products (lozenge) as a function of contact time in the oxidation of propane over Mo–V–Te oxide (open symbol) and Mo–V–Te–Nb oxide (closed symbol) catalysts

Catalyst calcination conditions are additional critical preparative variables that have a significant impact on the structure as well as the catalytic performance of Mo–V–Te–Nb oxide catalyst. From one precursor, two catalysts of very different crystal phases are obtained under different calcination atmospheres.[34] The catalyst calcined in nitrogen flow exhibits a high catalytic performance. In contrast, catalyst calcined in air is inactive toward propane oxidation.

3.3 V–P Oxides

3.3.1 V-P-O with Different Structures and Catalysis

V_2O_5 promoted by P or Mo is widely used for selective oxidation. V–P oxide catalysts are effective for the selective oxidation of *n*-butane to maleic anhydride.[35,36] The reaction is a 14-electron oxidation involving the abstraction of eight hydrogen atoms and insertion of three oxygen atoms (equation 9).

$$C_4H_{10} + \tfrac{7}{2}O_2 \longrightarrow C_4H_2O_3 + 4H_2O \qquad (9)$$

Among several crystalline phases of V–P oxides, crystalline phases having P/V ratios near unity are important for the selective oxidation of *n*-butane. The presence of a short V=O bond in the vanadyl group in its oxidized (V^{5+}) or reduced (V^{4+}) form, brings about structural anisotropy.[37] In most cases, the distorted octahedra are linked together to produce a chain of alternating short and long V–O bonds. The four corners are generally shared with single or double tetrahedra as in orthophosphates (PO_4) and pyrophosphates (P_2O_7), respectively. The structures of β-$VOPO_4$ and $(VO)_2P_2O_7$ are illustrated in Figure 5. β-$VOPO_4$ is composed of chains of highly distorted VO_6 octahedra sharing four oxygen atoms with four PO_4 groups. $(VO)_2P_2O_7$ comprises chains of V polyhedra linked by pyrophosphate groups. The V atoms are linked through oxygen atoms of vanadyl groups in V–O–V chains, and the V octahedra are linked into pairs through a common edge, forming a double chain. Although the structural determination of the X_1-phase (V^{5+}, P/V $= 1.0$) has not been accomplished, its structure is proposed to be similar to that of orthorhombic $(VO)_2P_2O_7$ having V–O–V chains.

Table 8 shows a comparison of selectivities toward maleic anhydride during the oxidation of *n*-butane. $(VO)_2P_2O_7$ is selective for the formation of maleic anhydride, while α-$VOPO_4$ and β-$VOPO_4$ are nonselective.[38] The bulk structure of $(VO)_2P_2O_7$ is retained during the *n*-butane oxidation, whereas the surface structure changes with the redox state of V between V^{4+} and V^{5+} during the *n*-butane oxidation.[39,40]

3.3.2 Catalytic Properties of $(VO)_2P_2O_7$

The catalytic properties of $(VO)_2P_2O_7$ are summarized as follows. 1) Ability of selective activation of alkanes. $(VO)_2P_2O_7$ is superior for the selective dehydrogenation of *n*-butane to butene to other crystalline V–P oxides, while few differences exist between the oxidation of butene and butadiene, which are considered reaction intermediates.[38] The abstraction of methylene hydrogen from *n*-butane is the slowest step. Hence this step determines the overall catalytic activity.[41] 2) Selectivity in forming anhydride from C_4 and C_5 alkanes, but not in selective oxidation of lower (C_2 and C_3) or higher (C_6–C_8) alkanes.[42] 3) The number of surface layers involving the catalytic reactions is limited to 2–3[38] in contrast to Bi–Mo–O catalysts.

Table 8 Oxidation of butane oxidation over V–P oxides

Catalyst	Activity[a] (10^{-4} mol g^{-1} h^{-1} at 713 K)	Selectivity (%) to maleic anhydride at 70% conversion
$(VO)_2P_2O_7$	11	71
α-$VOPO_4$	25	10
β-$VOPO_4$	15	9

$(VO)_2P_2O_7$ is prepared generally by the calcination of vanadyl hydrogen phosphate, $VOHPO_4 \cdot 0.5H_2O$. Preparation methods of $VOHPO_4 \cdot 0.5H_2O$ are classified into three types:[42] (1) Preparation in organic media (organic solvent method), such as the utilization of alcohols as solvents and as reducing agents for V^{5+} starting compounds, has a rose petal-like shape of the particles and is more active than the catalysts prepared by (2) and (3); (2) Preparation by a reduction of V_2O_5 followed by H_3PO_4 addition in aqueous solution, showing block-like morphology; and (3) Preparation by reduction of $VOPO_4 \cdot 2H_2O$, showing high selectivity to maleic anhydride. Most commercial catalysts are obtained by the organic solvent method. Good catalytic performance is achieved with a catalyst possessing a bulk P/V ration of 1.1;[42] the excess phosphorus is necessary to stabilize the V^{4+} ion in the active surface phase.

3.3.3 Mechanism and Anisotropy

$(VO)_2P_2O_7$ catalysis proceeds via a redox mechanism. The oxidation state of highly active and selective $(VO)_2P_2O_7$ catalysts for *n*-butane oxidation is close to 4+.[43] Temporal analysis of product (TAP) studies suggest that at least two types of surface oxygen species exist which are essential for maleic anhydride formation. The first type is strongly chemisorbed oxygen, which is responsible for *n*-butane activation and furan oxidation. The second is lattice oxygen in the surface layers, which is concerned with the allylic

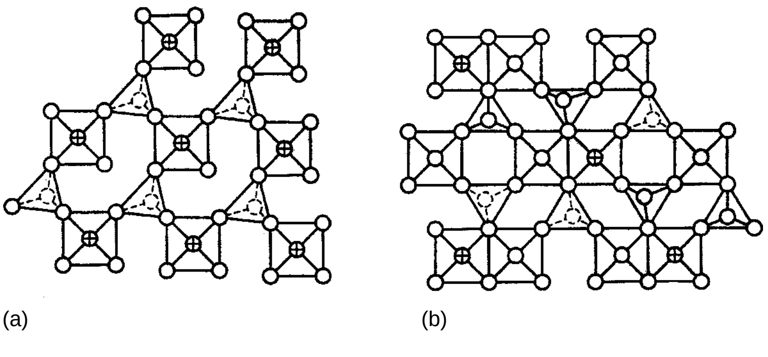

Figure 5 Crystal structures of (a) β–$VOPO_4$ and (b) $(VO)_2P_2O_7$. ($\oplus$) shows a vanadyl group (V=O)

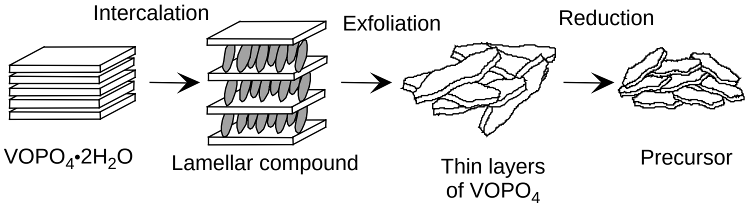

Figure 6 Concept of exfoliation–reduction method for preparation of $VOHPO_4 \cdot 0.5H_2O$ with thin microcrystallites

oxydehydrogenation of alkenes and oxygen insertion to form furan.[42,44]

The (100) plane of $(VO)_2P_2O_7$ is the active plane for formation of maleic anhydride. The side faces, such as the (001) plane, are nonselective for the reaction, that is, are active only for the formation of CO and CO_2. V^{4+}(=O)–O–V^{4+} sites, located on the (100) plane, are probably part of the active site for the formation of maleic anhydride.[5] The anisotropic transformation of $(VO)_2P_2O_7$ also is observed by XRD and Raman spectrometry; the oxidation of the (100) plane results in X1-phase, but side planes are oxidized to the nonselective β-phase,[40] in accord with the structure-sensitive behavior of $(VO)_2P_2O_7$ in its selectivity.

On the basis of this anisotropic selectivity, the control of the shape of $(VO)_2P_2O_7$ crystallites, that is, expansion of the (100) plane, is a promising approach to obtaining a selective catalyst. It is well known that $VOPO_4 \cdot 2H_2O$ possesses a layered structure with high capability for intercalation of various molecules.[45] Exfoliation techniques have been developed from intercalation of various layered materials, in which exfoliation occurs by delaminating stacked inorganic sheets in solvent by infinite swelling of their interlayer space. Previous studies report the preparation of precursor $VOHPO_4 \cdot 0.5H_2O$ by exfoliation of $VOPO_4 \cdot 2H_2O$ in alcohol, followed by reduction (Figure 6).[46,47] Stepwise thermal treatment of a suspension of $VOPO_4 \cdot 2H_2O$ crystallites in 2-butanol caused subsequent processes (intercalation, exfoliation, and reduction) leading to the formation of $VOHPO_4 \cdot 0.5H_2O$ crystallites, which were approximately $1 \sim 2\,\mu m$ in length and roughly $0.1\,\mu m$ in thickness with leaf-like shapes. The catalyst derived from this process was more active and selective than well-known rose petal–like crystallites ($\sim 1\,\mu m$) by the organic solvent method using isobutanol and benzyl alcohol. The higher activity of the catalyst prepared by the exfoliation technique is attributed to the high surface area (approximately $30\,m^2\,g^{-1}$ after the reaction for 200 h), and the higher selectivity is attributable to the preferential exposure of the basal (100) plane of $(VO)_2P_2O_7$ owing to the leaf shape as well as the pure phase of $(VO)_2P_2O_7$.

Disorder within the structure of $(VO)_2P_2O_7$ has been identified with catalytic activity. The number of V^{4+} defects in $(VO)_2P_2O_7$, as measured by magnetic susceptibility, correlates with the rate of n-butane oxidation. The structural disorder can enhance the oxidation and reduction of $(VO)_2P_2O_7$. The catalyst with high redox ability is effective for the operation under the high n-butane concentrations.[48]

3.4 Perovskite-Type Mixed Oxides

3.4.1 *Structure*

The perovskite-type mixed oxides have a general formula of ABO_3. The structure of the ideal cubic ABO_3 perovskite structure is illustrated in Figure 7. Cations with a large ionic radius have 12 coordination to oxygen atoms and occupy A-sites, while cations with small ionic radius have 6 coordination and occupy B-sites.[49] Ideally, A and O form a cubic closest packing, and B is contained in the octahedral voids in the packing. If the ionic radii of r_A, r_B, and r_O are to form a perovskite crystal structure, the tolerance factor (t) (equation 10) must lie within the range $0.8 < t < 1.0$, as well as $r_A > 0.090$ nm, $r_B > 0.051$ nm.[49] Thus, a great number of elements can form ideal or modified perovskites, depending

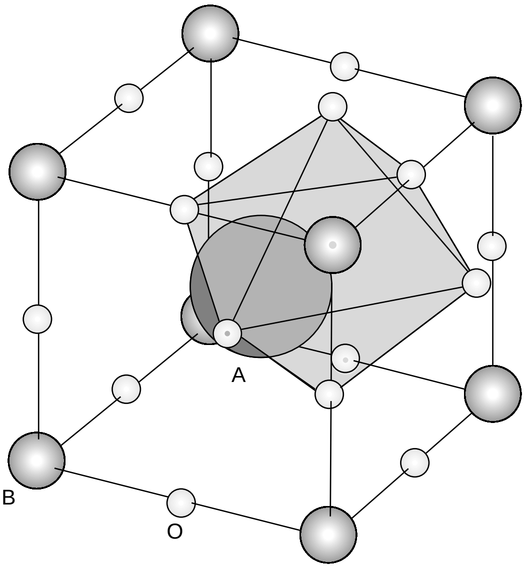

Figure 7 The structure of ABO_3 ideal perovskite. A-site; B-site; oxide ion

on the tolerance factor.

$$t = \frac{(r_A + r_O)}{\sqrt{2}(r_B + r_O)} \tag{10}$$

Deviations from the ideal structure with orthorhombic, rhombohedral, tetragonal, monoclinic, and triclinic symmetry are known, although the latter three are scarce and poorly characterized.[50–52] The cubic cell of $LaAlO_3$, $LaNiO_3$, or $LaCoO_3$ often has a small deformation from rhombohedral symmetry. The distorted structure usually exists at room temperature, but transforms to a cubic structure at high temperature.

Besides the ionic radii requirements, another condition that must be fulfilled is electroneutrality, which is attained by means of appropriate charge distribution of the form $A^{1+}B^{5+}O_3$, $A^{2+}B^{4+}O_3$, or $A^{3+}B^{3+}O_3$. Incorporating two cation types of different size and charge into B-sites (e.g. $AB_{0.5}B'_{0.5}O_3$) can modify the simple perovskite structure.

3.4.2 *Nonstoichiometry in Perovskites*

Partial substitution of A and B ions is allowed, yielding a plethora of compounds while preserving the perovskite structure. This brings about deficiencies of cations at the A- or B-sites or of oxygen anions (e.g. defective perovskites). Introduction of abnormal valency causes a change in electric properties, while the presence of oxide ion vacancies increases the mobility of oxide ions and, therefore, the ionic conductivity. Thus, perovskites have found wide application as electronic and catalytic materials.

Oxygen vacancies are more common than cationic vacancies (oxygen-excess perovskite). $LaCuO_{3-\delta}$ perovskite is an example. This compound is stable over a remarkably wide oxygen stoichiometry range, that is, $0.5 \geq \delta \geq 0.0$.[53] The stoichiometric $LaCuO_3$, containing 100% Cu^{3+}, loses oxygen upon heating under ambient oxygen pressure, yielding several $LaCuO_{3-\delta}$ oxygen deficient phases.[54] In contrast, few examples of oxygen-excess nonstoichiometry in perovskite oxides exist, such as $LaMnO_{3+\lambda}$, $Ba_{1-\lambda}La_{\lambda}TiO_{3+\lambda/2}$, and $EuTiO_{3+\lambda}$. In the case of $LaMnO_{3+\lambda}$, calcination of the individual oxides in air at 1473 K produces $LaMnO_{3.12}$.[55]

3.4.3 *Effects of A- and B-Sites on Catalysis*

Perovskite oxides are effective catalysts for various reactions, such as CO oxidation,[56,57] total[58,59] and partial oxidation[60,61] of hydrocarbons, NO_x decomposition,[62,63] hydrogenation,[64,65] hydrogenolysis,[66,67] and photocatalysis.[68–70] Two types of catalytic processes are proposed for the catalysis of perovskites, namely, suprafacial and intrafacial catalysis.[49] During suprafacial catalysis, the reactions between adsorbed species on the surface are much faster than reactions involving lattice oxygen, as in low-temperature oxidation of CO. In this case, the reaction rate appears to be correlated primarily with the electronic configurations of the surface transition metal ions.

During intrafacial catalysis, the removal of oxygen from the lattice of the catalyst or the reverse process, can occur at a comparable or higher rate than in other catalytic processes. High-temperature oxidations as well as reduction of NO are good examples. In these cases, the bond strength between metal and oxygen in the lattice becomes important. Over (A, A′)MnO_3 catalysts, the production rate of N_2 from N_2O increases in the order (La, Sr) < (La, K) < (La, La) < (Bi, K), in line with the decrease in the calculated binding energy of oxygen.[55]

When A-site elements in ABO_3 are rare earths and B-site elements are transition metals of the first row in the periodic table, the catalytic activity for oxidation is determined mainly by the transition metal.[56,71,72] In the case of propane oxidation (Figure 8), activity patterns show two peaks at Mn and Co regardless of the rare earth elements at the A-site.[73] This reaction is considered to proceed through a suprafacial process. According to crystal field theory, the octahedral (truncated octahedron at the surface) environment of the M^{3+} ions splits into two levels: the lower one (t_{2g}) contains orbitals that are repelled less by negative point charges than are the orbitals in the higher energy (e_g) level. Co and Mn perovskites have e_g levels occupied by fewer than one electron and t_{2g} levels that are half-filled or fully occupied, owing to the preferred adsorption on B cations with unfilled e_g levels and occupied t_{2g} levels (such as Mn and Co). The decomposition of N_2O on titanates is also suprafacial in nature, that is, the catalyst surface acts as a template, providing orbitals of suitable or proper symmetry and energy for the adsorption of N_2O.[74,75]

3.4.4 Designing Perovskite Catalysts

When trivalent A cations in $A^{3+}B^{3+}O_3$ are partially replaced by divalent A′ cations, charge compensation can be achieved by stoichiometric formation of either tetravalent B cations or positive holes. Valency change and nonstoichiometry are possible in perovskites without changing the fundamental structure. For example, in the case of families of $La_{1-x}A'_xBO_3$ (B=Co, Fe, Ni) oxides, substitution of A-site with a bivalent cation (A′=Sr, Eu) or a tetravalent cation (A′=Ce) led to a decrease or an increase, respectively, of methane combustion activity.[76] Eu or Sr substitution for La leads to higher oxidation states for Co, so that a higher amount of Sr results in a higher concentration of Co^{4+}, which is abnormal. However, Co^{4+} is unstable, therefore oxygen release can occur, ending in the formation of oxygen vacancies. In contrast, insertion of Ce^{4+} leads to a large amount of active sites for oxygen adsorption from the gas phase, causing higher catalytic activity for methane combustion.

The oxidation state of a B-site ion in La_2CuO_4 can be controlled by substitution at both A- and B-sites. The catalytic activity for the NO–CO reaction shows a maximum when Cu is in the +2 state. The rate of CO–O_2 reaction over $LaMn_{1-x}Cu_xO_3$ is very sensitive to the extent of Cu for Mn substitution. For $x = 0.4$, the rate is greater than that for either $LaMnO_3$ or La_2CuO_4 (note that $LaCuO_3$ cannot be prepared under ordinary conditions) by more than a factor of 10^2 for the initial activity, and a factor of 10 for the stationary activity. This large synergistic effect probably is due to an appropriate combination of the activation of CO by Cu and the high reactivity of the Mn–oxide oxygen.

Perovskites usually have small surface areas ($<10\,m^2\,g^{-1}$) because they are prepared by calcination at high temperatures (>1073 K). To increase the catalytic activity, various attempts to enhance surface area have been made using methods such as mist-drying, chelating, and metal-citric-cellulose complexing.[77,78] Although a surface area as high as $50\,m^2\,g^{-1}$ is obtained by these methods, it diminishes rapidly when the substance is exposed to high temperatures.

Another possible method for enhancing surface area is spreading perovskite as a thin layer or nano-particles on an appropriate high surface area support.[79] The major problem of this method is a solid-state reaction between the precursors of perovskite and the support, brought about by the high-temperature calcination to form perovskite. In the case of $LaCoO_3$, Co easily forms a spinel with Al_2O_3, but $LaCoO_3$ is highly dispersed on the surface of ZrO_2 as fine particles or thin over-layers when La–Co/ZrO_2 is calcined at 1123 K. The reaction between the substance (La–Co oxide) and ZrO_2 to form $La_2Zr_2O_7$ and Co_3O_4 occurred by calcination above 1123 K.

3.5 Heteropoly Compounds

Heteropolyacids are condensates of different types of oxoacids and involve inorganic metal-oxygen clusters (polyoxometalates). Among these acids, those with Keggin-type anions are widely used as catalysts because of their stability in solution and in the solid state.[80–83] Important properties of the Keggin-type heteropolyacids include: (1) high solubility in water and polar organic solvents; (2) a polybasic strong acidity (completely dissociative in water); (3) high oxidizing ability of Mo- and V-containing compounds; (4) formation of soluble or insoluble salts having unique functions; and (5) high thermal stability in the solid state.

3.5.1 Synthesis of Heteropolyanions and Structures

The formation of a typical Keggin-type heteropolyacid, $H_3PW_{12}O_{40}$, is given by equation (11).[84] As shown in Figure 9, the structure has overall tetrahedral symmetry and is based on a central PO_4 tetrahedron surrounded by $12WO_6$ octahedra arranged in four groups of three edge-shared octahedra, W_3O_{13}. These W_3 triplets are linked by corners shared with each other and the central PO_4. The Keggin structure has been characterized by X-ray diffraction, UV, NMR, and IR spectroscopy.

$$23H^+ + HPO_4^{2-} + 12WO_4^{2-} \longrightarrow PW_{12}O_{40}^{3-} + 12H_2O \quad (11)$$

Heteropolyanions with W or Mo atoms as a polyatom (addenda atom) are listed in Table 9.[85] The thermal stability increases in the sequence of $H_4SiMo_{12}O_{40} < H_3PMo_{12}O_{40} < H_4SiW_{12}O_{40} < H_3PW_{12}O_{40}$, where $H_3PW_{12}O_{40}$ decomposes when heated higher than 673 K.[86]

In aqueous solution, the Keggin structure, for example, $PW_{12}O_{40}^{3-}$, is stable at about pH 1.0.[84] At pH 1.5–2.0,

the Keggin structure is converted to a lacunary anion, $H_xPW_{11}O_{39}^{(7-x)-}$, which can act as a ligand in compounds with metal cations and metal complexes.[87]

3.5.2 Acidic Properties

Heteropolyacids are strong acids that dissociate completely in aqueous solution. The acidity of nonaqueous solutions of $H_3PW_{12}O_{40}$ is higher by 1–1.5 units of the Hammett acidity function than the acidity of $HClO_4$ or H_2SO_4.[80,88] As a liquid acid in CH_3CN, $H_3PW_{12}O_{40}$ has been characterized as a superacid by calorimetry.[89] The order of acid strength is estimated to be $H_3PW_{12}O_{40} > CF_3SO_3H >$ PTS $> H_2SO_4 > CF_3COOH > ClC_6H_4COOH$.

Indicator color changes demonstrate that solid $H_3PW_{12}O_{40}$ possesses acidity greater than −13.16 in H_0.[90] As solid acids, microcalorimetry of NH_3 adsorption and temperature programmed desorption (TPD) of NH_3 reveal that acid strength is in the order; $H_3PW_{12}O_{40} > Cs_{2.5}H_{0.5}PW_{12}O_{40} >$ H-ZSM-5 (Si/Al = 40) $> SiO_2–Al_2O_3$.[91] This indicates that the acid strength of anhydrous solid $H_3PW_{12}O_{40}$ is higher than that of zeolites including H-ZSM-5 and can be classified as super acidity.[92,93] Protons of $H_3PW_{12}O_{40}$ are localized on the bridging oxygen atoms (e.g. W–O–W) of the polyanions in the crystal lattice. The acid centers are considered to be at the bridging oxygen on the surface of anion. The studies using ^{13}C NMR spectroscopy with mesityl oxide as indicator shows that the three protons of $H_3PW_{12}O_{40}$ have the same strength.

Supporting heteropoly acids on other solids with high surface areas is a useful method for improving catalytic performance. In general, strong interactions of heteropoly acids with supports are observed at low loadings and the intrinsic properties of heteropoly acids prevail at high loadings. The supports promote changes in acid strength and the structure of the aggregates. Basic solids such as Al_2O_3 and MgO tend to decompose heteropolyacids.[94–97]

3.5.3 Solid Heteropolyacids

Acid Form – Pseudoliquid Phase Behavior.[80,98] Owing to a high affinity for polar molecules, large quantities of molecules such as alcohols and ether are absorbed within the bulk phase of crystalline heteropolyacids. The amounts of pyridine, methanol, and 2-propanol absorbed correspond to 50–100 times that which can be adsorbed on the surface, while nonpolar molecules like ethylene and benzene are adsorbed at the surface only. Catalytic reactions of polar molecules occur both on the surface and in the bulk, so that the solid heteropolyacid behaves as a highly concentrated solution, called a 'pseudoliquid phase'. The dehydration of alcohols, various conversions of methanol and dimethyl ether to hydrocarbons in gas–solid systems, and the alkylation of phenol and pinacol rearrangements can all occur in the pseudoliquid.[80,99] The transient response using isotopically labeled 2-propanol provides evidence for the pseudoliquid phase behavior of $H_3PW_{12}O_{40}$. This behavior influences the selectivity, for example, the alkene/alkane ratio, in the conversion of dimethyl ether.

Acidic Salts of Heteropolyacids. Although the acid form of heteropolyacid itself is a useful solid acid, the number of acidic sites on the surface is relatively small because of the low surface area (about $5\,m^2\,g^{-1}$). Substitution of the proton by an alkaline cation produces interesting effects on the surface area and pore structures. Salts with large monovalent ions, such as Cs^+, are insoluble in water and possess high surface areas,[93,100] while the acid forms are highly soluble in water. Partial substitution of protons with Cs^+ ions results in unique changes in the surface area and hence in the number of acidic sites on the surface. As shown in Figure 10, surface area increased when the Cs content, x in $Cs_xH_{3-x}PW_{12}O_{40}$, changed from $x = 2$ ($1\,m^2\,g^{-1}$) to $x = 3$ ($156\,m^2\,g^{-1}$), although it decreased

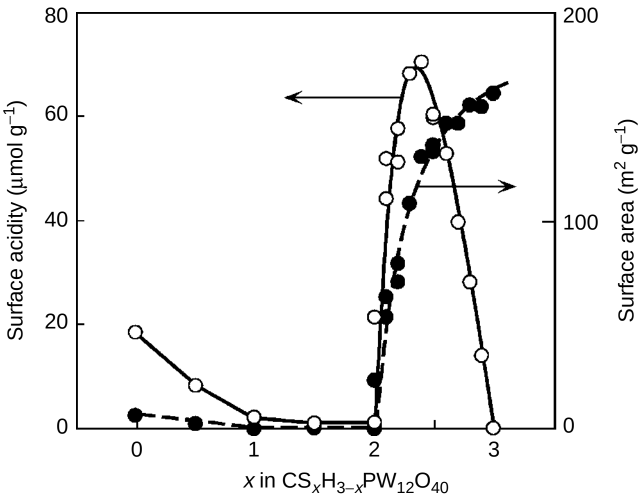

Figure 10 Changes in the surface area and surface acidity of $Cs_xH_{3-x}PW_{12}O_{40}$ as a function of the Cs content

slightly from $x = 0$ ($6\,m^2\,g^{-1}$) to $x = 2$. The acid amount on the surface (surface acidity), estimated from the surface area and the formal concentration of protons attached to the polyanion, decreased initially with the Cs content, but sharply increased when x exceeded 2, with a maximum at $x = 2.5$. Salts of heteropolyacids with Rb and K give changes in the surface area similar to those of Cs salts.[101] A marked increase in the surface area is observed at $x = 1.8$ for the Rb salts. In the case of K salts, the change in the surface area is rather arbitrary.

As shown in Figure 11, the pore sizes of $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ (abbreviated as Cs2.5) are bimodal distributions in the range from micropore to mesopore.[91,102] The mesopores (about 4 nm) correspond to the voids between the primary particles (crystallites; about 10 nm in size), and the micropores correspond to the spaces between the crystal planes formed by misaligned fragments.[102–104] $Cs_{2.1}H_{0.9}PW_{12}O_{40}$ (abbreviated as Cs2.1) possesses only micropores, for which the peak is 0.51 nm.[102–104] Adsorptions of various molecules, such as N_2 (molecular size (MS) = 0.36 nm), n-butane (MS = 0.43 nm), isobutane (MS = 0.50 nm), benzene (MS = 0.59 nm), 2,2-dimethylpropane (MS = 0.62 nm), and 1,3,5-trimethylbenzene (MS = 0.75 nm) reveal that the pore-width of $Cs_{2.1}H_{0.9}PW_{12}O_{40}$ is in the range of 0.43–0.50 nm. Proposed models for Cs2.5 and Cs2.1 are illustrated in Figure 12.

During a titration preparation method, $Cs_3PW_{12}O_{40}$ crystallites are formed initially, followed by epitaxial adsorption of $H_3PW_{12}O_{40}$ on the surface of $Cs_3PW_{12}O_{40}$ crystallites.[91] When the Cs content, x, is low, ultrafine particles of $Cs_3PW_{12}O_{40}$ (8–10 nm in diameter) are thickly covered by $H_3PW_{12}O_{40}$ upon drying the solution. Heat treatment converts them to particles having a nearly uniform composition and

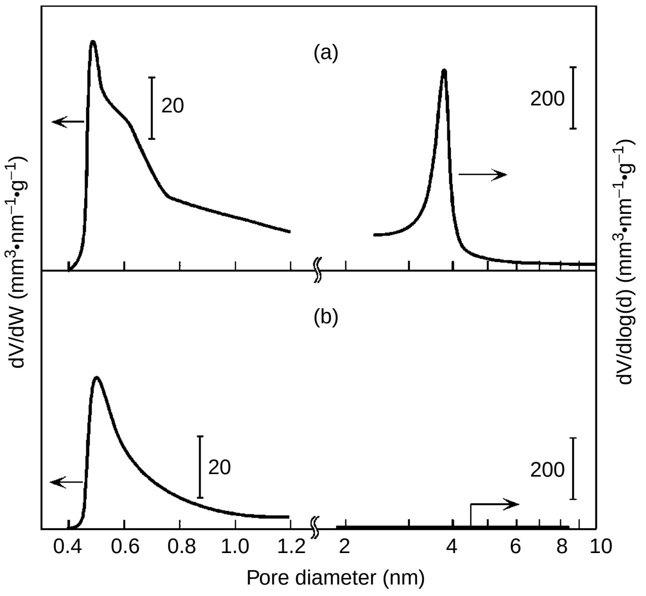

Figure 11 Pore-size distributions of $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ (a) and $Cs_{2.1}H_{0.9}PW_{12}O_{40}$ (b)

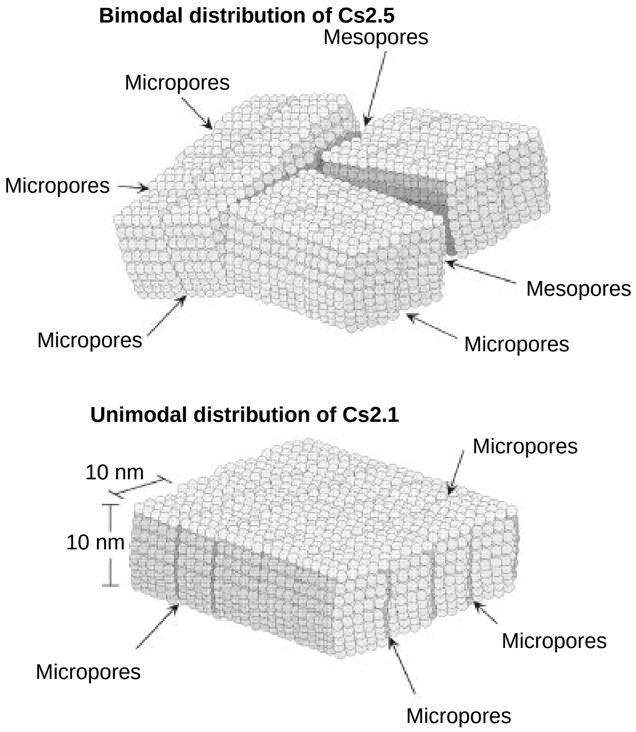

Figure 12 Model of pores for $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ and $Cs_{2.1}H_{0.9}PW_{12}O_{40}$

a size similar to what existed before heat treatment. At $x = 2.5$, $H_3PW_{12}O_{40}$ forms very thin films or small islands on $Cs_3PW_{12}O_{40}$ crystallites after drying. Heat treatment produces fine particles having a uniform composition of $Cs_{2.5}H_{0.5}PW_{12}O_{40}$. The unusual increase in the surface area for $x = 2–3$ can be understood by this mechanism.

3.5.4 *Acid Catalyzed Reactions*

Table 10 summarizes examples of acid-catalyzed reactions over heteropoly compounds. Supporting and composite catalysts consisting of silica or MCM-41 and $H_3PW_{12}O_{40}$ or $H_4SiW_{12}O_{40}$ possess excellent catalytic performance.[105–109] Well-dispersed heteropoly acids show high catalytic activities during liquid-phase alkylation of aromatics. $H_3PW_{12}O_{40}$ supported on MCM-41 is highly active for alkylation of aromatics with added shape selectivity. $H_3PW_{12}O_{40}/SiO_2$ catalyzes Diels–Alder reactions of quinones. This catalyst is active under mild conditions and can be easily recovered and reused. $H_3PW_{12}O_{40}$ subsumed in a silica matrix by an in situ sol-gel method shows higher activity than Amberlyst and zeolite H-ZSM-5.

The acidic salts of heteropolyacids, in which the protons are partially substituted with Cs^+, are active for acid-catalyzed reactions such as Friedel–Crafts reactions,[110] Ritter-type reactions,[111] and skeletal isomerization of alkanes.[112–118] The

specific catalytic properties of the Cs salts are attributed to a hydrophobic surface and porosity as well as strong acidity.

3.5.5 *Water-tolerant Catalysis by $Cs_{2.5}H_{0.5}PW_{12}O_{40}$*[119]

Generally, solid acids are severely poisoned by water and lose their catalytic activities in aqueous solution. An important feature of Cs2.5 is its high activity for acid-catalyzed reactions, even in the presence of a large excess of water. The activity of Cs2.5 (per weight) toward hydrolysis of ethyl acetate in excess water is 3 and 35 times higher than those of H-ZSM-5 (Si/Al = 40) and H-ZSM-5 (Si/Al = 628), respectively,[120] while $SiO_2-Al_2O_3$ and Al_2O_3 are inactive. The specific activity of Cs2.5 (per unit of acid amount) was seven times higher than those of the two H-ZSM-5 catalysts, which are commercial water-tolerant solid acid catalysts used for a liquid-phase hydration of cyclohexene.

Hydrophobicity of a solid surface can be evaluated semiquantitatively by comparison of water and benzene adsorption.[121] Figure 13 shows the ratio of the adsorption area of benzene to that of water as a function of the relative pressure of the adsorbates, where the adsorption area is defined as the product of the adsorption amount and molecular cross sectional area. From the ratio of adsorption area of benzene to that of water, the hydrophobicity of solid acid surface is evaluated to occur in the order: H-ZSM-5 (Si/Al = 628) > $Cs_3PW_{12}O_{40}$ (Cs3) > H-ZSM-5 (Si/Al = 40) > $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ (Cs2.5) > $SiO_2-Al_2O_3$ > Al_2O_3.[122] Thus, it is concluded that the surface of Cs2.5 has a hydrophobic nature similar to that of H-ZSM-5 (Si/Al = 40). The hydrophobic character of the Cs2.5 surface probably prevents the acidic protons from becoming poisoned by water. The hydrophobic surface as well as the strong acidity of Cs2.5 are reasons for the high activity toward the water-related reactions.

A feature of Cs2.5 is its mesopores, in which bulky molecules can access the active sites. Thus, potential of Cs2.5 as a water-tolerant catalyst is especially evident in reactions involving large size reactants and products. Table 11 shows catalytic activity for hydrolysis of 2-methylphenyl acetate. Cs2.5 exhibits significantly superior activity against other

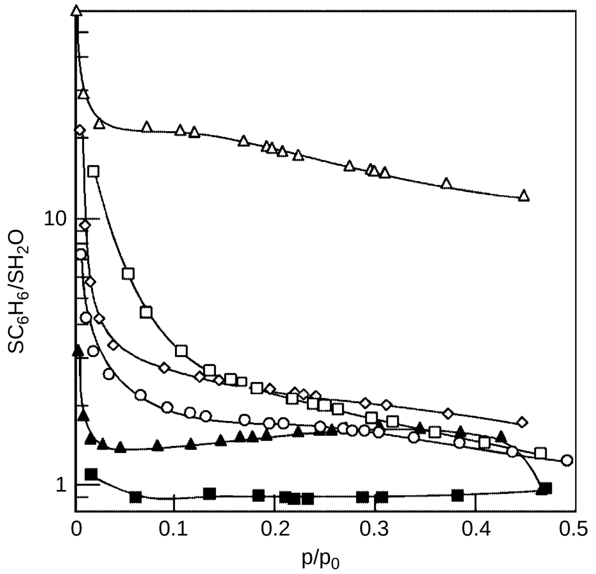

Figure 13 Hydrophobicity of solid acids evaluated from the adsorptions of benzene and water: $Cs_{2.5}H_{0.5}$ $PW_{12}O_{40}$ (○), Cs_3 $PW_{12}O_{40}$ (□), H-ZSM-5 (Si/Al = 628) (△), H-ZSM-5 (Si/Al = 40) (◇), Al_2O_3 (■), and $SiO_2-Al_2O_3$ (▲). S_{C6H6} and S_{H2O} are adsorption areas of benzene and water, respectively

solid acids. H-ZSM-5, which is active for the hydrolysis of ethyl acetate, is inactive for hydrolysis of 2-methylphenyl acetate, because the large reactant cannot approach the acid sites located in the micropores.

3.5.6 *Bifunctional Catalysts of Heteropolyacids and Cs Salts*

Pd modified $H_4SiW_{12}O_{40}/SiO_2$ (bifunctional catalyst) is effective for skeletal isomerization of *n*-pentane in the presence of hydrogen.[123] The catalyst optimized in Pd and $H_4SiW_{12}O_{40}$ loadings exhibits very high selectivity toward branched heptanes (>95%). The space-time yield of this catalyst is three times greater than that found for Pd–H-β zeolite, which is one of the best catalysts known for this reaction. A mechanism based on a classical bifunctional catalysis is proposed, involving an acid-catalyzed reaction and dehydrogenation-hydrogenation.[115]

Pt-promoted Cs2.5 catalyst also is efficient for the skeletal isomerization of *n*-butane,[121] *n*-pentane,[116] *n*-hexane,[117,118] and *n*-heptane.[117] Pt–Cs2.5 supported on silica is effective for isomerization of cyclohexane and the hydroisomerization of benzene to methylcyclopentane.[122]

Several acid-catalyzed reactions are used as test reactions to demonstrate the shape selectivity of the microporous heteropoly compound, Cs2.1, having only micropores. Catalytic activities of Pt–Cs2.1 and Pt/SiO_2 toward the oxidation of various molecules are summarized in Table 12.[124] Two catalysts are active for the oxidation of CH_4, CO, and *n*-butane. In contrast, Pt–Cs2.1 is relatively inactive for the oxidation of isobutene, 2,2-dimethyl pentane, and benzene, while Pt/SiO_2 shows high catalytic activity. This result clearly demonstrates that the ultramicropores of Pt–Cs2.1 can distinguish *n*-butane from isobutane; only *n*-butane is adsorbed into the pores and subsequently oxidized. The pore-width of Cs2.1 is in the range of $0.43 \sim 0.50$ nm, demonstrated by the adsorption of various molecules (See Section 3.5.3).

Another example of catalysis over a bifunctional heteropolyacid is the direct synthesis of acetic acid from ethene.

Pd-promoted $H_4SiW_{12}O_{40}/SiO_2$ is effective for this reaction in a mixture of ethene, water, and oxygen; this process has been commercialized since 1997.[125] The reaction is proposed to proceed through hydration of ethene, followed by oxidation of ethanol. The selectivity toward acetic acid reaches 86% over $Pd/H_4SiW_{12}O_{40}$–SiO_2.

3.5.7 Redox Properties and Oxidation Catalysis

Mo-heteropolyanions with a Keggin structure are readily reduced to give heteropoly blue in solution. A trend exists toward anions with X of higher charge (small value of n) being more easily reduced, while the reduction potential decreases in the order V > Mo > W. In the case of $XMnW_{11}O_{40}H_2{}^{n-}$, the Mn^{2+} in the anion is oxidized by O_2.

The oxidizing ability of the alkali salt is estimated from the rate of its reduction by H_2 and CO.[126] The rate of reduction by H_2, normalized to catalyst weight, represents the oxidizing ability of the catalyst bulk. Similarly, the rate of reduction by CO, divided by the surface area, expresses the oxidizing ability of the surface. The oxidizing ability in both cases decreases monotonically with an increase in neutralization by alkali, except for the reduction by H_2 of $Cs_{2.5}PMo_{12}O_{40}$, for which a higher value than the monotonous change was observed. This high value is due to a very high surface area and rigid secondary structure.

Table 13, presents a summary of oxidation reactions catalyzed by heteropoly compounds.[127–129] Vapor-phase oxidation of methacrolein to methacrylic acid has been commercialized using heteropoly compounds (220×10^3 tonnes/year).[130] Heteropoly compounds exhibit high catalytic performance for this reaction, different from simple single oxides such as MoO_3 and V_2O_5. The main component of the catalyst is $H_3PMo_{12}O_{40}$ or its salts, in which V is substituted for one or two Mo atoms. Cs salts increase the stability of the catalysts; the acidic salts are the active components. In the oxidation of acrolein to acrylic acid over $K_xH_{3-x}PMo_{12}O_{40}$, maximum selectivity is obtained at $x = 2.5$. A drop in selectivity at lower values of x is associated with increasing concentrations of decomposition products from the thermally unstable $H_3PMo_{12}O_{40}$ component[131]

Table 13 Oxidation reactions catalyzed by heteropoly compounds

Reaction	Catalyst
Homogeneous oxidation	
Alkyl sulfide + O_2 → sulfone	$H_{3+n}PMo_{12-n}V_nO_{40}$
Ketone + O_2 → acid and aldehyde	$H_5PMo_{10}V_2O_{40}$
Alkylcyclohexadiene + O_2 → alkylbenzene	$H_5PMo_{10}V_2O_{40}$
1-Octene + H_2O_2 → octane oxide	$(CP)_3PW_{12}O_{40}{}^a$
1-Octene + H_2O_2 → heptanoic acid	$(CP)_3PW_{12}O_{40}{}^a$
Cyclohexene + H_2O_2 → adipic acid	$H_3PMo_6W_6O_{40}$
Tetramethylphenol + H_2O_2 → tetramethylquinone	$H_3PMo_{12}O_{40}$
Heterogeneous oxidation with O_2	
Methacrolein → methacrylic acid	$CsH_3PVMo_{11}O_{40}$
Isobutylic acid → methacrylic acid	$H_4PV_{12}Mo_{10}O_{40}$
Isobutene → methacrolein	$PbFeBiMo_{12}O_{40}$
Butene → maleic anhydride	$Cs_{2.5}H_{0.5}PMo_{12}O_x + VO^{2+}$
Butane → maleic anhydride	$BiPMo_{12}O_x + VO^{2+}$
Isobutane → methacrylic acid	$H_3PMo_{12}O_{40}$
Pentane → maleic anhydride	$H_5PV_2Mo_{10}O_{40}$

[a]CP = cetylpyridinium ion.

A possible mechanism for oxidation of methacrolein over $H_3PMo_{12}O_{40}$ is given by equation (12). The first step, in which a diol or ester-type intermediate forms from methacrolein and $H_3PMo_{12}O_{40}$, is reversible and rapid, being catalyzed by the acidic sites. The dehydrogenation of a diol or ester is the likely rate-determining step, because the rates correlate not to the acid strength but to the oxidizing ability.[127]

$$\mathrm{H_2C{=}C(Me)CHO \longrightarrow H_2C{=}C(Me)CH(OM)_2 \longrightarrow H_2C{=}C(Me)CO_2H} \qquad \mathrm{M = H\ or\ Mo} \tag{12}$$

Another route to methacrylic acid is via oxidative dehydrogenation of isobutyric acid (equation 13). This reaction is catalyzed by molybdovanadophosphoric acid ($H_{3+n}PMo_{12-n}V_nO_{40}$; $n = 0$–3), whose redox potential and acidity are well-balanced for effecting this reaction. The acidity is necessary, although excess acidity accelerates the decomposition of isobutyric acid into CO and propene.

$$\mathrm{Me_2CHCO_2H + \tfrac{1}{2}O_2 \longrightarrow H_2C{=}C(Me)CO_2H} \tag{13}$$

The acidity and oxidizing ability work cooperatively for oxidation of methacrolein, while they function competitively for oxidative dehydrogenation of isobutyric acid.[127] These two reactions also differ in that the former is a surface-type and the latter a bulk-type. From this standpoint, different considerations in effective catalyst design are necessary.

3.6 Solid Acid and Base Catalysts

3.6.1 Acid and Basic Properties of Oxides

Aluminum oxide is a widely used catalyst, mainly as a support. The surface of Al_2O_3 possesses both acidic and basic sites after heat treatment above 670 K. The acid sites are mainly Lewis acid sites; strong Brønsted sites are absent. The Lewis acid site is visualized as a coordinatively unsaturated Al atom formed by dehydroxylation, and the weak Broønsted sites act as acidic surface hydroxyls, while the basic sites are considered to be basic hydroxyls and oxide ions. Three OH groups are

present: loosely adsorbed water, surface hydroxyl groups, and other OH types that interact weakly with neighboring functional groups.[14,132]

Al_2O_3 catalyzes various kinds of reactions, such as dehydrohalogenation, dehydration, hydration, deamination, and aldol condensation. During the dehydrohalogenation of 1,1,2-trichloroethane, Al_2O_3 yields different products from acidic $SiO_2-Al_2O_3$ and basic $KOH-SiO_2$, probably because of a concerted mechanism both acid- and base-catalyzed. The importance of the acid-base pair sites has been proposed in dehydration reactins as well.[14] It is remarkable that Al_2O_3 is effective for the activation of H–H and C–H bonds at low temperatures. The C–H bond probably is dissociated as $RH \rightarrow R^- + H^+$, because the rate decreases with an increase in the pK_a value of alkanes.

Niobium pentoxide ($Nb_2O_5{\cdot}5H_2O$) has acidity corresponding to 70% $H_2SO_4(H_0 = -5.6)$ and exhibits high catalytic activity, selectivity, and stability for acid-catalyzed reactions in which water molecules participate. For the hydration of ethylene, the activity of niobium pentoxide is higher than that of H_3PO_4/SiO_2.[133] For the esterification of ethanol with acetic acid, niobium pentoxide possesses a higher activity than do resin and $SiO_2-Al_2O_3$. Synthesis of 2,5-dimethyl-2,4-hexadiene (an intermediate for an agricultural chemical) from isobutene and isobutyraldehyde has been performed using Nb_2O_5. MoO_3 and WO_3 are weak acids and active for the isomerization of n-butene.[14]

Alkaline earth oxides are well-known basic oxides. MgO and CaO possess basic sites, created by heat treatment above 673 K. Most (90%) of the basic sites on CaO are surface species O^{2-} that are strongly basic, together with a small quantity of OH groups. The order of basic strength of alkaline earth metal oxides is BaO > SrO > CaO > MgO.[14]

In 1-butene, isomerization with a high *cis* to *trans* ratio to 2-butene is characteristic of basic oxides such as MgO and CaO, owing to the high stability of *cis*-allyl anion intermediates, as compared to *trans*-allylic anions. For the double bond isomerization of ethers, activity is in the order CaO > SrO > La_2O_3 > MgO $\gg$ ThO_2, ZrO_2[134] (in agreement with base strength).

MgO, modified with a metal ion, is useful for the formation of unsaturated compounds by the reaction of methanol with ketones, esters, and nitriles (equation 14). The reaction is initiated by dehydrogenation of methanol followed by aldol addition and subsequent dehydration. The dehydrogenation activity of MgO is enhanced by the addition of Cr^{3+}, Fe^{3+}, and Mn^{2+}.[135]

$$RCH_2X + MeOH \longrightarrow H_2C{=}CRX + H_2 + H_2 \qquad (14)$$

$$X = CN, COR, CO_2R; R = H, Me$$

ZrO_2 contains both acidic and basic sites and its bifunctional nature is pronounced compared with Al_2O_3. The highest acid strength of ZrO_2 is $H_0 = 1.5$. The highest base strength of ZrO_2 is$H- = 18.4$.[14] Although the strengths are rather weak, the bifunctional nature of ZrO_2 makes it highly selective for the formation of 1-butene from 2-butanol. ZrO_2 also catalyzes dehydration of 1-cyclohexylethanol and the elimination of ammonia from 2-butanamine.[136] The reactions probably are initiated by the abstraction of H^+ by basic sites; the acidic sites then stabilize the carbanion formed. ZrO_2 will hydrogenate dienes or CO, with isobutene being the main product from the hydrogenation of CO.[132] Direct hydrogenation of aromatic carboxylic acids to the corresponding aldehydes is selectively catalyzed by ZrO_2.

ThO_2 shows catalytic behavior similar to ZrO_2. The selectivity of ThO_2 (prepared by hydrolysis of the nitrate) for the formation of 1-octene from 2-octanol is very high (99%).[14]

The acid strength of oxoacid salts in the solid state increases with the electronegativity of the metal ion, and hence catalytic activity increases with electronegativity. Figure 14 shows an example of selectivity, in which the selectivity of double bond isomerization of butene over metal sulfates changes with the electronegativity.[14]

The maximum acid strength of mixed oxides increases with average electronegativity (Figure 15).[14] However, no general rule about the basicity of mixed oxides has been formulated. The acid sites on $SiO_2-Al_2O_3$ are more strongly acidic than $H_0 = -8.2$, and involve both Brønsted and Lewis acids. $SiO_2-Al_2O_3$ catalyzes a wide variety of reactions such as propene polymerization, cumene cracking, and o-xylene isomerization. SiO_2-TiO_2 also is strongly acidic. SiO_2-MgO possesses a large number of acidic as well as basic sites

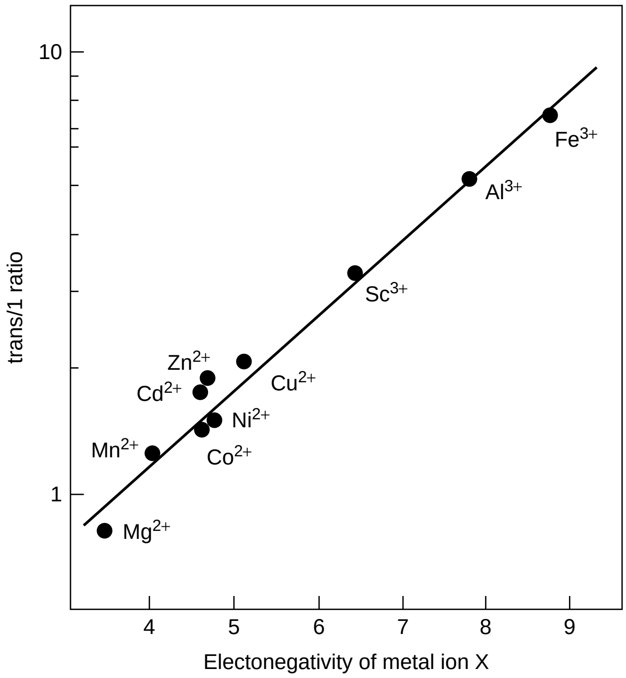

Figure 14 Effect of acid strength on the selectivity observed for isomerization of *cis*-2-butene over metal sulfates

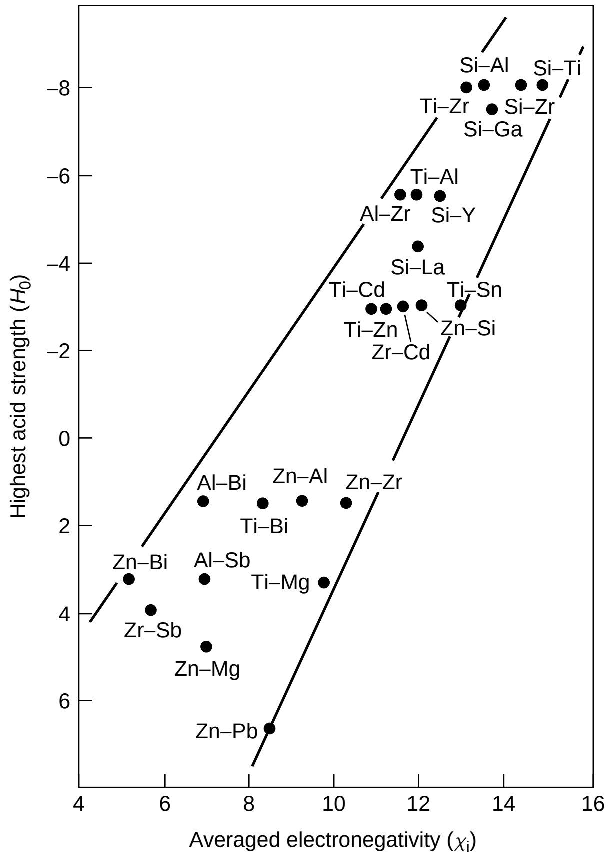

Figure 15 Highest acid strength versus average electronegativity of metal ions of mixed oxides (molar ratio = 1)

and catalyzes bifunctionally the conversion of ethanol to butadiene.[137]

WO_3-ZrO_2 is active in various acid-catalyzed reactions involving skeletal isomerization of alkanes,[138,139] xylene isomerization,[140] and hydration of olefins.[141,142] Catalytic activity is heavily dependent on calcination temperature. Maximum activity for ethene hydration and isomerization of n-butane is obtained when the catalyst is calcined at 1073 and 923 K, respectively.[138,142] Calcination at high temperatures leads to the formation of two-dimensional polytungstate domains, which is proposed to be essential for formation of strong acid sites. In addition, calcination at high temperatures induces surface hydrophobicity,[142] which is an important factor influencing catalytic activity in water-participating reactions,[119] because hydrophobicity either increases the access of olefins to the acid sites[143] or suppresses the poisoning effect of water.[119] The hydrophobicity as well as the strong acidity of WO_3-ZrO_2 calcined at high temperature is responsible for the high activity toward the hydrolysis of ethene.[142]

MoO_3-ZrO_2 is active in acid-catalyzed reactions. In addition, this catalyst possesses an unique acidic function that reversibly accelerates acid-catalyzed reactions such as dehydration of 2-butanol in the gas phase by addition of water vapor when the catalyst is calcined at temperatures higher than 773 K.[144] Conventional solid acids like $SiO_2-Al_2O_3$ are rapidly deactivated by water.

3.6.2 Solid Superacids and Superbases

A superacid is an acid whose acidity (acid strength) is greater than that of 100% H_2SO_4 ($H_0 = -11.94$). SO_4^{2-}/ZrO_2 and SO_4^{2-}/TiO_2 have acid strengths near $H_0 = -14.52$.[1498] These catalysts are active for skeletal isomerization of n-butane at room temperature, but the deactivation is significant. SO_4^{2-}/ZrO_2 also catalyzes acylation, while SO_4^{2-}/TiO_2, $SiO_2-Al_2O_3$, and H-ZSM-5 are inactive.[145]

Catalytic activity of SO_4^{2-}/ZrO_2 is sensitive to pretreatment. By heating $Zr(OH)_4$ at 373–673 K, active catalysts were obtained, but their activities are greatly decreased by treatment at 723 K. Crystallization temperature of ZrO_2 is 683 K and leads to undesirable effects.[146]

SO_4^{2-}/ZrO_2 catalyzes reactions such as cracking, skeletal isomerization, acylation, esterification, and polymerization. In the alkylation of isobutane with butenes, SO_4^{2-}/ZrO_2 is highly active and gives alkylates analogous to cases involving H_2SO_4. The structure of the catalytically active species or of the species responsible for the highly acidic properties involves an organic sulfate structure with a metal cation.[145,146]

The addition of Pt to SO_4^{2-}/ZrO_2 resulted in a drastic increase in catalytic activity and catalyst life for the skeletal isomerization of pentane in the presence of hydrogen. The roles of Pt include: (1) dissociated hydrogen on Pt which spills over to the SO_4^{2-}/ZrO_2 surface to form H^+; (2) dissociated hydrogen that hydrogenates the carbonaceous residue; and (3) the addition of Pt that suppresses acid strength to prevent the formation of carbonaceous materials.[147]

The solid superbase $Na/NaOH/Al_2O_3$ has been synthesized. This catalyst, prepared by treating Al_2O_3 with NaOH followed by addition of metallic Na, possesses basic sites stronger than $H_0 = 35$.[148] $Na/NaOH/Al_2O_3$ is used in an industrial process for the selective double bond isomerization of 5-vinylbicyclo-[2,2,l]heptene. When prepared by the addition of NaN_3 to MgO followed by heat treatment, the catalyst exhibits strong basicity and possesses high catalytic activity for decomposition of methyl formate to CO and methanol.[149]

1 INTRODUCTION

Oxygen comprises approximately 21% of the Earth's atmosphere and nearly 47% of its crust, thus making it the most abundant terrestrial element. By far, the greatest amount of this oxygen is found in combination with silicon and aluminum in the form of complex aluminosilicates that make up the vast proportion of igneous rocks. Smaller amounts are found as concentrated deposits of anhydrous oxides, hydroxides, carbonates, sulfates, or other oxyanions, which can be exploited commercially for their elemental components. Indeed, the earlier studies by mineralogists and chemists who elucidated the compositions and structures of these naturally occurring compounds of oxygen provided the basis for the rich and varied solid-state chemistry that has evolved in the modern laboratory.

This article will be concerned with the chemistry of inorganic solid compounds or composites with interesting and useful properties in which the valence of oxygen is -2. Readers interested in molecular oxides, oxyhalides, molecular oxygenyl complexes, peroxides, superoxides, or ozonides should consult established publications[1–6] and the index of this encyclopedia.

Oxygen is a highly reactive element, forming at least one binary oxide with virtually all of the known elements (the exceptions being Radon and the lighter noble gases) as well as a wide variety of interesting and useful ternary and quaternary compounds. Although many gaseous oxides are known at standard temperatures and pressures, particularly those of the lighter members of groups 15–17 as well a few liquids (e.g. P_4O_6 and Mn_2O_7), by far the largest number are solids. Within this latter class the physical properties vary greatly, depending upon the position of the combining element in the periodic table and its formal valence. Thus we find, for instance, refractory, electrically insulating oxides such as ZrO_2 and Cr_2O_3 with melting points of 2670 and 2450 °C, highly reactive low-melting oxides such as CrO_3 (mp 190 °C) or V_2O_5 (mp 685 °C) as well as partially reduced oxides such as MoO_2 or ReO_3 whose electrical conductivities rival those of conventional metals.

The ability of oxygen to form this wide variety of compounds results from a number of favorable factors. One is a high electronegativity, 3.5 on the Pauling scale, which is a measure of its desire to acquire negative electronic charge and is second only to fluorine in this respect. A second very important factor is that it has a high electron affinity, which can be looked upon as the ability or capacity to acquire an electron. A third factor is its ability to form strong chemical bonds with most elements that may be ionic or covalent in nature depending upon the electronegativity of the combining element. In covalently bonded environments, oxygen may adapt coordination numbers of 2, 3, or 4. This is the result of the ability of oxygen to hybridize sp, sp^2, or sp^3, allowing it to form strong σ type covalent bonds in three dimensions leading to the extended network structures that characterize so many oxides. Further, when one or more p orbitals are not utilized in hybridization, they may be used to form weaker, but nonetheless important, metal-oxygen π bonds by overlap of oxygen 2p orbitals with properly oriented d orbitals of transition metal ions. Such interactions may dramatically affect the electrical and magnetic properties of the material.

2 TRENDS IN THE PROPERTIES OF BINARY OXIDES[1–3,7]

This section gives a brief overview of some of the more important properties of the binary oxides of the elements. Some of the more important aspects that must be considered in evaluating a compound are its thermodynamic stability and chemical reactivity, particularly with respect to oxidation or reduction as well as reactivity with such constituents of the atmosphere as dioxygen, water vapor, and carbon dioxide, since these factors will determine the commercial availability of the compound and the need for any particular precautions in its handling or storage in the laboratory.

2.1 Acid–Base Properties

The reactivity of oxides towards water follows well-defined trends based upon the electronegativity, size, oxidation number, and position in the periodic table. Thus elements of groups 1 and 2, with the exception of Be, are strongly basic, being converted to their respective hydroxides on contact with water, which absorb carbon dioxide from the air or liberate ammonia from ammonium salts. In the case of the alkali hydroxides, thermal dehydration to form the oxide takes place only at very high temperatures except for LiOH, which can be decomposed to the oxide above 925 °C. The somewhat less basic properties of the divalent alkaline-earth oxides from Mg to Ba is illustrated by the fact that the oxides can be regenerated from their hydroxides at temperatures progressively increasing from 400 to 700 °C as the size of the alkaline-earth metal increases. The situation is further complicated by the fact that both the alkali and alkali earth hydroxides readily absorb carbon dioxide from the air to form extremely stable carbonates. Thus, alkali metal oxides are not likely to be found in the chemical stockroom, while those of the alkaline earths that are should always be looked upon with suspicion. In the case of Mg and Ca, ignition at 500 and 1000 °C respectively is normally sufficient to destroy any hydroxide or carbonate present while in the case of Ba and Sr, heating in the presence of H_2 or C at temperatures above 1200 °C is required to break the strong C–O bond and regenerate the pure oxide:

$$BaCO_3 + H_2 = BaO + H_2O + CO \quad (1)$$

A similar but less formidable trend is observed for the group 3 metals and the trivalent rare earths where hydroxide and/or carbonate removal from the commercially available materials is assured by heating at 800–1000 °C for the lighter members of the series while progressively lower temperatures are required for the heavier members. The tendency of small charge, large size cations to yield basic oxides is illustrated by the fact that Ag_20 and Tl_20 are strongly basic in all their reactions.

Quite different behavior is found for the oxides of groups 15 through 17. Here these covalent, molecular oxides react with water to form some of the strongest acids known, many of which are strongly oxidizing. In general, the acid behavior becomes less pronounced as one proceeds down a given group or when the oxide has a valence less than the group valence. Thus, nitric and sulfuric acids are much stronger acids than phosphoric or selenic acids. On the other hand, these two latter acids are much stronger than phosphorus acid, H_3PO_3, or selenous acid, H_2SeO_3. Often the reaction with water takes place readily but there are some exceptions. Thus, P_2O_5 is an effective desiccant for the removal of trace quantities of water from gas streams but the reaction of SO_3 with water is kinetically limited and commercially, sulfuric acid is manufactured from SO_3 by passing the latter through concentrated H_2SO_4 to form pyrosulfuric acid, $H_2SO_4{\cdot}SO_3$, which is then diluted with water to form sulfuric acid of the desired concentration.

With regard to the rest of the periodic table, the acid-base behavior is usually less pronounced. Indeed, many of these oxides, particularly those in the trivalent state, are amphoteric, reacting readily with stronger acids or bases. Typically, however, many of these oxides are kinetically inhibited and will not react easily with water or with aqueous reagents. Thus, Cr_2O_3 is immune to concentrated aqueous acids or bases but will react readily with solid oxides at elevated temperatures. Similar behaviors are noted for the oxides of group 4 and for Nb and Ta in the group valency. NiO, which on the basis of size and charge would be expected to have pronounced basic characteristics, reacts slowly if at all with concentrated aqueous acids but does display basic properties in high-temperature solid-state reactions. On the other hand, there are many acidic oxides that are essentially insoluble in water but will react readily with aqueous hydroxide solutions, or in some cases alkali carbonates, to form oxyanion salts. These are typically high-valent oxides such as V_2O_5, MoO_3, and CrO_3.

2.2 Valence State Trends

A well-known property of oxygen is that it tends to stabilize the higher valencies of the elements with which it combines. Indeed, while fluorine may have a higher electronegativity and is noted for its ability to stabilize high oxidation states, the highest valence known for a given binary compound of a transition metal is often an oxide. Thus, one finds Mn(VII) Mn_2O_7 but MnF_5 is the highest valent fluoride. Similarly, OsO_4 is well established but the highest valent fluoride is OsF_6. A general trend among the transition metals is that the higher oxidation states will tend to be more stable as one goes down a given periodic group while the group valence will become less accessible as one goes from group 3 to group 12. Thus, for group 4, the dioxide is the most stable and lower valent oxides can be prepared only for titanium. Further, one notes that the relative ease of reduction of Ti(IV) can be responsible

for the bluish cast found in some titania based white pigments. Similarly, CrO_3 is highly oxidizing while WO_3 is the most stable binary oxide of tungsten. Although higher oxidation states of Fe and Ni can be stabilized in mixed-metal oxides, Fe_2O_3 and NiO represent the highest valent binary oxides of these two members. For osmium, OsO_2 can be prepared by the reduction of the volatile, molecular OsO_4, which is well known for the preparation of stained biological slides. All oxides of Pt are easily decomposed although it is possible to prepare PtO_3. Cu_2O and Ag_2O are well established but the existence of Au_2O is not. The only divalent group 11 oxide is CuO, AgO being a mixture of the mono- and trivalent states. The existence of Cu_2O_3 is questionable but Au_2O_3 is well established but again unstable with respect to decomposition to the elements at temperature above 160 °C. Cu(III) is stabilized by mixed oxide formation, the best-known example being $YBa_2Cu_3O_7$ and related compounds, which form the recently discovered class of high-temperature superconducting cuprate oxides. Except for the metal–metal bonded Hg_2O, only the divalent state is known for group 12 oxides.

In the case of right-hand main group oxides, the general observation is that compounds with a valence two less than the group valence will be thermodynamically more stable as one goes down the group. Thus while Al_2O_3 and Ga_2O_3 are the only known solid binary oxides of these two elements, an unstable In_2O has been observed while Tl_2O, PbO, and Bi_2O_3 are the stable oxides for the heaviest members of groups 13 through 15. Indeed, Bi_2O_5 is not well established and PoO_3 does not exist, in contrast to the well-known SO_3.

The halogens form a variety of binary compounds, all of which are highly unstable and, with the exception of gaseous ClO_2, of little economic value. Here the oxygen chemistry is dominated by oxyhalogen acids and their salts. Two binary oxides of xenon are known, both of which are highly unstable. White crystals of XeO_3 are obtained by the careful evaporation of dilute solution of $Xe(OH)_6$ produced by the hydrolytic decomposition of XeF_4.

$$6XeF_4 + 18H_20 = 2Xe(OH)_6 + 4Xe + 3O_2 + 24HF \qquad (2)$$

XeO_4, like the trioxide, is highly unstable and explosive. This gaseous oxide is obtained by the action of concentrated sulfuric acid on Ba_2XeO_6 solutions.

3 OXIDE CRYSTAL STRUCTURES

3.1 Oxide Structures Derived from Closest Packing of Spheres[8–10]

The high electronegativity of oxygen imparts a significant ionic character to the bonds formed by it with metals in formal valences of four or less, the effect being particularly pronounced for the lower values. The omni-directional character of ionic bonds mandates that the structures be 3D in nature and this in fact is found to be the case even where there may be significant covalent character to the bonds. However, as the electronegativity of the positive end of the dipole increases, the structures tend to become more anisotropic in nature. In this case, one sees clear evidence for chains or sheets of strongly bonded atoms whose properties are one or two dimensional. Finally, in the cases of the nonmetallic main group elements and transition metals in high valence states, a definite trend towards molecular bonding is observed. This may be either in the form of neutral molecules held together by van der Waals forces or, more often, as small covalently bound oxyanions in combination with group 1 and 2 cations (e.g. Na_2SO_4), where the extended interactions are essentially ionic.

An elegant description of the most common 3D oxide structures can be given in terms of space filling models derived from the closest packing of spheres. The assumption is made that ions can be treated as hard spheres with well-defined ionic radii. When they come in contact with one another, the repulsive forces rise exponentially owing to the interaction of the respective electron shells. The model postulates that the most stable arrangements of equal sized spheres will be those that fill space most efficiently leading to maximum density. In two dimensions, the most efficient way to pack equal sized spheres is to form equilateral triangles of spheres, which are then stacked side by side to form a layer in which each sphere is now surrounded by six other spheres to form a layer with hexagonal symmetry (Figure 1(a)).

Note that for each close-packed (CP) atom there exist also two triangular shaped interstices. These interstices form two sublattices labeled P and R, either of which (but not both at the same time) may serve as a nesting spot so that similar layers of close-packed spheres can be stacked one on top of the other to generate a three-dimensional CP lattice. Figure 1(b) shows a two-layer arrangement in which the P positions have been utilized. Note that if the R position had been chosen, the arrangement would look the same except for the translation. The bottom layer is designated as the A layer and the top the B layer. When one proceeds to add a third layer, there are two choices, which lead to spatially different arrangements. If the nesting spot is chosen that lies directly above the A layer, then so-called ABA packing results. If this motif is continued

...... ABABABABA ......

a lattice is generated with hexagonal symmetry that is referred to as hexagonal closest packing (HCP). On the other hand, if the R interstice sublattice is chosen for the nesting, this layer is labeled as C (Figure 1(c)). The arrangement is spatially different and is called ABC. By placing a fourth layer over the original A layer, this motif can be continued indefinitely

...... ABCABCABCABC ......

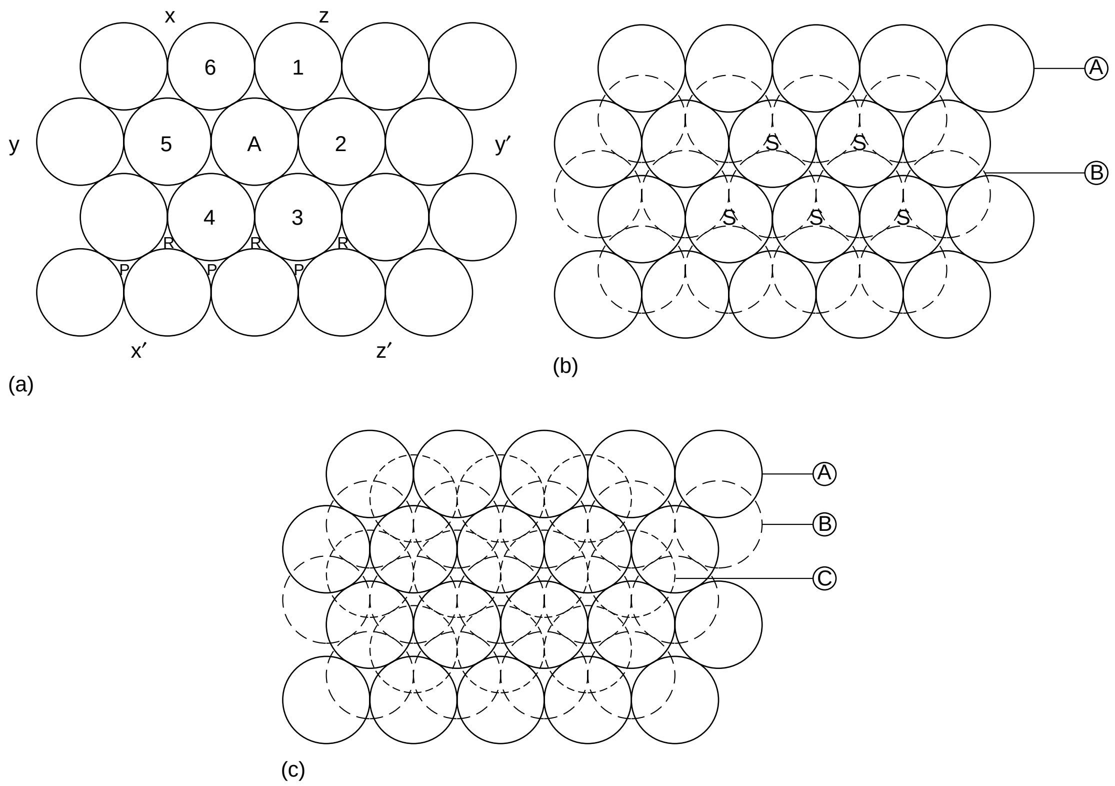

Figure 1 (a) A close-packed layer of equal sized spheres. (b) The layer labeled B is added below A and nests in the P positions shown in (c)

and a lattice is generated that has face-centered cubic symmetry. The stacking arrangement is referred to as cubic close packing (CCP).

These two packing schemes form the basis for the most common structures derived from the closest packing of spheres. Many other arrangements that are a mixture of the two sequences are possible and are seen in nature, such as . . ..ABAC. . .. or . . ..ABCAC. . . or others with larger repeat motifs (see Section 3.11), but these occur with less frequency than the simple ABA and ABCA arrangements. However, all conserve space with the same efficiency, approximately 74% of the volume being filled by spheres. Further, each sphere is surrounded by 12 other spheres leading to a regular icosahedral coordination symmetry for each close-packed atom. The efficacy of this simple model is shown by the fact that hexagonal and cubic CP structures are adopted by 67% of the group 1 through 11 and lanthanide metals while another 28% adopt the simple body-centered cubic arrangement, which is quasi-close packed with a 68% space filling efficiency.

For metallic elements, only one type of sphere is needed. However, in compound oxides two or more 'spheres' of different sizes must be accommodated. To do this, the interstices of the hard sphere lattice are utilized and since O^{-2} is normally the larger ion, it is generally considered to comprise the close-packed array. Within any such array, there are two types of interstices; those with tetrahedral symmetry and those

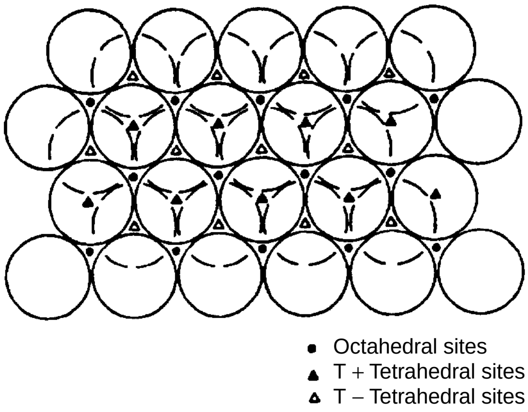

Figure 2 Three close-packed layers in a CCP sequence

with octahedral symmetry, which are distributed as shown in Figure 2. These are commonly referred to as 'tetrahedral holes' and 'octahedral holes'. There are two tetrahedral holes per CP atom but only one octahedral hole per CP atom. Within each layer there are two types of tetrahedral holes, one forming a sublattice with their apices pointing up and the other with their apices pointing down as viewed normal to the stacking direction. These are labeled T+ and T− respectively in Figure 2. The centers of the octahedral holes are midway

between the two CP layers while tetrahedral sites lie off center, one sublattice being nearer to one layer and vice-versa.

The structures will have the greatest stability when the cations can be inserted into the structure and just be in contact with the anions. Thus, in a hard sphere model, cations entering a tetrahedral hole must have a radius 0.224 times that of the anion while the octahedral hole will be most stable when the radius ratio of the cation to anion is exactly 0.414. Since these conditions will be met only by chance, in practice what is observed is that the anions are moved apart to accommodate the larger cation and will continue to do so until a larger coordination number can be achieved, either by a switch from the tetrahedral to the octahedral site or to a nonclose-packed structure with a larger coordination number. For instance, the center of a cube anion can just accommodate a cation whose radius is 0.732 that of the anion leading to eightfold cuboidal coordination. Finally, a close-packed array can be maintained when the cation and anion have similar sizes. Here, a metallic sublattice is formed by partial replacement of the anions in an ordered fashion. Some examples of simple structures derived from the closest packing of spheres are described in more detail below.

If, on the other hand, the radius ratio rules are violated on the downside, that is to say the hard sphere cation and anion no longer touch, the structure is longer stable and another structure should be adopted. For instance, if $r^+/r^- < 0.224$, then tetrahedral coordination is no longer possible but a threefold planar triangular coordination can be found by locating the cation in the trigonal hole centered in the plane of the close-packed layer. Such coordination should be stable for $0.15 \le r^+/r^- \le 0.224$. In fact, however, trigonal coordination is rare in chemical systems other than those of boron.

In order to use these concepts to predict structures, one needs a listing of radii and it should be recalled that a crystal radius cannot be measured directly. Rather, one measures an interatomic distance from which a decision has to be made as to the relative contribution of the interacting species. However, a number of compilations of ionic radii have been made, the most notable being those of Pauling, and were based upon semiempirical calculations. These largely have been replaced by the 'experimental' radii of Shannon and Prewitt.[11] The data set is based upon the assignment of a radius of 1.19 Å to F^-, and from this deriving the best radii for other ions based upon their extensive study of the crystallographic literature. A further complication in applying these rules is that the ionic radius of a given atom is dependent to some extent upon its coordination number. Thus, the tetrahedral radius of a cation is about 6% smaller than its octahedral radius, while its cubic or eightfold radius is expected to be about 3% larger, which is borne out experimentally (*see* ***Bond Lengths in Inorganic Solids & Liquids***).

It should be pointed out that the application of the radius rules to the prediction of structure often fails. The theory is strictly applicable to only the most ionic of chemical systems and the introduction of covalent effects will inevitably lead to modifications of the ideal structure and oftentimes what will be seen are structures distantly related to the actual hard sphere model. However, the model provides a convenient basis for visualizing the structure. What is remarkable is that it works as well as it does in predicting what type of oxides should form in a given system. It is particularly useful for predicting the structures of transition metal binary and ternary oxide systems and in a sense explains the instability of alkali and alkaline-earth oxides with respect to moisture, carbon dioxide, and their further reaction with oxygen. On the other hand, it is of limited value in predicting the structure of complex silicates or for the more covalent main group oxides.

3.2 Binary Oxide Structures Based upon Close Packing[8,10]

3.2.1 MO Structures

One of the simplest structures is the sodium chloride or rock salt structure shown in Figure 3(a). Here the anions are CCP and all of the octahedral holes are filled leading to perfect octahedral coordination for both the cation and anion. This is a highly 3D structure and is found for oxides formed with a wide variety of medium and large divalent cations. These include the oxides of the alkaline earths except beryllium (which is too small), CdO, and the divalent oxides of Mn, Fe, Co, and Ni.

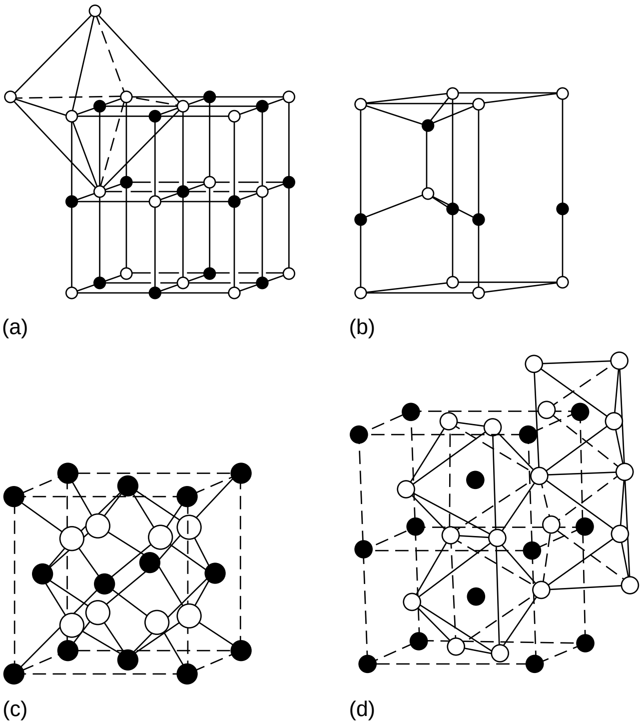

Figure 3 Unit cells for (a) Rock salt, (b) Wurtzite, (c) Fluorite (d) Rutile

With several other transition metal monoxides, covalent and special electronic effects that are not compatible with the ideal structure manifest themselves. As examples, PdO and PtO display the characteristic tendencies of heavier d^8 ions for square-planar coordination by adopting different structures while a severe Jahn–Teller distortion yields essentially fourfold planar coordination in CuO. In the cases of TiO, VO, and NbO, formation of weak metal to metal bonds are seen as defect variants of the rock salt structure.

So-called ternary or mixed oxide systems based on the rock salt structure are well established. Thus $LiFeO_2$ exists both in a disordered form in which Li and Fe are randomly distributed on the metal sites, and as an ordered variant with tetragonal symmetry. Rhombohedral distortions are found for $LiNiO_2$, $LiVO_2$, and $NaFeO_2$ in which the cations are ordered on different sublattices. The HCP counterpart of the sodium chloride structure, the so-called Nickel Arsenide stucture (*see* ***Chalcogenides: Solid-state Chemistry***), is found only for the heavier members of the Oxygen family.

Both ZnO and the low-temperature form of BeO have the wurtzite structure (Figure 3(b)) in which the cations occupy one half of the tetrahedral sites in an ordered three-dimensional fashion in an HCP arrangement of oxygens. This small cation structure and its CCP analog, the zinc blende structure, are found for small metallic elements, which tend to form strong sp^3 covalent bonds. Indeed, these structures are much more common for sulfides and the heavier chalcogenides (*see* ***Chalcogenides: Solid-state Chemistry***). $LiBO_2$ and $LiGaO_2$ have superstructures based on wurtzite (ZnS) in which the cations are ordered on tetrahedral sites. β-BeO has a wurtzite related structure but here the cations are ordered in tetrahedral sites such that the BeO_4 tetrahedra share faces leading to an anomalously short Be–Be distance of 2.24 Å.

3.2.2 MO_2 and M_2O Structures

The Fluorite (CaF_2) structure is shown in Figure 3(c). This is a structure for large cations and as such can be described in terms of a cubic closest packing of cations in which all of the tetrahedral holes are filled by the anions. In so doing, a cubic, eightfold coordination of the cation is achieved. The structure is found for cerium dioxide, hafnium dioxide, and the high-temperature form of ZrO_2 as well for as a number of actinide dioxides such as ThO_2, UO_2, and AmO_2. PrO_2 at high pressures also has this structure. Again, the bonding in this structure extends uniformly in three dimensions and has a strong covalent component owing to the high formal charge on the cation. As a result, fluorite type oxides tend to be extremely refractory with those of Ce, Zr, Hf, U and Th all having melting points in excess of 2500 °C.

In the antifluorite structure, the positions of the cation and anions in the fluorite structure are juxtaposed with the cations being tetrahedrally coordinated. One might expect this structure to be stable for small cations. However, all monovalent cations, with the exception of Li^+, are quite large and normally would be expected to be in six or eightfold coordination in oxygen. Nonetheless this is the stable structure for all of the monoxides of the alkali metals except Cs_2O. Although this may seem surprising from the point of view of the arguments present here, it is entirely consistent with the fact that the oxides cannot be prepared by direct combination of the elements; instead peroxides or superoxides are formed that do have distorted versions of the rock salt structure. The monoxides also react with moisture in the air to form hydroxides that also have distorted versions of the rock salt structure.

The structure of Cs_2O deserves mention. It can be considered as derived from a CCP of the large cesium ions in which 100% of the octahedral holes are filled in alternate layers by oxygens leading to a layer structure. The layers are pushed away from each other so that the Cs–Cs distances are about 4.2 Å but collapse upon the oxygens to yield extremely short Cs–O lengths. The structure is effectively that of $CdCl_2$ with the cation and anion positions interchanged. The bizarre nature of this structure is underscored by the fact that cesium reacts with oxygen to form not only a peroxide and superoxide but several suboxides as well.

The rutile structure is characteristic of a number of transition metal dioxides (rutile is a polymorphic form of TiO_2). Cassiterite (SnO_2), PoO_2, and one modification of both GeO_2 and PbO_2 also have this structure, given in Figure 3(d). Here the oxygens are in hexagonal closest packing and one half of the octahedral holes in each layer are filled in an ordered fashion. The oxide ions are in trigonal planar coordination with the metal ions. The overall lattice type is tetragonal. Again the structure is three-dimensionally cross-linked with strong M–O bonds and as a result most binary oxides with this structure have very high melting points. Rutile-type oxides containing one or more d electrons often display remarkable electronic and magnetic properties. Some of them undergo electronically driven distortions (see Section 4.3.2). In rutile itself, the Ti atoms are at the center of the edge-sharing octahedra and are equidistant from one another. However, when one or more d electrons are present, the metal atoms may move off center along the chain direction to form an alternating pattern of short and long metal–metal distances, the short distance being as short or shorter than that expected for a metal–metal bond as shown in Figure 4. Such distortions occur in MoO_2, WO_2, and

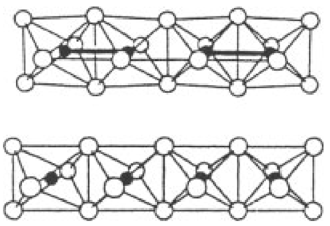

Figure 4 Sequence of edge-sharing TiO_6 octahedral in rutile showing equal spacing of Ti (a). Distorted chains seen in VO_2 and MoO_2 with metal–metal bonds (b)

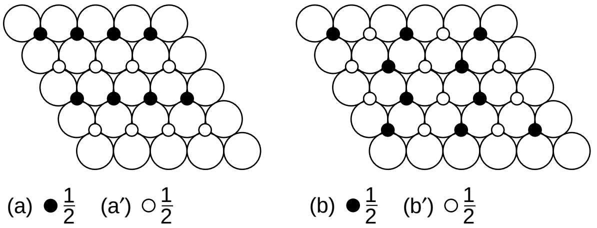

Figure 5 Pattern of octahedral site occupancies between pairs of close-packed layers in (a) rutile and (b) wolframite. Small shaded circles are octahedral sites above the plane of paper. Small open circles are sites below the plane

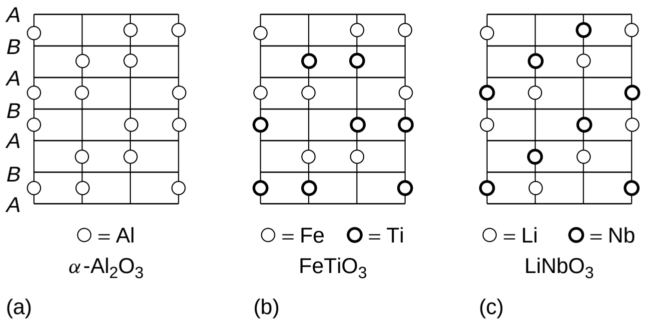

Figure 6 Elevations along hexagonal *c* axis for (a) corundum, (b) ilmenite, (c) lithium niobate

the low-temperature form of VO_2. In MoO_2, the short Mo–Mo distance is 2.51 Å, considerably less than the Mo–Mo distance of 2.725 Å in molybdenum metal itself. A different but related distortion is found in NbO_2.

The structure and distorted variants of it are also found for a number of mixed transition metal oxides. In the trirutile structure, the tetragonal *c* axis of the simple unit cell is tripled and the titanium sites are no longer equivalent. The mineral tapiolite, $FeTa_2O_6$, has this structure in which the Fe and Ta occupy separate crystallographic positions. The ferrous ion can be replaced by Mg^{+2} and other divalent transition metal cations such as Co^{+2} and Ni^{+2}. Antimonates of the form MSb_2O_6 (M^{+2} = Mg, Fe, Co, Ni, Zn) also form with the trirutile structure. Examples are known in which the transition metals are mixed on the two sites. This occurs for WCr_2O_6, which might more correctly be formulated $Cr(Cr_{0.5}W_{0.5})_2O_6$.

The arrangement of the filling of half of the octahedral holes to form the rutile structure is only one of several possible. Figure 5 shows two possible fillings for 50% occupancy. If sites represented by small black circles are filled by metal atoms above the plane of the paper while the small white circles are filled below the plane as shown in Figure 5(a), a rutile lattice is generated where chains are formed in alternate layers. Figure 5(b) shows a different ordering found in the mineral $FeWO_4$, wolframite, which is a common structure for a variety of transition metal tungstates, molybdates, and vanadates (see Section 3.4.5). The cations in the mineral columbite (niobite), $(Fe,Mn)Nb_2O_6$, also utilize the positions shown in Figure 5(b). A three-layer sequence is required to complete the unit cell. More detailed discussion of these and other variants can be found in Wells.[12]

3.2.3 M_2O_3 Type Structures and Related Ternarys

One of the most common structures for sesquioxides of small to medium sized cations that favor sixfold coordination with oxygen is the corundum structure (α-Al_2O_3). Here, the oxygens are placed in an HCP array but only 2/3 of the octahedral sites are occupied following the motif shown in Figure 6(a). Strong Al–O–Al cross linking takes place in three dimensions in which AlO_6 octahedra share not only corners but edges and faces as well. These properties are reflected in the fact that the mineral corundum is the second hardest substance known, is chemically inert, and has a melting point above 2000 °C. Other corundum type oxides include Ti_2O_3, V_2O_3, Cr_2O_3, α-Fe_2O_3, Rh_2O_3, α-Ga_2O_3, and one form of In_2O_3.

A well-known ternary structure derived from the corundum arrangement is the ilmenite ($FeTiO_3$) structure where Al sites are now occupied exclusively by Fe and Ti in alternate layers (Figure 6(b)). The structure is stable for cations that have similar sizes. Typically, one cation is divalent and the other tetravalent (2:4 ilmenites) but $NaSbO_3$ is an example of a 1:5 ilmenite. While size considerations might lead one to expect that $LiNbO_3$ would have this structure, it turns out that it adopts the somewhat different but related arrangement shown in Figure 6(c) where ordering of Li and Nb takes place in each layer.

Trivalent group 3 and rare earth cations are larger on average than those of the transition metals and the lighter main group metals. However, the effects of the *lanthanide contraction* result in a considerable difference in the octahedral radii of La^{+3} and Lu^{+3}, for example, 1.17 versus 1.00 Å. The lightest member of the trivalent group 3 elements, Sc^{+3}, has an octahedral radius of 0.88 Å, 0.07 to 0.20 Å larger than those of the trivalent first period transition metals and Al^{+3}, which typically form oxides with the corundum or ilmenite structures. As a result these elements have a greater tendency to form compounds in which higher coordination can be achieved. While sixfold coordination is observed, eightfold coordination is more common, while in mixed oxide systems coordination numbers of 7, 9, 10, and 12, particularly for the larger members of this series, are not unusual.

Three principal types of structure are noted for the rare earth oxides designated as the A, B, and C rare earth structures. The A rare earth structure is the stable room temperature structure for the lighter rare earths from La to Nd while the C rare earth structure is the stable polymorphs for Sm through Lu. The B form is seen for several oxides at intermediate temperatures and/or high pressures. All polymorphic forms have been observed for several of the rare earths. Other

structures are also observed for temperatures above 2000 °C. A comprehensive review of binary oxide chemistry of the lanthanides, including other oxidation states, is given by Eyring.[13]

The dominant feature of the A rare earth structure is a distorted MO_6 octahedron in which one of the faces is capped by a 7th oxygen. The metal-oxygen bond distances vary from about 2.35 to 2.45 Å for the octahedral bonds while the face-capping bond is about 0.3 Å longer. Thus, while this structure cannot really be described in terms of closest packing of spheres, the C rare earth structure can be. It is related to that of CaF_2 but the edges of the unit cell must be doubled yielding the composition $M_{16}O_{32}$. Then 8 anions are removed from the structure in an ordered fashion and the remaining oxygens are moved off of their idealized positions. The net effect is to destroy the cubic metal coordination by oxygen of the fluorite structure and replace it with what might be called a distorted octahedral arrangement, which has shared edges. The lower coordination number of this structure as compared with the 7 coordinate A structure is consistent with the smaller size of the cations for which it is stable. The C rare earth structure is also adopted by α-Mn_2O_3 (Bixbyite), In_2O_3 and Tl_2O_3. The latter two adopt the corundum structure at high pressures.

In the corundum structure, the metal atoms are in crystallographic sites with variable coordinates. Because edge and face sharing of MO_6 octahedra can result in an abnormally close approach of the metal atoms to one another, such interactions can be minimized if the atoms move off center away from one another. However, in Ti_2O_3, the Ti atoms are only 2.58 Å apart in face-shared octahedra and the d^1 electrons are used to form a metal–metal bond. This compound is a semiconductor, but between 125 to 325 °C a broad structural transition takes place where this bond is broken, thus providing free electrons for electrical conduction and the compound now displays metallic conductivity.[14] V_2O_3 also has this structure but has a more complex temperature dependence of its conductivity.

3.2.4 MO_3 Structures

The ReO_3 structure is an interesting application of the concept of closest packing of spheres. The unit cell of the structure is shown in Figure 7(a). The basic building block is a cubic closest packing of oxygens in which one-quarter of the octahedral holes are filled in an ordered fashion while one-quarter of the oxygens are removed in a similar fashion. As a result, a three-dimensional network of ReO_6 octahedra is formed in which all vertices are shared with other octahedra (Figure 7(b)). Although the cubic structure is unique to ReO_3 in oxide systems (WO_3 has a distorted version of it, however), ternary structures derived from this 3D octahedral network are among the most important in oxide chemistry and will be discussed in Section 3.4.1. ReO_3 is a bright red, lustrous, metallic looking material and in fact displays excellent metallic conductivity. The electronic aspects of this structure are very

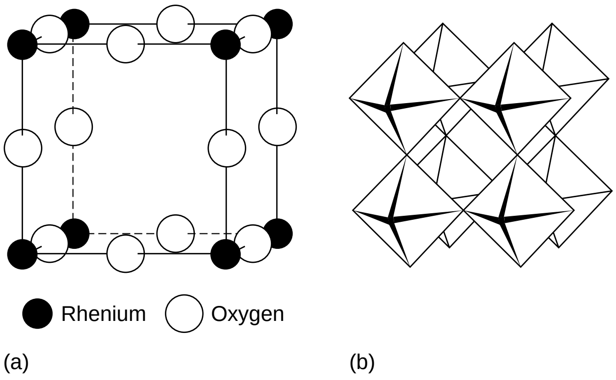

Figure 7 Unit cell of the ReO_3 structure (a). Diagram showing the 3D corner sharing of ReO_6 octahedra (b)

important and may in part explain why the structure is so unusual for binary oxide systems (see Section 4.3.1).

Indeed, in species with +6 oxidation states, high degrees of covalency are expected, high coordination numbers are unusual, and corner sharing of polyhedra does not occur to any extent unless mitigated by the presence of other cations. A good example of this is the structure of CrO_3 where the structure is built up of infinite chains of corner-sharing tetrahedra. Thus, with considerably fewer bonds to be broken, CrO_3 melts at 197 °C while WO_3 melts at nearly 1500 °C although it does have a significant vapor pressure at 1000 °C. The structure of MoO_3 is intermediate between these two. Basic building blocks are double chains of MoO_6 octahedra that share edges and corners to form a layer structure in which the layers are held together by van der Waals forces. Thus, MoO_3 has a significant vapor pressure above 550 °C and melts at 795 °C.

3.3 Other Transition Metal Oxides

This is meant to be a limited overview of some of the more interesting or representative oxides, which because of increased covalency usually cannot be described in terms of structures derived from closest packing of spheres.

3.3.1 Monovalent Oxides of Copper, Silver, and Thallium

Isostructural Cu_2O and Ag_2O illustrate the tendency of these group 12 d^{10} ions to be two-coordinate. While higher coordination numbers of 4 or 6 might be expected, it appears that a stronger bond can be obtained as a result of the hybridization of ns and np_z orbitals with the $(n-1)d_{z^2}$ orbitals of the metal atoms. Figure 8 shows one of the two interpenetrating Cu–O sublattices that form the cuprite structure found for both Cu_2O and Ag_2O. The linear coordination of Cu by O and the tetrahedral coordination of oxygen by Cu is clearly seen. Two-coordinate copper is seen in mixed oxides, the most important being the ‘123’

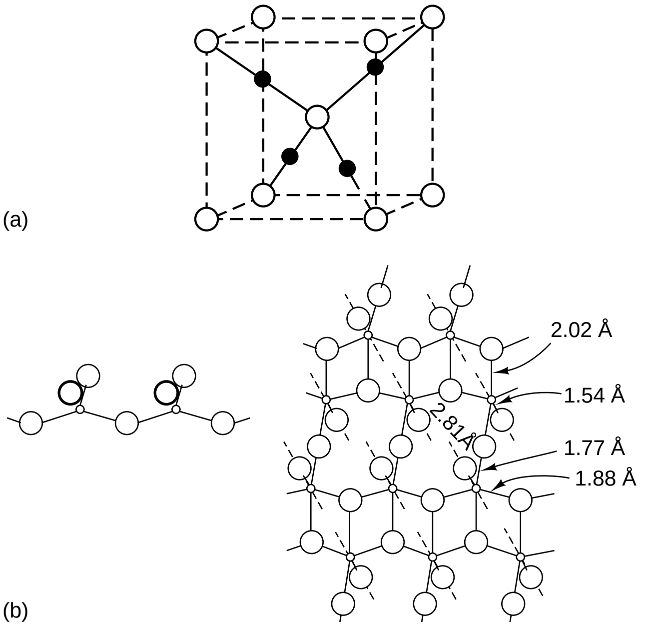

Figure 8 Unit cell (a) and structure (b) of Cu_2O. Note linear coordination of Cu (black circles) by oxygen

superconducting oxides such as $YBa_2Cu_3O_{7-\delta}$, which lose their superconductivity as the result of oxygen loss (i.e. $\delta > 0.5$) in which a portion of the copper becomes linearly coordinated.

Tl_2O is a variant of the anti-CdI_2 structure, which is the HCP counterpart to the anti-$CdCl_2$ structure discussed in connection with Cs_2O (Section 3.2.2). For the thallium compound, there is a 12 layer stacking sequence in which the lone pair plays an important role.

3.3.2 Group 5 and 15 Pentoxides

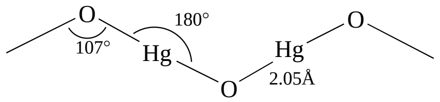
The basic building blocks of V_2O_5 are double chains of badly distorted VO_4 tetrahedra that share 3 vertices with other tetrahedra similar to those found in the polymeric metavanadate ion, $(VO_3)_n{}^{-n}$. These chains are then connected to one another to form V_2O_5 layers. Thus, the complete oxygen coordination of each vanadium is a distorted square pyramid. The bond distances range from 1.59 to 2.02 Å with the short distance being that of the unshared vertex, which points into the gap. A sixth oxygen on vanadiums in the neighboring layer at 2.81 Å is much too long to be considered as bonding. However, it does seem to play a role in limiting what species can be intercalated into this phase and sometimes descriptions of its structure are given in terms of an ‘idealised’ octahedral coordination.[14,15]

Both Nb_2O_5 and Ta_2O_5 have a complex crystal chemistry, each with several polymorphic forms, two of which will be described here. The high-temperature form of Nb_2O_5 utilizes two different sized corner-sharing ReO_3-like blocks that are joined by edge sharing to form infinite planar slabs. The details of the structure are described in Section 3.5. The H form of Ta_2O_5 is formed by edge-sharing TaO_6 octahedra, which also share edges with corner-sharing pentagonal bipyramidal TaO_7 groups, illustrating the tendency of pentavalent Ta to enter into sevenfold coordination. We note in summary that the crystal chemistry of V_2O_5 is strikingly different from the other two members and that overall it is extremely complex. Further, these basic characteristics of their crystal chemistry are often maintained when they enter into mixed oxide formation.

Sb_2O_5 has a structure similar to one of the Nb_2O_5 polymorphs in which distorted SbO_6 octahedra share edges and corners to build a complicated 3D framework. Pure Bi_2O_5 has not been prepared. As_2O_5 may be prepared by the careful dehydration of its hydrate $As_2O_5{\cdot}4H_20$. It has a complex 3D structure formed by the sharing of edges and corners of both AsO_4 tetrahedra and AsO_6 octahedra. The three polymorphic forms of solid P_2O_5 are all based on the linking of tetrahedral PO_4 groups through three of their four corners. One form has P_4O_{10} molecules, identical to those found in the gaseous state. A second consists of layers having the composition P_2O_5 and the third is a 3D structure containing rings built from ten PO_4 groups.

3.3.3 Mercury(II) Oxides

The stable orthorhombic form of HgO can be prepared by the gentle heating of mercury(I) or (II) nitrate in air. The structure (**1**) can be described as consisting of zig-zag Hg–O–Hg chains in which Hg is in linear twofold coordination with oxygen and the Hg–O–Hg angle is 109°.



(**1**)

The Hg–O distances within the chains is 2.03 Å while the closest interchain distance is 2.82 Å. If a Hg^{+2} salt solution is treated with warm, aqueous NaOH for several hours, metastable crystals of HgO form that have the hexagonal cinnabar (HgS) structure. Again the basic building blocks are O–Hg–O chains but now they wrap in a helical fashion and are cross-linked to other chains by Hg–O bonds to form a highly distorted octahedron of oxygens about each mercury with the motif of 2 short linear Hg–O bonds being maintained.

3.3.4 Heavier Group 14 Oxides

The stable, dark blue form of SnO is isostructural with the tetragonal form of PbO that is shown in Figure 9. It is a layer structure in which a square array of oxygens is

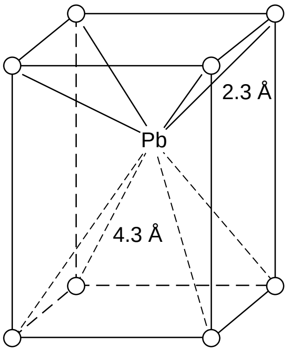


Figure 9 Unit cell of PbO illustrating inert pair effect

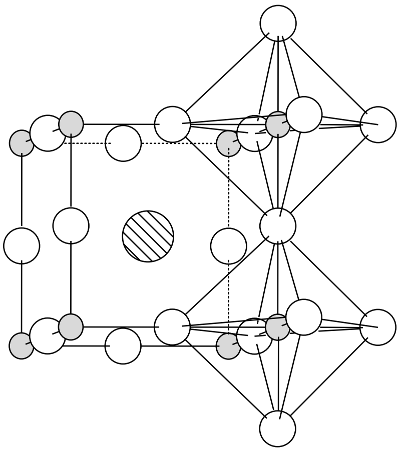

Figure 10 Perovskite structure, ABO_3 (large cross hatched circle is A, small shaded circles are B)

sandwiched between two partially occupied lead layers with a van der Waals gap between each Pb–O–Pb unit. The Pb (or Sn) sits at the apex of a square pyramid having an oxide ion base. This unusual coordination is believed to arise from a sterochemically active electron pair on the metal, which is directed out into the gap.

Other unstable monoxides of these two elements have been reported. Tin also forms the very stable SnO_2 found in nature as the mineral cassiterite. This compound has the rutile structure as discussed previously. PbO_2 also has a rutile isomorph while α-PbO_2 has a columbite structure (Section 3.2.2). If PbO is oxidized in air between 300 and 570 °C, the stable oxide Pb_3O_4 is obtained, commonly referred to as 'red lead'. This is a mixed-valence oxide in which the positions of Pb(II) and Pb(IV) are clearly defined and thus one might consider it to be a ternary structure. Indeed, $MgSb_2O_4$ is isomorphous to Pb_3O_4 as is $NiAs_2O_4$. Here one finds chains of essentially regular PbO_6 octahedra that share opposite edges. These chains are linked to one another by Pb(II) in a roughly pyramidal coordination. In the arsenic and antimony isomorphs, the Mg^{+2} and Ni^{+2} occupy the Pb(IV) positions. The unusual pyramidal coordination is again due to the stereochemically active lone electron pair on the group 14 and 15 ions.

3.4 Major Ternary Oxide Structures[8–10,16]

3.4.1 *Perovskite Structure*

Ternary oxides of the type ABO_3 in which A is a large cation such as an alkali, alkaline earth, or rare earth ion and B is a medium sized ion with a preference for octahedral coordination, typically a transition metal, are often found with the perovskite structure shown in Figure 10. Alternate spellings such as perowskite or perewskite are sometimes seen. The structure can be looked upon as a rhenium oxide type lattice in which the ordered vacancy in the cubic close-packed oxygen lattice is now filled by the large A cation. A large variety of oxides adopt this structure, either in the simple cubic symmetry shown or with varying degrees of distortion to lower symmetry as is the case with the mineral perovskite ($CaTiO_3$) itself. In addition, many more complex oxides form structures in which perovskite-like slabs or layers can be identified sandwiched between other basic structural units. For the ideal perovskite structure, the A and B cations should just be in contact with their oxygen nearest neighbors and deviations from the ideal symmetry might be expected when this condition is not met. In fact, a considerable leeway exists that can be empirically quantified by the so-called Goldschmidt tolerance factor t, which can be derived from the geometry of the ideal cell:

$$t = \frac{R_A + R_O}{\sqrt{2}(R_B + R_O)} \quad (3)$$

where R_A, R_B, and R_O are the ionic radii of the A, B and oxygen atoms. The value of t is 1 for the ideal structure. In general, the cubic structure is maintained for t greater than about 0.95 but below that distortions to tetragonal, rhombohedral, or orthorhombic symmetry usually take place, which have been reviewed by S. Geller[17] and more recently by Attfield[18] and Woodward.[19] So-called double perovskites of the type $A_2BB'O_6$, where the unit cell is doubled and cations of two types are found ordered on the B sites, are quite common. In particular, Sr_2FeMoO_6 and related compounds are of current interest because they are both ferrimagnetic at room temperature and show large magnetoresistive effects.[20] In fact, however, most perovskites are distorted, the most common one being the orthorhombic $GdFeO_3$ type. The net effect here is that the coordination number of Gd with oxygen is lowered to 8 by distortion of the Fe–O octahedron.

The large number of compounds found with perovskite based structures arises from several factors other than the great stability implied by the permitted variation in t and the subsequent distortions that take place with the maintenance of the basic framework. One factor is that the A and B sites are

relatively insensitive to charge distributions and the structure is found for valence combinations of 1:5, 2:4, and 3:3 of the A and B cations. In addition, the structure can withstand considerable departures from ideal stoichiometry, particularly with respect to the A cation and the oxide ion. For example, the so-called tungsten oxide bronzes A_xWO_3 exist with the cubic perovskite structure for $0.3 \leq x \leq 1$, while $LaTiO_3$ can be rendered deficient in oxygen without loss of structure by replacing 50% of the La^{+3} by Sr^{+2} to form $La_{0.5}Sr_{0.5}TiO_{2.5}$. Reaction of CaO and Fe_2O_3 in air yields the oxygen deficient perowskite $CaFeO_{2.5}$.[21]

This structure has been utilized by solid-state chemists as a template to stabilize transition metals in so-called unusual valence states $SrMoO_3$, $LaTiO_3$, $LaMnO_3$, $CaMnO_3$, $BaCrO_3$ (perovskite related), $Sr_{1-x}Nb0_3$, and so on. In addition, perovskites and perovskite related phases in which the transition metal contains 1 or more d electrons often have interesting electrical and magnetic properties including, semiconducivity, metallic conductivity, superconductivity, and antiferro-, ferri-, and ferromagnetic behavior. Those having no d electrons such as $BaTiO_3$, $NaNbO_3$, and $KTaO_3$ are useful ferroelectric materials that have distorted perovskite structures at room temperature but become cubic at higher temperatures (see Section 6.8 and *see Ferroelectricity*). A variety of structure-property relationships in perovskites have been reviewed recently by Pena and Fiero.[22]

3.4.2 The Spinel Structure

This is a structure for small to medium sized cations whose ideal composition takes the form AB_2O_4. The basic structure is derived from a cubic closest packing of spheres with a doubled face-centered cubic unit cell. Such a cell contains 32 octahedral holes and 64 tetrahedral holes, which can be broken down into a number of crystallographically different sublattices. Thus, in the spinel structure 50% of the octahedral holes are designated as B positions and one eighth of the tetrahedral holes as A sites, yielding the composition $A_8B_{16}O_{32}$ for the unit cell. The structure is difficult to view in three dimensions and is shown here as a projection down one of the cubic axes with the atom elevations with respect to that direction given in parentheses in Figure 11.

The A and B cations can have valences between 1 and 6, the only requirement being that their sum adds up to 8. Although typically thought of as a structure for transition metal ions, spinels form with a number of the smaller alkali and alkaline-earth cations as well as post-transition metals such as Zn^{+2}, Cd^{+2}, Ga^{+3}, In^{+3}, Ge^{+4}, and Sn^{+4}. Some examples include $TiCo_2O_4$, $CdCr_2O_4$, $FeCr_2O_4$, Fe_3O_4, $ZnAl_2O_4$, $FeGa_2O_4$, NiV_2O_4.

Assignment of A or B sites to cations in spinel type oxides based upon their chemical formulae can often be misleading. Thus, for the mixed-valence oxide $NiFe_2O_4$, we might conclude that the Ni^{+2} ions are on the tetrahedral A

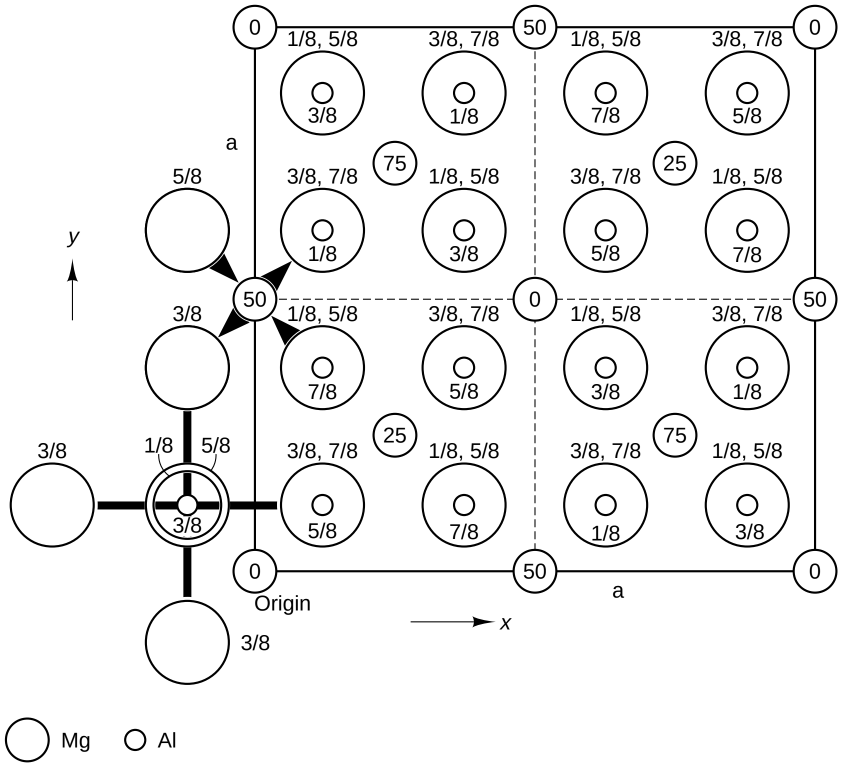

Figure 11 Projection of the spinel structure down one of the fourfold cube axes showing representive octahedral and tetrahedral sites. Fractions represent relative elevations of ions

sites while the Fe^{+3} ions were on the B sites as implied by the formula. In fact, the actual distribution places all the Ni^{+2} on octahedral sites and half of the iron in tetrahedral sites giving a site preference formula of $Fe^{+3}[Ni^{+2}{}_{0.5}Fe^{+3}{}_{0.5}]_2O_4$. Such an arrangement is referred to as an *inverse* spinel. On the other hand, the mineral spinel, $MgAl_2O_4$ and $Ni^{+2}Cr_2{}^{+3}O_4$, have the site distributions predicted by the chemical formula and are referred to as *normal* spinels.

The factors that determine whether or not a spinel is normal or inverse are complex. Moreover, the actual distribution may be only partially inverse. Thus, $MgFe_2O_4$ has a structure that is 90% inverse, while $NiAl_2O_4$ is about 75% inverse. Large differences in ion charge seem to favor a normal site distribution and inverse structures are most often found in 2:3 spinels, although inverse 4:2 spinels are known. One factor that appears to play a role is an ion's site preference energy for octahedral sites, which can be estimated from *crystal field theory* considerations. Although easy to apply, the method yields the correct result only about 2/3 of the time. Another, more complex explanation based upon phase field, size, and charge relationships has been given by Burdett and is much more accurate.[23] Inverse spinels, particularly those containing iron, are by far the most intensively studied of the two forms because of their useful magnetic properties and are often referred to as ferrites (*see* ***Magnetic Oxides*** and ***Magnetism of Extended Arrays in Inorganic Solids***).

Oxides with spinel-like superstructures can be produced by partially replacing atoms in the A or B sites with a third species or by removing A or B cations to produce an ordered superstructure. Thus, the spinel $LiFe_5O_8$ forms where all of the normal tetrahedral sites are filled by Fe^{+3} while the octahedral sites are broken into fourfold sublattices, one of which is occupied exclusively by Li. Such changes result in small movements of the oxygens from their ideal positions. In γ-Fe_2O_3, 2/3 of the octahedral sites occupied by Li in $LiFe_5O_8$ are vacant and the remainder filled by iron yielding the composition $Fe_{21.33}O_{32}$ for the basic spinel unit. In such systems, structures that are ordered at room temperature may become randomized by heating. Thus, $LiFe_5O_8$ becomes disordered above 755 °C.

3.4.3 The Garnet Structure

The garnet group of minerals have the general formula $A_3B_2(SiO_4)_3$ where, in naturally occurring substances, A typically will be Ca^{+2}, Fe^{+2}, Mg^{+2} or Mn^{+2} while B = Al^{+3}, Cr^{+3}, Fe^{+3}, Mn^{+3}, Ti^{+4}, V^{+4} or Zr^{+4}. In the 1950s, it was found that rare earth iron oxides having this structure behaved as *ferrimagnets* with commercially useful properties. They are also of interest because of their optical properties. The garnet structure can be rewritten as $A_3B_2T_3O_{12}$ to represent its three-dimensional nature. Typically, A is a large cation preferring a coordination number higher than 6, B is a typical octahedral cation, while T is a small cation, such as Al^{+3}. The basic building blocks of the structure are BO_6 octahedra and TO_4 tetrahedra. Each octahedron shares its six corners with individual TO_4 groups while the latter share each of their corners with BO_6 units. The result is a $B_2T_3O_{12}$ framework with eightfold dodecahedral cavities that can accommodate the large A cations. Some typical examples of compounds with the garnet structure are $Y_5Fe_3O_{12}$, $Dy_5Al_3O_{12}$, $Ca_3Cr_2Si_3O_{12}$, and $Mg_3Al_2Si_3O_{12}$.

As with spinel-type oxides, the chemical formula of compounds with the garnet structure can sometimes be misleading. For instance, in the normal pressure form of $CaGeO_3$, calcium is in sixfold and Ge in fourfold coordination with oxygen but at high pressures it transforms to the garnet structure where Ca is now in eightfold coordination and the sixfold sites are occupied by equal amounts of Ca and Ge, viz. $Ca_3[Ca_{0.5}Ge_{0.5}]_2Ge_3O_{12}$.

3.4.4 The Pyrochlore Structure

The mineral pyrochlore has the chemical formula $CaNaNb_2O_6F$. Since the fluoride and oxide ions have similar sizes as is also the case with Na^+ and Ca^{+2}, it is not surprising that this structure is adopted by a number of ternary oxides and reformulated as $A_2B_2O_7$. Ideal pyrochlores have a cubic structure whose dimensions correspond to a doubled fluorite cell. The structure may be derived from the fluorite structure by removing one eighth of the anions in an ordered fashion and then moving a portion of the remaining O^{-2} off of their ideal positions to provide a distorted octahedral environment for the B cations. The remaining cation sites retain their eightfold cuboidal coordination and are occupied by the larger A cations. Pyrochlore oxides have been of interest because of the variety of interesting properties they display, which may include high electrical or ionic conductivity, catalytic activity, and ferroelectric behavior.

The most common pyrochlores have 3:4 charge arrangements such as $La_2Ti_2O_7$ or 2:5 arrangements exemplified by $Cd_2Nb_2O_7$, which is of interest as a ferroelectric material. Pyrochlores, like perovskite oxides, are of interest owing to their ability to stabilize unusual oxidation states (e.g. $Cd_2Re_2O_7$ and $Sc_2Pt_2O_7$) and owing to their interesting electrical and magnetic properties as well. OH^- and F^- may substitute for O^{-2} to yield cation deficient pyrochlores such as $BiTa_2O_6F$ and $Sb^{+3}(Sb^{+5})_2O_6OH$. Defect pyrchlores have been studied for possible applications as solid electrolytes. Normally, the structure is stable for 3:4 pyrochlores when r_A^{+3}/r_B^{+4} is between 1.2 and 1.6. However, high-pressure synthesis will raise the upper limit to about 1.90 as exemplified by $Gd_2Ge_2O_7$.[24]

3.4.5 The Scheelite, Wolframite and Related Structures

The mineral Scheelite, $CaWO_4$, was named after the famous nineteenth century chemist Carl Wilhelm Scheele. The ideal structure, shown in Figure 12, has tetragonal

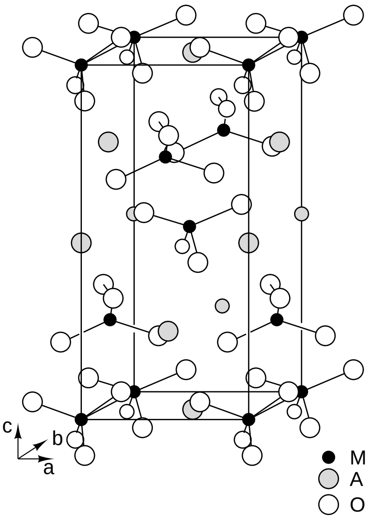

Figure 12 Unit cell of the sheelite structure

symmetry in which discrete WO_4^{-2} tetrahedra are found arranged in a nearly perfect cubic packing in which the corners of the tetrahedra point towards the center to provide a slightly distorted cubic coordination for the large Ca^{+2} ion. $CaMoO_4$ and $PbMoO_4$ are isomorphic. Monoclinically distorted versions of this structure are found for a number of rare earth niobates and tantalates, which in themselves form an interesting chemistry. Zircon, $ZrSiO_4$, in which Zr is in eightfold coordination has a different structure.

A medium to small cation counterpart to the Scheelite structure is that of wolframite, (Fe,Mn)WO_4. Here both the tungsten and the divalent metal cations are in octahedral coordination. This ABO_4 structure can be derived from a hexagonal closest packing of oxygens in which two sublattices, each comprising 25% of the octahedral holes are occupied by the A and B cations, the B cations typically being smaller and higher charged than the A cations. The A cations have nearly regular octahedral coordination while the BO_6 groups are distorted considerably (see Section 3.2.2.).

A variety of related structures can be identified with 6,8, and 12-fold coordination of the A cation and four or sixfold coordination of the anion. In fact, the chemistry of ABO_4 ternarys is extremely complicated with solid solutions and phase transitions being common. Lattice defects may be introduced easily by appropriate dopings. Scheelites and its relatives have been studied intensively for their properties as heterogeneous catalysts, as host materials for impurity activated luminescent materials, and for specialized optical uses (*see* ***Oxide Catalysts in Solid-state Chemistry*** and Section 4.4).

3.4.6 Beta Alumina and Nasicon Structures

β-Alumina, originally believed to be a polymorph of Al_2O_3, actually has the composition $Na_{1+x}Al_{11}O_{17(1+x/2)}$. The interest in this compound arises from the very high mobilities found for the sodium ions and as a result this and related compounds have been studied for use as solid electrolytes in high energy density batteries, which operate under extremely corrosive conditions (*see* ***Ionic Conductors***). The Al–O framework of the structure is related to that of spinel and exists as slabs that are held together by Na^+ ions and occasional oxygen atoms as shown in Figure 13. The connecting oxygens have been likened to pillars in a parking garage as shown in the diagram. The interlayer distances are about 4 Å wide. The fact that the Na–O bonds are quite long and not all their positions are occupied, the ideal value of x being 2, results in abnormally high ionic conductivities since the Na^+ ions are relatively free to move. β''-alumina is a derivative of β-alumina stabilized by the presence of magnesium, $Na_{1+y}Mg_yAl_{11-y}O_{17}$, where the value of y is typically about 0.66. These materials have ionic conductivities that surpass those of the β analogs. Na may be also be replaced by other alkali metals as well as alkaline earths and lanthanides.[25,26]

Sodium zirconium phosphate $NaZr_2(PO_4)_3$ has a three-dimensional structure with hexagonal symmetry formed by a framework of corner-sharing tetrahedral PO_4 groups and octahedral ZrO_6 groups. A set of ordered octahedral sites are found along the hexagonal c axis occupied by Na^+. There also exist empty octahedral sites within the CP layers that are filled in the otherwise isomorphous compound, $Na_4Zr_2(SiO_4)_3$. Both compounds are poor sodium ion conductors but the solid solutions $Na_{1+x}Zr_2P_{3-x}Si_xO_{12}$ have high Na^+ mobility and have been given the acronym NASICON (Sodium Superionic Conductor).[9]

3.5 Crystallographic Shear Structures[27]

Mo_9O_{26} is sometimes written as $MoO_{2.89}$ and $Mo_{10}O_{29}$ as $MoO_{2.90}$, which might imply that these oxides are part of a solid solution series. They are not; rather their structures are those of a well-defined homologous series based upon the principle of crystallographic shear. The latter is a term used to describe the generation of complex structures from fairly simple ones by the translation of one or more portions of the structure with respect to the remainder. It has been applied with great success to describe a series of reduced oxides of molybdenum and tungsten having general formulas such as M_nO_{3n-1} ($n = 8-12, 14$) and M_nO_{3n-2}, a similar homologous series of titanium oxides of the type Ti_nO_{2n-1}, ($n = 4$ to 10), binary oxides of niobium(V) and niobium(IV) as well as a variety of complex mixed transition metal and mixed-valence oxides such as $TiNb_2O_7$, $Nb_{25}O_{62}$, $W_3Nb_{14}O_{44}$, and $Ti_2Nb_{10}O_{29}$. The molybdenum and tungsten oxides are derived from an idealized ReO_3 lattice by introducing edge sharing between MoO_6 octahedra while the TiO_{2n-1} series is derived from the rutile structure by introducing face sharing as a result of the shear operation.

The process is illustrated for Mo_9O_{26}, which is part of the series Mo_nO_{3n-1} with $n = 9$. The crystallographic

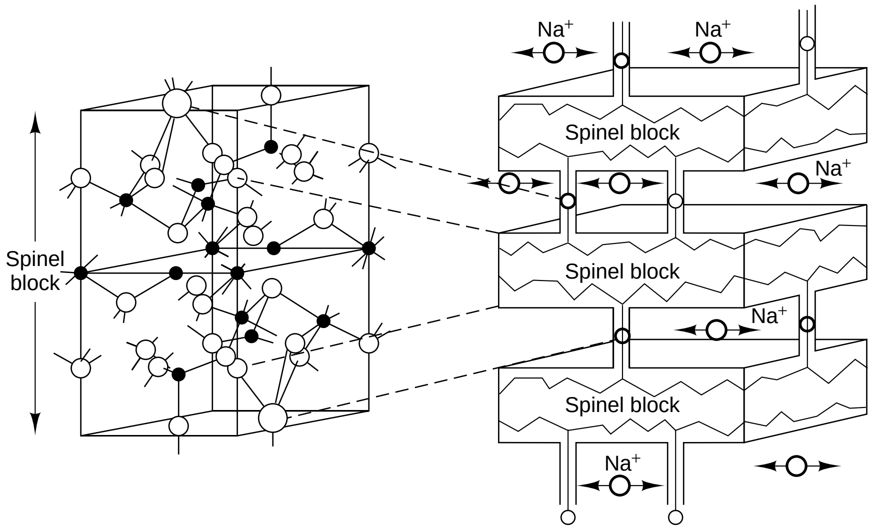

Figure 13 Layering of β-alumina

shear operation takes place along planes of ordered oxygen vacancies introduced into the ReO_3-like idealized MoO_3 lattice as a result of reduction (Figure 14(a)). These vacancies are eliminated by the shear operation with the result that blocks of the ideal ReO_3 structure are now separated by regions containing four MoO_6 octahedra sharing edges (Figure 14(b)). The ReO_3-like blocks extend infinitely in two dimensions but their length in the third is determined by the value of n. $Mo_{10}O_{29}$ is similar in structure; however, the ReO_3 block is longer.

The simplest member of a shear structure derived from rutile is that found for Ti_5O_9 where $n = 5$. A block of the structure is shown in Figure 15. Here, edge and corner-sharing TiO_6 blocks of the rutile type, five octahedra thick, are joined by face sharing to similar five unit blocks. As the level of reduction decreases, the size of the rutile block increases but the crystallographic shear remains the same.

Reduction need not occur in order for crystallographic shear to take place. All that is required is that an oxygen deficiency be introduced as is the case in the H form of Nb_2O_5. Here,

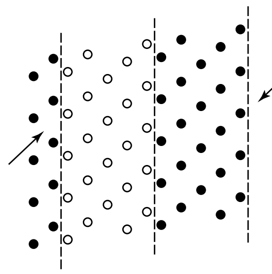

Figure 15 Layer of the crystallographic shear Ti_5O_9 structure

3×4 ReO_3-like blocks, one layer thick, and infinite blocks 3×5 octahedra thick result from a double shear operation along directions approximately 90 degrees apart. In addition, one out of every 27 Nb is located in a tetrahedral hole leading to an extremely complicated structure. The H structure is one of at least 14 polymorphic forms of Nb_2O_5, 10 of which are based on crystallographic shear.

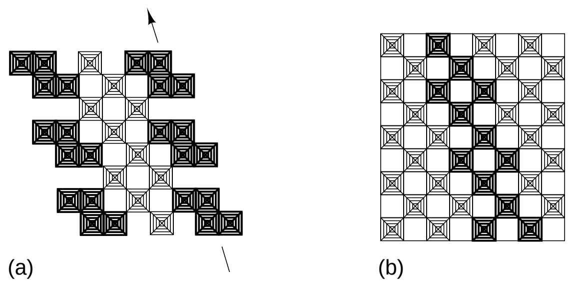

Figure 14 Corner-sharing ReO_3 like layer (a). Same layer after having undergone crystallographic shear (b)

3.6 Tetragonal and Hexagonal Tungsten Bronzes[8–10,16]

Oxide bronzes are ternary transition metal oxides of the type $A_xM_yO_z$ in which A is typically a large cation and M is a transition metal, some or all of which are in a reduced valence state. They often are brightly colored, have metallic luster, display a range of stoichiometry, and have high electrical conductivity. Although for particular systems exceptions to one or more of the above properties can be cited, their structures, without exception, are derived from corner-sharing MO_6 octahedra of the ReO_3-type. The structure may be modified by the insertion of a large cation into a vacancy in the lattice to form the perovskite structure, or more likely by

some distortion of the ideal structure by crystallographic shear or internal rotation.

As mentioned in Section 3.4.1, a simple perovskite is found for the series Na_xWO_3 for $0.30 \leq x \leq 1.0$. However, there is a second structure found for $x \leq 0.40$, or if Na is replaced by K and x is between approximately 0.45 and 0.57. Here, a tetragonal distortion occurs that yields the so-called tetragonal tungsten bronze (TTB) structure. This can be considered as being derived from a normal perovskite (Figure 16(a)) by an internal rotation of a 2×2 block of the perovskite structure as shown in Figure 16(b). The result is the formation of four large pentagonal shaped tunnels where the large cations reside and four small triangular tunnels, which are empty. The structure requires that the value of x be no larger than 0.60, otherwise there would not be enough vacant sites present to permit the formation of the empty triangular tunnels. Studies of potassium TTBs of lower K content indicate that the occupancy of the pentagonal sites is favored over the 12-fold perovskite-like sites. where the K–O bond distance is only 2.72 Å. This is much shorter than the expected 2.99 Å, based on Shannon–Prewitt radii. The potassium atoms in the pentagonal tunnels have an irregular 15-fold coordination derived from a pentagonal prism in which the sides are capped by oxygen atoms. The K–O bond distances range from 2.8–3.35 Å, six of which are formed with oxygens at the corners of a distorted trigonal prism 2.8–2.9 Å distant inscribed within the pentagonal prism.[28]

Phases formed in the WO_3 rich portion of the WO_3-Nb_2O_5 system have complex structures that display blocks of the TTB type intergrown with ReO_3-like blocks. $K_6Li_4Nb_{10}O_{30}$ has a TTB-related structure where the small Li^+ is found in the triangular tunnels in ninefold coordination. A derivative structure is shown by $Ba_{0.15}WO_3$, which contains ribbons of pentagonal tunnels condensed so that the square perovskite channels are eliminated. The value of x is limited to ≤ 0.167 by the structure.[29]

Alkali tungsten bronzes of the type M_xWO_3, M = K, Rb, or Cs with $0.16 \leq x \sim 0.3$ may adopt the hexagonal tungsten bronze (HTB) structure in which the large Cs atoms reside in hexagonal tunnels formed by six WO_6 octahedra in 12-fold coordination. The limit of x, as determined by the structure is 1/3. The structure is of interest since these compounds display superconductivity with T_c values between 1 and 7 K. It is also found for several mixed oxides of Nb and Ta with large A cations.

3.7 Molybdenum Oxide Bronzes[30–32]

Alkali molybdenum oxide bronzes with the cubic perovskite or TTB structure are unstable and can only be prepared at high pressures. The more common normal pressure structures are derived from ReO_3 by crystallographic shear and are of interest because of their quasi-low dimensional electrical and magnetic properties. Like their perovskite tungsten counterparts, they may be brightly colored and display metallic conductivity, However, their structures are more complex with a higher degree of MO_6 edge sharing where layers are formed in which the large A cations reside. Three of the more interesting types will be described here.

$K_{0.30}MoO_3$ is the prototype for the so-called blue bronzes of the type $A_{0.3}MoO_3$ where A = K, Rb, Tl. All possess a monoclinic C-centered unit cell. Although the compound is actually stoichiometric with a formula $K_3Mo_{10}O_{30}$, the general practice is to use the decimal formulation in keeping with the nonstoichiometric tungsten bronzes. The basic building blocks are clusters of ten MoO_6 octahedra that share edges as shown in Figure 17(a). These then share corners in two dimensions to build layers of composition MoO_3 that are held together by K^+.

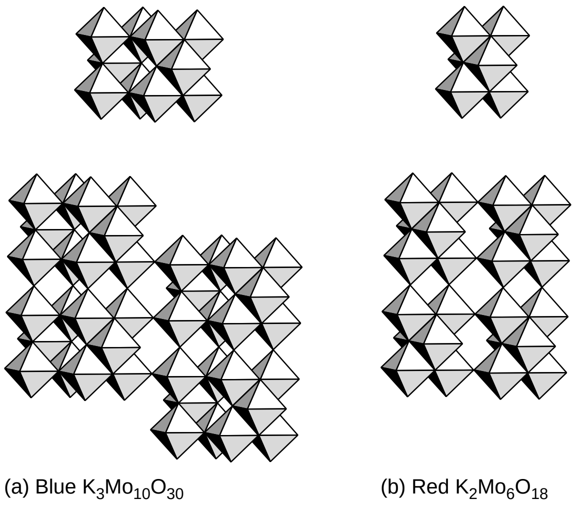

Figure 17 Mo–O slabs in $K_{0.30}MoO_3$ (a) and for $K_{0.33}MoO_3$ (b)

Although the structure is three dimensional overall, the MoO_3 network is two dimensional. Further, effective overlap of molybdenum t_{2g} and oxygen p_z orbitals occurs along the monoclinic *b* directions, which provides for effective delocalization of electrons in this direction. Electronically then, this compound behaves as a quasi-one-dimensional material. Furthermore, bond valence calculations based upon observed bond distances indicate that over 80% of the d electron density is associated with Mo atoms that run along the *b* axis. This is confirmed by measurements of electrical conductivity performed on large single crystals prepared by fused salt electrolysis, which show that the conductivity is metallic at room temperature and two orders of magnitude higher along the *b* parallel to the layers than perpendicular to them.

A broad transition to semiconducting behavior is observed at 180 K in $K_{0.30}MoO_3$, which is attributed to a *charge density wave* (CDW) predicted as a mechanism by Peierls and H. Fröhlich as a means of lowering the electronic energy of a one-dimensional metal.[31] A specific heat change is also associated with the transition and X-ray diffuse scattering has shown that the transition at 180 K leads to an incommensurate, semiconducting CDW state with a wave vector equal to 0.26b*.[33] The rubidium and thallium analogs appear to behave similarly.

The 'purple' molybdenum bronzes have the general formula AMo_6O_{17}, where A = Li, Na, K or Tl. The potassium and thallium members have trigonal structures while the Li and Na compounds show different types of distortions, which result in monoclinic symmetry. The ideal value of A in this structure should be 1.0; however, it seems to be closer to 0.9 for all members except Tl. Only for the Na compound has a slight stoichiometry range ($0.84 \leq x \leq 0.96$) been observed. The origin of this behavior is not clear although it may be electronic in nature.

The idealized structure of $K_{0.9}Mo_6O_{17}$ is shown in Figure 18. The structure consists of infinite slabs of MoO_6 octahedra, four units thick, sharing corners in a ReO_3-like fashion and terminated by MoO_4 tetrahedra to form a six-unit layer having the composition Mo_6O_{17}. These units are held together by K^+. The Mo–O arrangement is similar to that of the monoclinic form of Mo_4O_{11}. Although the Tl and Na compounds have different symmetries, the basic structure remains essentially unchanged.

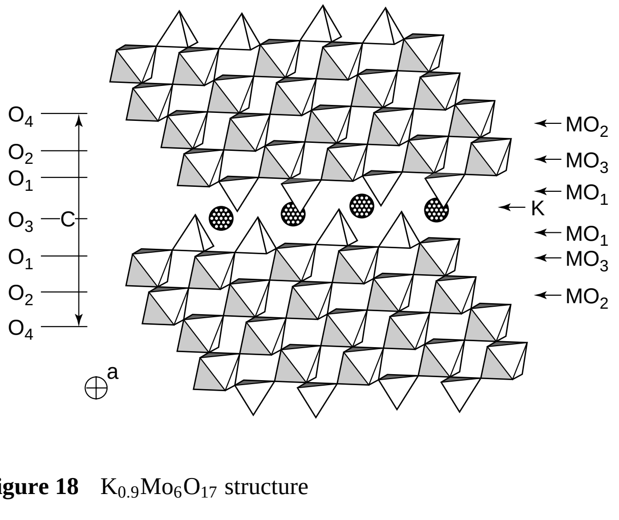

Figure 18 $K_{0.9}Mo_6O_{17}$ structure

The structure of the Li compound shown in Figure 19 is noticeably different. The layered ReO_3-like Mo–O network has been partially destroyed. It is now only three units thick and the surfaces are a combination of corner-sharing tetrahedra and octahedra. Octahedra in adjacent layers are then bridged by other MoO_4 tetrahedra to form a weakly cross-linked Mo–O network. The lithium ions are coordinated by 9 oxygens and reside in cavities created as a result of the cross linking. Although the Mo–O network is truly three dimensional, the d electrons remain confined to the ReO_3-like layers and the material displays quasi-two dimensional electronic properties.[32,34] Low-temperature anomalies in the electrical and magnetic properties of these compounds exist with the Na, K, and Tl compounds behaving in a quite similar fashion showing metal to metal transitions between 70 and 100 K. In contrast, the Li compound retains its metallic conductivity down to 24 K where it undergoes a relatively sharp transition to semiconducting behavior followed by a transition to the superconducting state at 1.9 K.[35] In all cases, the conductivity is several orders of magnitude higher parallel to the layers than perpendicular to them.

A final class of Mo oxide bronzes are the 'red' bronzes, which have the general formula $A_{0.33}MoO_3$, A = Li, K, Rb, Cs, and Tl. Like the blue bronze $K_{0.3}MoO_3$, they are stoichiometric and might more correctly be formulated $K_2Mo_6O_{18}$. The heavier members are monoclinic and isostructural while the triclinic Li compound has a different structure, which will not be discussed here.[36] The basic building block of the $K_{0.33}MoO_3$ structure is a cluster of six edge-sharing MoO_6 octahedra Figure 17(b), which link corners in one dimension to form chains. These chains then link by partial corner sharing to form infinite MoO_3 slabs, which are separated by K^+ in an irregular eightfold coordination with oxygen. In this compound, the Mo–O distances along the monoclinic *b* axis are too long for effective Mo–O $d_{t_{2g}}$-p_π overlap for electron delocalization to occur. As a result, the compounds are semiconductors with conductivities several orders of magnitude lower than the metallic blue or purple bronzes.

3.8 Vanadium Bronzes

Like molybdenum and tungsten, vanadium forms a variety of nonstoichiometric oxides with the alkali metals and other cations, for example, Cu^+, Ag^+, Zn^{+2}, or Al^{+3}, which have bronze-like properties.[37–39] These compounds can be made by heating appropriate mixtures of V_2O_5 and the desired alkali metal carbonate or oxide in platinum vessels under argon at 700–800 °C and then cooling slowly over

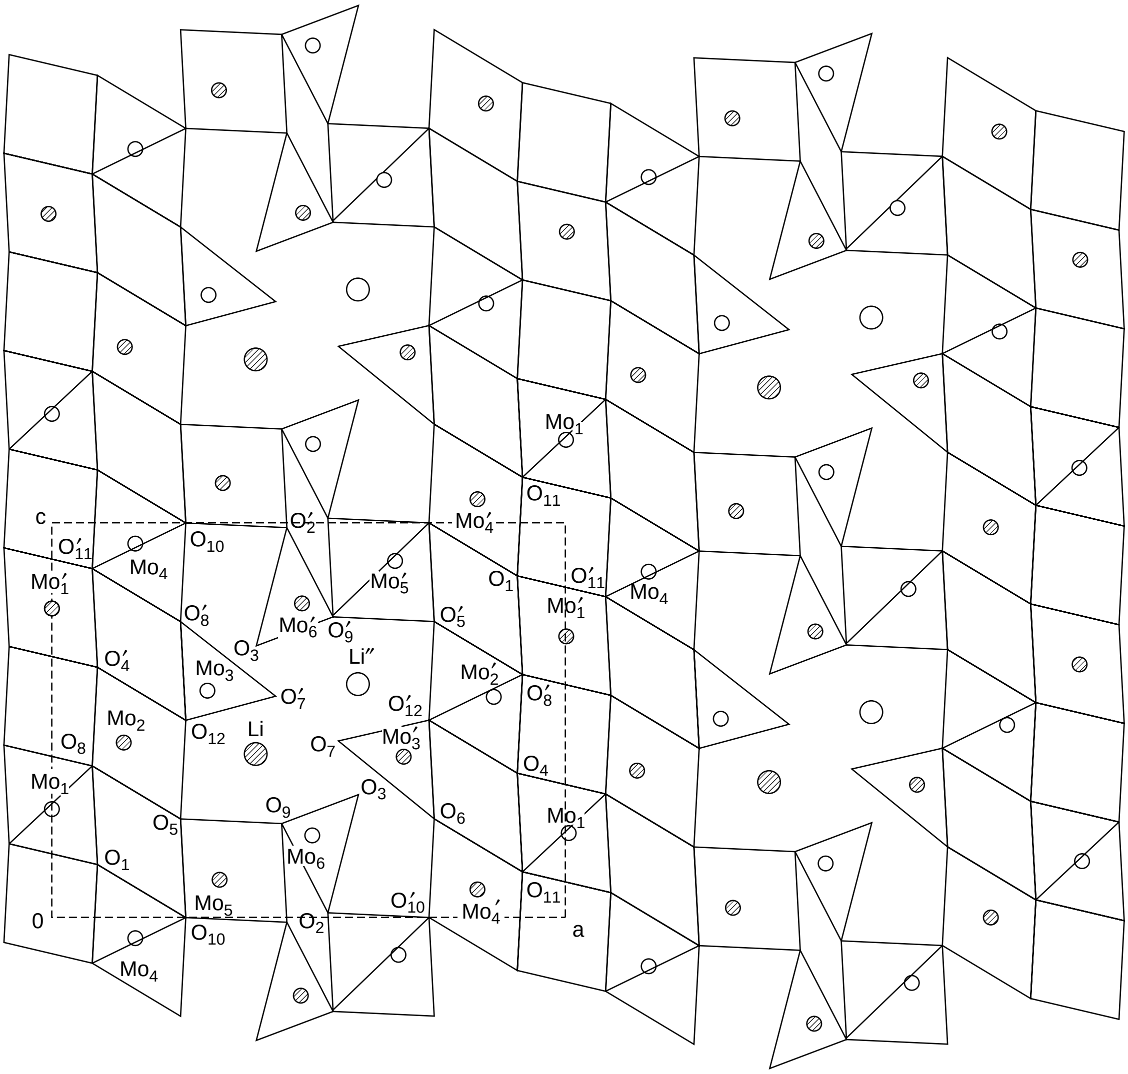

Figure 19 $Li_{0.9}Mo_6O_{17}$ layer

a period of several days. The sodium system illustrates the complexity of these bronzes, which are discussed here as examples. Four distinct structure types are noted for $Na_xV_2O_5$: Unlike the molybdenum bronzes, they display wide ranges of stoichiometry but like them they display complex quasi-low dimensional structures.

α-orthorhombic, $0 < x \leq 0.02$

β-monoclinic, $0.22 \leq x \leq 0.40$

α'-monoclinic, $0.65 \leq x \leq 0.69$

β'-orthorhombic, $0.70 \leq 0.70 \leq 1.0$

The α-orthorhombic phase has the layer structure of V_2O_5 itself with the alkali metals inserted in between the layers. For Na^+, the substitution of what appears to be an inappropriately large cation into a small trigonal prismatic hole is quite limited. However, the smaller Li^+ ion may substitute up to $x \leq 0.13$. A diagram of the structure of the β form is shown in Figure 20. Here layers are formed by corner-sharing distorted square pyramidal VO_5 groups. The layers overlap one another in such a fashion to form tunnels in which the Na^+ reside. Various sites in the tunnels are available but not all can be occupied simultaneously.[40] The most stable phase appears to have a composition $Na_{0.33}V_2O_5$ but the value of x can be extended to about 0.40 for Na^+ by the utilization of alternate sites for the alkali ions. In the case of Li, values of x up to 0.49 have been observed with slight modifications of the V–O layer arrangement.

The electrical conductivity of the material is complex behaving partly like an anisotropic semiconductor and partly like a metal. The metal to semiconductor transition appears to be sample dependent since various workers have reported transition temperatures ranging from 130 to 340 K for samples

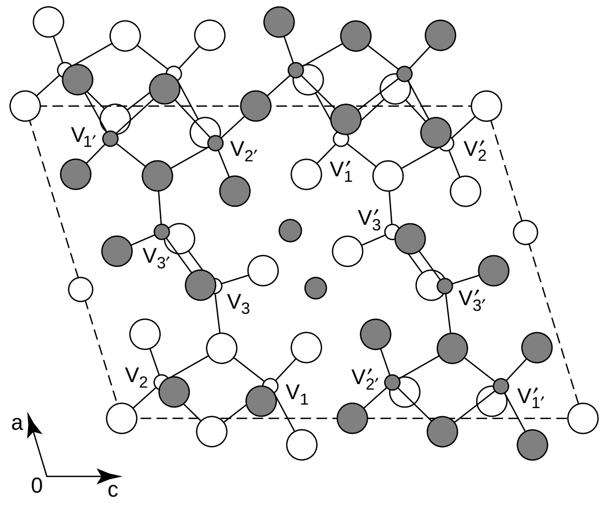

Figure 20 Projection of the β-$Na_xV_2O_5$ structure

of apparently similar composition, while others have reported seeing semiconducting behavior only from room temperature to 500 °C.[41] Because of the partial occupancy of the available cation sites and the relatively well-defined path for ion migration within the tunnels, high cation mobility is to be expected for these compounds. Lithium ion conductivities of the order of 10^{-4} S cm^{-1} are observed at 500 °C for $Li_xV_2O_5$. This conductivity decreases as Li is added ostensively because of the resultant decrease in the number of sites available for ion migration.[42]

3.9 Silica, Silicates, Borates, and Phosphates[8,43–46]

The chemistry of boron, silicon, and phosphorus with oxygen is not only one of the richest in terms of chemical diversity but also among the most commercially important. It is discussed in detail under ***Borates: Solid-state Chemistry***; ***Phosphates: Solid-state Chemistry*** and ***Silicon: Inorganic Chemistry***. However, there is a commonalty of a number of factors that affects their chemistry and distinguishes them from other oxide systems that should be noted. The first is that their chemistry is essentially that of the group valency. Although a limited phosphite (P(III)) chemistry exists, only an ill-defined amorphous silicon ‘monoxide’ is known and conventional boron chemistry is limited to the trivalent state. The second is that they all possess small coordination numbers with well-defined coordination polyhedra, typically triangular planar or tetrahedral in the case of boron, which cannot expand its octet. While Si and P can expand their octet, this rarely happens in oxides, although 6 coordinate Si is occasionally seen in a few high-pressure polymorphs and certainly is important as a short-lived reaction intermediate. However, these basic MO_3 and MO_4 building blocks easily condense by corner sharing in all three systems to form M–O–M complex anions, infinite chains, sheets, and ultimately 3 dimensional cross-linked framework structures. Thirdly, the flexibility of the interconnects between these coordination polyhedra is evidenced by the fact that the M–O–M angles varies from about 115 to essentially linear, which provides for easy accommodation of a wide range of ternary cations and for structures with a varying degree of openness.[44] This flexibility leads to the formation of a number of polymorphic forms, particularly those sensitive to pressure.

Not surprisingly, these small differences in bonding energetics leads to the formation of noncrystalline materials, that is, glasses in which entropy is the deciding factor in determining the form of the stable phase. The tendency towards glass formation is particularly evident with alkali phosphates. Boric oxide itself is difficult to crystallize and while silica glasses form easily they are subject to recrystallization (devitrification) at high temperatures. The glasses known to the ancients were silicate-based materials but the twentieth century has seen increasing needs for glasses with different properties for a variety of applications, which utilize not only borate or phosphates but also a variety of other elements as well. Oxide glasses are discussed in depth under ***Noncrystalline Solids***.

Silica, SiO_2, is an extremely important industrial chemical and exists is several forms. The classical view of silica is that the three principal crystalline forms of silica are quartz, tridymite, and cristobelite, each of which undergoes a *martensitic transformation*, which involves minor structural changes without the breaking of Si–O bonds. In all three structural types, the basic building blocks are the SiO_4 tetrahedra, which share their corners with other tetrahedra. Of these three forms, the most open structure is that of cristobelite while the densest is quartz as shown in Figure 21. There are also two very dense forms of silica that occur at high pressures; coesite (d = 3.01 gm cc^{-1}), which retains

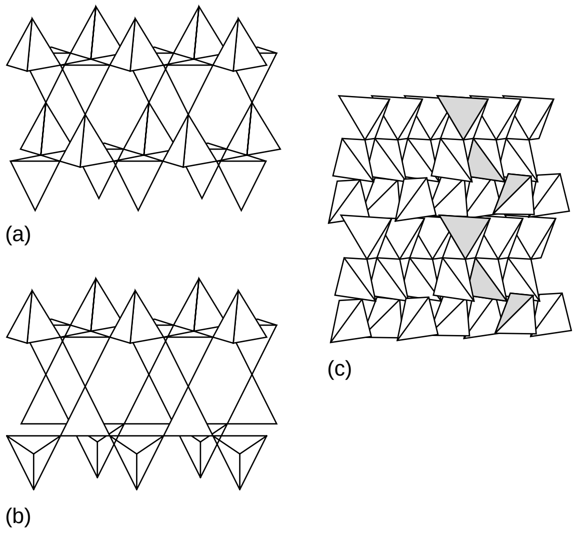

Figure 21 Relative openness of silica polymorphs as illustrated by packings of SiO_4 tetrahedra. $\beta\beta$-cristobelite (a). β-tridymite (b). β-quartz. Shaded tetrahedra shows helical nature of the structure (c)

the tetrahedral coordination of Si by O, and stishovite, which is formed above 150 K bar, in which the Si is now in sixfold coordination with oxygen and displays the rutile structure.

There is a considerable amount of evidence that quartz and cristobelite are the only normal pressure forms of silica while tridymites are considered to be defect structures stabilized by impurities. However this view has been questioned by Hill and Roy, who were able to prepare tridymite from very pure silicon and water.[47]

There are a variety of other silicas. These include the metastable silica-W, which has a very low density ($1.97\,g\,cm^{-3}$), and whose structure consists of edge-sharing chains of SiO_4 tetrahedra, the microcrystalline diatomaceous earths, various forms of noncrystalline silica including vitreous silica (glassy silica), and the finely divided amorphous silicas such as dry silica gel, fumed silicas, and colloidal silicas.

Silicates and aluminosilicates represent the largest class of inorganic compounds known comprising more than three quarters of the earths crust. Although their study as naturally occurring materials is normally considered to be the purview of the discipline of mineralogy or geochemistry, their rich chemistry has been exploited by chemists to produce a variety of useful materials derived from silicate-based compounds. The basic building block of silicates is the SiO_4 tetrahedron, which, by various combinations of corner sharing, can create a vast variety of structures ranging from materials that contain simple orthosilicate anions, $SiO_4{}^{-4}$, to more complicated structures containing Si–O networks in the form of chains, sheets, multilayer slabs, and finally complex, cross-linked, three-dimensional structures containing tunnels and cavities that can accommodate a variety of organic and inorganic species. The complexity and variety of these structures is increased by the partial replacement of silicon by trivalent Al in the SiO_4 tetrahedra to produce aluminosilicates that include not only the vast majority of igneous rocks but also the layered clays, micas, and the complex zeolite 3D and zeolite related materials (*see **Zeolites***).

Because of its small size and s^2p^1 electronic ground state, boron is unique among the elements with its predilection for sp^2 hybridized trigonal planar coordination. However, given the acidic character of the unfilled octet, hybridization to tetrahedral BO_4 configurations is also important. These simple elementary units may be found as discrete anions but more often they are utilized as building blocks of more complicated ions or as part of extended two and three-dimensional structures.

An extensive chemistry of phosphorus and oxygen exists, the preponderance of which deals with aqueous chemistry with great interest focused upon those of biological importance. A broad review of phosphorus oxygen chemistry is given in ***Phosphates***. Reduced transition metal oxide phosphates and silicates are discussed in Section 3.12.

Alkali phosphates are typically prepared by the dehydration of crystalline orthophosphates. The phosphate building block is the PO_4 tetrahedron, which shares corners to form discrete anion units the simplest being the diphosphate (or pyrophosphate) ion $P_2O_7{}^{-4}$ and the well-known linear triphosphate ion $P_30_{10}{}^{-5}$ widely found in detergents and water softeners. Pyrophosphates and related pyrovanadates formed with di- tri- and tetravalent cations have been the object of intense study since they display a variety of polymorphic forms where the P–O–P angle is particularly sensitive to the size and coordination requirements of the ternary ion. Polyphosphates of general formula $M_n(PO_3)_n$ exist as infinite chains of PO_4 tetrahedra sharing two corners or as ring type members with 3 to 10 P, the most common being the trimer and the tetramer. Polyphosphate ions of general formula $[(PO_3)_nO]^{(n+2)-}$ with n up to 16 are well established. Finally, there are framework structures in which PO_4 tetrahedra share three or more corners. For example, $AlPO_4$ has three polymorphs, each an ordered variant of the three forms of silicon dioxide. YPO_4 on the other hand contains discrete $PO_4{}^{-3}$ anions.

3.10 Oxides with Defect Structures[9,19,31,48]

Nonstoichiometry is a pervasive aspect of oxide chemistry, particularly where the cation can assume two or more valences or aliovalent cation substitutions are facile. These can be classified into three rather broad ranges. Class I includes systems where the nonstoichiometry approaches or exceeds that which cannot be detected by classical methods of chemical analysis (i.e., less than 1 part in 1000) but may manifest itself in dramatic changes in electrical or optical properties. Class II includes systems where the nonstoichiometry is of the order of several mole % and readily discernible by chemical analysis, density measurements, or X-ray diffraction measurements of unit cell constants. Class III are those systems with broad ranges of nonstoichiometry such as the alkali metal tungsten bronzes.

The nonstoichiometry may be found on the oxygen sites as is the case with stabilized zirconia $(Y_xZr_{1-x})O_{2-x/2}$, metal deficient oxides such as $Fe_{1-x}O$, anion excess oxides such as UO_{2+x} and systems that display combinations of these effects. The vacancies in such systems may cluster or ultimately may order by some mechanism such as crystallographic shear. Catlow has discussed such systems in detail.[49]

As an example of the first type of nonstoichiometry, pellets of TiO_2 were heated in hydrogen at temperatures between 500 to 700 °C. Thermogravimetric analysis established that the oxygen stoichiometry decreased slightly from $TiO_{2.000}$ to $TiO_{1.993}$, the resistivity of the samples decreased by over five orders of magnitude.[50] An alternate method of introducing mobile d electrons is to replace a portion of the oxygen by fluorine, viz., $TiO_{2-x}F_x$. Samples of TiO_2 that were heated at 700 °C in HF diluted with an Ar/H_2 mixture were found to have the composition $TiO_{1.998}F_{0.002}$ had a resistivity of only 2.5 ohm-cm.[50]

FeO, in contrast to TiO_2, is very difficult to prepare in an Fe:O ratio equal to 1 and apparently does not exist at normal

pressures.[50] Stoichiometric FeO reportedly can be prepared by heating ferrous oxalate in vacuo but the finely divided product picks up oxygen rapidly in air. As the oxygen content of the wustite phase of FeO increases from $FeO_{1.06}$ to $FeO_{1.19}$, the observed density and the lattice constant of the cubic rock salt unit cell decrease, indicating that the compound is deficient in iron rather than containing an excess of oxygen. Therefore, it should be formulated as $Fe_{1-x}O$ where it is found that $0.06 \leq x \leq 0.14$. X-ray and neutron diffraction studies suggest that, rather than the vacant cation sites in the NaCl-like lattice being randomly distributed, a significant portion of the Fe^{+3} occupies tetrahedral interstices that are stabilized by a cluster of 4 octahedral cation vacancies designated as a (4:1) cluster. More complex defect arrays such as the 6:2, 8:3, or 16:5 clusters shown in Figure 22 also form. The binding energy due to coulomb interactions between the vacancies and interstitials in these clusters has been calculated to be between 2.0 and 2.5 eV, which serves in part to explain the stability of these defect phases. More complex defect clusters have been postulated and are discussed by Catlow.[49]

TiO has a defect sodium chloride superstructure in which 5/6 of both the Ti and O sites are occupied in an ordered fashion. The defect nature of structure allows for both cation and anion deficiency and as a result it is stable for Ti:O ratios between 0.75 and 1.4 with the percentage of Ti sites filled approaching unity at high Ti:O ratios while at low ratios the oxygen sites approach complete filling.

Fluorite type oxides are particularly prone to nonstoichiometric effects. This most commonly occurs in the form of cation nonstoichiometry induced by partial reduction of the cation or by replacement of a portion of the oxide by fluoride. Anion excess phases can occur as a result of cation oxidation or by replacement with higher valence impurities. The dominant defect in this structure involves the migration of oxygen to the large cuboidal interstice resulting in the formation of a vacancy at a normal lattice site. A vacancy of this type is called a Frenkel defect.

These large cuboidal interstices play an important role in gross anion excess fluorites such as UO_{2+x}, $x \leq 0.25$. However, the excess oxygen is not found at the centers of these sites but is displaced along the ⟨110⟩ and ⟨111⟩ directions

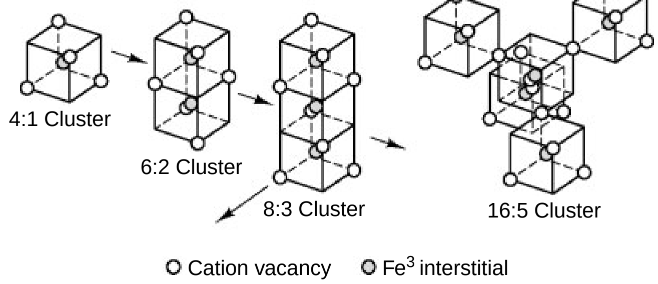

Figure 22 Defect clustering in $Fe_{1-x}O$

while two near neighbor lattice oxygens are displaced towards neighboring cubic interstices. As in $Fe_{1-x}O$, defect clustering is also postulated to occur. In this case, clusters of 6 or 9 defect units are postulated. Such clusters have been found by diffraction studies of anion excess alkaline-earth fluorides, which have this structure.[51]

Anion deficient fluorite oxides of the rare earths and actinide elements are well established as are those based on hafnia or zirconia. The latter is of particular interest since the cubic fluorite structure in pure ZrO_2 exists only above 870 °C, transforming at lower temperatures to a denser monoclinic form. However, the cubic form can be stabilized by doping with several mole percent of CaO or Y_2O_3 so that the phase transition does not take place upon cooling. This permits the manufacture of so-called stabilized zirconia containers, valued for their chemical inertness and refractory properties. Further, stabilized zirconias are part of a class of solid materials called fast ion conductors (or superionic conductors), which have unusually high oxide ion mobilities and display electrical conductivities above 600 °C, which approach those of fused salts (*see* ***Ionic Conductors***). Stabilized zirconias are used as oxygen sensors and as solid electrolytes in fuel cells. Defect clustering plays an important role in the ion movement that is discussed in more detail in ***Defects in Solids***.

The perovskite based tungsten oxide bronzes are examples of a third class of nonstoichiometric materials where there is a broad range of defect composition. The properties of these cation deficient materials were discussed in Section 3.4.1. In addition, anion deficient perovskites are well established. The X-ray powder diffraction patterns for the $SrTiO_{3-x}$ and $SrVO_{3-x}$ systems show only the lines of a simple perovskite over the range $0 \leq x \leq 0.5$ indicating that the anion vacancies are not ordered. In other cases, such as $SrFeO_{3-x}$, distortion of the simple perovskite structure occurs when $x \geq 0.12$ while a mixture of phases is seen for nominal values of $x \geq 0.28$. Oxides of the type $LaBO_3$ (B = Cr, Mn, Fe, Co) are known to have mobile oxide ions at high temperatures whose mobility is defect mediated.[52] An ordering of vacancies occurs in $Ca_2Fe_2O_5$, which has a superstructure related to perovskite. The ordering is accompanied by movement of some Fe ions so that layers of octahedral FeO_6 and tetrahedral FeO_4 can be identified. Vacancy ordering occurs in $LaNiO_{3-x}$ in which definite line phases have been observed for $La_nNi_nO_{3-1}$ with $n = 7, 9, 13$ and 30.[53]

A phase that was once thought to have an excess of oxygen is $LaMnO_{3+x}$ where the ‘excess’ oxygen was believed to be accommodated at interstitial sites. Tofield and Scott[54] studied a phase of nominal composition $LaMnO_{3.12}$ using neutron diffraction. Although they considered interstitial models, their results show that the compound is actually $La_{0.94}\square_{0.06}Mn_{0.98}\square_{0.02}O_3$, where $\square$ represents lattice vacancies. The level of nonstoichiometry is much less in $LaVO_{3-x}$ ($x < 0.05$) and not determinable for the Cr and Fe analogs.[55]

3.11 Intergrowth Structures

Intergrowth phases occur when slabs of two or more well-defined structural sequences can interface with one another to form an ordered or disordered sequence. A good example of a simple ordered intergrowth structure is that of K_2NiF_4. One way to view this structure, shown in Figure 23, is as a series of perovskite cells stacked one on top of the other but displaced by a translation of 1/2 in both the tetragonal a and b directions. The structure is a common one for oxides of the transition metals with the larger alkaline earth and rare earth cations. An alternate description of the structure is one that contains alternating layers of the perovskite (ABO_3) and rock salt (AO type).

Many systems that form perovskites also form K_2NiF_4 type oxides, for example, $SrTiO_3$ and Sr_2TiO_4. The latter can be considered as the first member of a general homologous series $A'_2[A_{n-1}Bn0_{3n+1}]$ where $n \leq 4$ and A′ and A may or may not be the same. Here a perovskite slab can be looked upon as a TiO_2 layer sandwiched between two SrO layers that are in register with each other. The ideal, ordered structure of $Sr_3Ti_2O_7$ ($n = 2$) should contain a double perovskite layer separated by an SrO layer, as shown in Figure 23(b), but in fact high-resolution electron microscopy HREM studies of a typical sample of $Sr_3Ti_2O_7$ show intergrowth regions where $n = 2$, 3, 4, 5, 7, and 8 are clearly evident. Other areas of the crystal show large domains with the composition $SrTiO_3$ so that the average composition is $Sr_3Ti_2O_7$.[55]

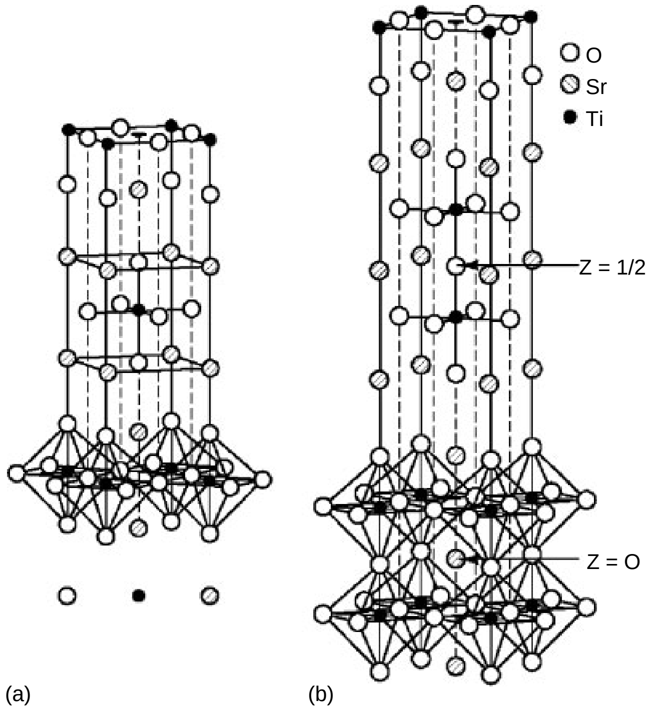

Figure 23 Unit cell of Sr_2TiO_4 (K_2NiF_4 type) at right. Unit cell of $Sr_3Ti_2O_7$

La_2CuO_4 also has the K_2NiF_4 structure at high temperatures. However, La^{+3} is too small to fit comfortably into the close-packed cavities and upon cooling, it transforms to an orthorhombically distorted variant in which there are four short Cu–O bonds in the ab plane and two long bonds along the c axial direction. In addition, the distorted CuO_6 octahedra are tilted slightly with respect to the unit cell edges and a slight excess of oxygen is introduced, $La_2CuO_{4+\delta}$, $\delta < 0.03$. However, if a small amount of Sr is substituted for La, then the normal tetragonal K_2NiF_4 form is stabilized for $La_{2-x}Sr_xCuO_4$ ($0.10 \leq x \leq 0.27$) with a stoichiometric oxygen content. These phases were found to be superconducting between $T = 25-40$ K with the maximum value of T_c being for $X = 0.15$.[56] Shortly thereafter the now famous yttrium barium copper oxide, $YBa_2Cu_3O_{7-\partial}$, was discovered with a $T_c = 93$ K.[57] This can be looked upon as a tripled perovskite unit in which Ba and Y occupy the A cation positions in an ordered fashion. The ideal oxygen stoichiometry of 7 is then achieved by removal all of the oxygen in the 001 plane about Y and along 2 opposite edges of Cu(1) as seen in Figure 24(a). This results in a pyramidal coordination of Cu(2), which exists as an infinite planar net perpendicular to the c axis, and a square coordination of Cu(1) in the form of chains running along the b axis.

The structure is conveniently described as an intergrowth structure of the following layers stacked along the orthorhombic c axis

$$\text{–Cu(1)O–BaO–Cu(2)O}_2\text{–Y–Cu(2)O}_2\text{–BaO–}$$

Oxygen may be removed progressively by heating under controlled partial pressures of O_2 between 400 and 950 °C. As oxygen is removed disrupting the CuO_2 planes, T_c decreases. The orthorhombic phase is stable up to $\delta = 0.5$. Here a transformation to the tetragonal form takes place and is stable for $0.5 \leq \delta \leq 1.0$, the end member of which is shown in

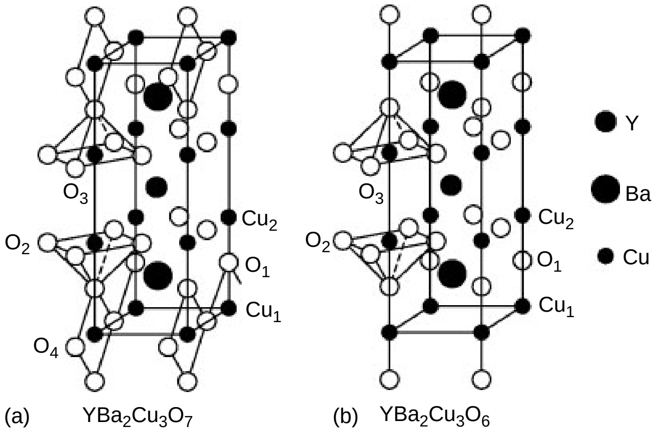

Figure 24 Unit cells of $YBa_2Cu_3O_7$ (a) and $YBa_2Cu_3O_6$ (b) Pyramidal, planar, and linear coordination of Cu by O is highlighted

Figure 24(b) where Cu(1) is now in linear coordination with oxygen. This phase is not superconducting. Thus for the $YBa_2Cu_3O_{7-\delta}$, $0 \leq \delta \leq 01.0$, the intergrowth sequence might be reformulated

$$–CuO_{1-x}–BaO–CuO_2–Y–CuO_2–BaO–.$$

If a second CuO chain is inserted into $YBa_2Cu_3O_7$, the compound $YBa_2Cu_4O_8$ is obtained with $T_c = 80\,K$, while $Y_2Ba_4Cu_7O_{14}$ ($T_c = 40\,K$) is an intergrowth of these two structures. $Tl_2Ba_2Ca_2Cu_3O_{10}$ with a $T_c = 125\,K$ is a member of the homologous intergrowth series $(TlO)_nBa_2Ca_{m-1}Cu_mO_{2+m}$ with $n = 1$ and $m = 1–4$ or $n = 2$ and $m = 1–3$. Such intergrowth structures in layered cuprates have been studied extensively by HREM, which reveals a variety of complex nonrecurrent intergrowth features. These structures have been reviewed by Raveau and coworkers.[58,59,60] The relationships between intergrowths and superconducting behavior are discussed in ***Superconductivity***.

Closely related in structure to the RP phases are the so-called Dion–Jacobsen (DJ) phases that have the general formula $A'[A_{n-1}B_n0_{3n+1}]$, where n is typically 2 or 3. These phases have one half the number of cations between the perovskite layers as do RP and they are typically alkali metal cations, an example of which would be $CsCa_2Nb_3O_{10}$. Aurivillius phases, such as $Bi_2W_2O_9$, are intergrowths of two dimensional perovskite slabs and $Bi_2O_2{}^{+2}$ layers. An interesting feature of RP, DJ, and Aurivillius phases is that the layered cations can often be replaced easily by ion-exchange or intercalation methods and thus are templates for preparing new materials with controlled properties (see Section 5.6 and 5.7).[61]

An interesting example of intergrowth structures are a series of magnetic oxides based upon the structure of $PbFe_{12}O_{19}$, magnetoplumbite. The structure can be described in terms of five HCP layers of 4 oxygens each, in which one of the layers has one-quarter of its oxygen replaced by the large Pb^{+2} ion to yield a PbO_{19} framework. The iron then fill octahedral and tetrahedral holes in a spinel-like fashion. The layer sequencing is BABAB. A closely related compound is $BaFe_{12}O_{19}$, which differs from magnetoplumbite in that the sixth layer of the structure has been translated so that the 10 layer stacking sequence

BABABCACAC

now occurs. Phases of the type $Ba_2M_2Fe_{12}O_{22}$, ($M = Zn^{+2}$, Mg^{+2}, or a divalent transition metal cation) are formed when a second BaO_3 layer is inserted into a five-layer magnetoplumbite cell along with two small cations to maintain electro-neutrality. A great variety of intergrowth structures utilizing these two sequences along with that of spinel have been observed.[62] Some of these may have extremely long repeat distances (up to 1600 Å) along the CP direction that are best observed by HREM. Magnetic interactions in these structures appear to be important since they do not form if an attempt is made to replace Fe^{+3} by nonmagnetic ions such as Al^{+3} (*see* ***Magnetic Oxides***).

The compound $La_5Mo_4O_{16}$ is of interest since is one of the few examples of 4d oxides that display strong ferromagnetic-like interactions, being a so-called metamagnet below 180 K. The structure consists of perovskite-like layers of corner-sharing MoO_6 octahedra sandwiched between insulating Mo_2O_{10} clusters that have an extremely short Mo–Mo bond of 2.406 Å (see Section 4.2). The Mo in the perovskite layers have valences of 4 and 5 and are ordered in alternate MoO_6 octahedra.[63] Partial replacement of the tetravalent Mo by divalent 3d transition metal ions and Mg^{+2} can be achieved resulting in reduction or elimination of the metamagnetic properties.[64] A rhenium analog, $La_5MnRe_3O_{16}$, has also been reported.[65]

A homologous series of cesium tungsten oxides having the formula $Cs_{2n}W_{4n-1}O_{12n}$ has been reported. The general structure consists of slabs composed of layers of the hexagonal tungsten bronze and the pyrochlore type. The alkali cations reside in between the layers and in the tunnels formed within the slabs.[66]

3.12 Reduced Transition Metal Phosphates

The fact that boron, silicon, or phosphorus will not normally enter into sixfold coordination with oxygen offers chemists the possibility of using these elements to interrupt the formation of high density three-dimensional transition metal oxide structures based on octahedral coordination and isolate them with the more flexible polyhedra of the main group elements. Two relatively new classes of reduced transition metal oxides are phosphates of molybdenum and tungsten in reduced valence states. While one might expected that they would be similar, they are not. The structure of the tungsten analogs are built up of ReO_3-like slabs of WO_6 octahedra in which monophosphate (PO_4) or diphosphate (P_2O_7) groups bridge the WO_3 layers. In the process, the d electrons of tungsten are confined to the slabs creating the opportunity for quasi-low dimensional electrical and magnetic behavior.

Large channels exist between the phosphate-terminated slabs, which may accommodate ternary ions. These bronzes can be divided into the following categories according to the phosphate bridging group used and the nature of the principal channel created in the structure. (1) Monophosphate tungsten bronzes ($MPTB_p$) contain pentagonal tunnels and have the general formula $(PO_4)_4(WO_3)_{2m}$ where $m = 2$, $4 \leq m \leq 10$ and also represents the number of WO_3 layers between the terminating phosphate groups as shown in Figure 25(a). (2) Monophosphate tungsten bronzes containing hexagonal tunnels ($MPTB_h$) of the type $A_x(PO_2)_4(WO_3)_{2m}$. Here the channels are large enough to accept moderately large cations, ($A = Na$, K) where $x = 1.75–3$, the limit being 2 for K and about 3 for Na. Values for m

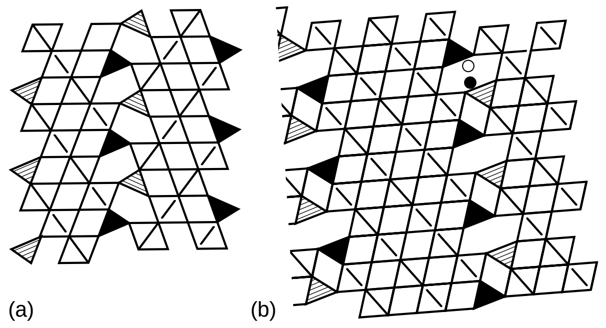

Figure 25 MPTB$_p$ layer with $m = 4$ (a). MPTB$_h$ with $m = 7$, $K_{1.4}P_4W_{14}O_{50}$ (b). PO_4 groups in black. Note pentagonal and hexagonal tunnels

are between 4 and 13. (3) Diphosphate tungsten bronzes containing P_2O_7 units and having pentagonal channels, (DPTB$_p$). These have the formula $(PO_2)_4(WO_3)_{2m}$, $m = 4-16$. (4) Diphosphate tungsten bronzes with hexagonal tunnels (DPTB$_h$). These have the general composition $A_x(P_2O_4)_2(WO_3)_{2m}$ ($A = Na^+$, K^+, Rb^+, Tl^+, Ba^{+2}) and values of m between 4 and 20, depending in part on the nature of the A cation. The structures and properties have been reviewed by Borel,[67] Greenblatt[68,69] and more recently by Labbé.[70]

In contrast, the phosphate molybdenum oxides contain MoO_6 octahedra or limited groups of edge and corner-sharing MoO_6 octahedra. These are isolated from one another by mono- or diphosphate ions that share corners or edges with the oxygens of the MoO_6 octahedra such that structures are formed that contain large voids or tunnels that can accommodate large guest ions. Since the MoO_6 octahedra do not form a continuous Mo–O network, electronic conduction is prevented and the materials are insulators. A large variety of these phases exist that are discussed in detail elsewhere.[67]

3.12.1 Other Reduced Transition Metal Phosphates

Mixed-valence transition metal phosphates have been found for Ti, V, and Nb. Their crystal chemistry and properties are more closely related to those of the Mo analogs in that they have mixed frameworks of MO_6 octahedra that are partially or wholly isolated from one another by intervening phosphate groups and the d electrons do not appear to be delocalized. A particularly rich chemistry exists for the vanadium analogs. Details of their structural properties have been reviewed by Borel and coworkers.[67,70]

If silica is introduced into a reduced phospho-molybdate system, Mo can be stabilized in the trivalent state. The structure of MoP_3SiO_{11} is built from MoO_6 octahedra that share all six corners with diphosphate groups, which in turn share their remaining corners with disilicate units.[71] A number of mixed-valence Mo(III),Mo(IV) oxides of the type $AMo_3P_6O_{12}Si_2O_{25}$ have also been reported.

4 STRUCTURE-PROPERTY RELATIONSHIPS IN OXIDES

4.1 Introduction

The relationship between the structure of a solid and its resultant physical properties have made oxides the object of intense activity from both a practical and theoretical point of view. Several examples of structure-property relationships are discussed briefly below, many of which are discussed in detail elsewhere. Three examples will be discussed in somewhat greater detail.

Main group oxides with three-dimensional structures or transition metal oxides with d^0 or d^{10} configurations are wideband gap materials and are colorless when pure. As such they may serve as transparent optical materials or hosts for such applications as lasers or luminescent materials when properly doped. Others that lack a center of symmetry may have ferroelectric or ferroic properties that make them useful for a variety of device applications. Some of these may have nonlinear optical properties so important to modern communication networks (see Sections 6.3 and 6.5 and *see* ***Luminescence*** and *see Ferroelectricity*).

On the other hand, transition metals with unpaired d electrons and main group oxides with mixed valences or with defect structures often display high electrical conductivity. In some cases, this conductivity may be metallic in nature provided the structure allows for proper overlap of the atomic orbitals of the metals, either with each other, or more often, with oxygen. Some examples of this behavior are given in Section 4.2. Low-valent electron-rich oxides often have structures with metal–metal bonds. Certain structures will be stable for localized cluster interactions resulting in insulating materials while other structures stabilize extended systems of metal–metal bonds that are often highly conducting. These structures are discussed in Section 4.2.

Cooperative magnetic effects are one of the most sensitive of structure-property relationships (*see* ***Magnetism of Extended Arrays in Inorganic Solids***). While useful magnetic oxides are limited to only a few structure types (*see* ***Magnetic Oxides***), anomalous magnetic behavior is observed in a number of metallic and narrow band semiconductors, which are of great interest since they often are not well understood. Anomalous magnetic effects are often associated with quasi-low dimensional, considered by some to be a precursor to superconductivity. Indeed, the strong diamagnetism associated with the superconducting state could be considered to be an extreme case of an anomalous magnetic effect. Although the origins of high-temperature superconductivity are still a matter of intense debate, it is generally agreed that the phenomenon is extremely structure sensitive (*see* ***Superconductivity***).

One final effect of unpaired d electrons is the formation of intensely colored materials particularly when defects or mixed valences are involved. This, coupled with the valence

stabilization often imparted by the structure, causes oxides to be highly valued as pigments (see Section 6.3.6).

Oxides with layered structure or those whose structures contain large tunnels or cavities may display abnormal ion movement or serve as templates for heterogeneous catalysis (*see* ***Ionic Conductors***; ***Intercalation Chemistry***; ***Oxide Catalysts in Solid-state Chemistry***; and ***Zeolites***). Many oxides are stabilized by the formation of structures that are highly defective nature and have similar properties to those listed above (*see* ***Defects in Solids***). The strong bonds, which result in three-dimensional cross-linked structures, give rise to inert, refractory materials that have a variety of uses (see Section 5.3.6 and *Ceramics*).

4.2 Oxides with Strong Metal–Metal Bonds

For many years, strong metal–metal interactions were largely regarded as chemical curiosities of little interest exemplified by some suboxides of the heavier alkali metals and a few 4 or 5d elements, principally Mo, Nb, and Re. However, research since 1978 has shown that the phenomenon is much more widespread than previously thought. A few reviews covering work through about 1985 on Mo and Nb cluster oxides exist.[72–75]

The chemistry of the alkali metals suboxides such as Rb_6O, Cs_7O, Rb_9O_2, and $Cs_{11}O_3$ has been reviewed by Simon[76,77] and will not be discussed here. Rather, this section will concentrate on transition metal compounds where d electrons are utilized in bonding.

Diagonal M_2 clusters are quite common being found for several rutile and NaCl variants as discussed previously, which include Ti, V, Nb, Mo, and W as well as other oxides of Re, Ru, Os, Ir, Pt, and Ag. Larger, isolated clusters containing 3,4,6,7,8,10 or more atoms have been discovered in a variety of low-valent molybdenum and niobium oxides. For instance, trigonal clusters in which the metal atoms are 2.51 Å apart are found in $Zn_2Mo_3O_8$ and related compounds. This compound is an electrical insulator and is diamagnetic in support of the idea that the Mo d electrons are localized in forming three strong metal–metal bonds. Approximate molecular orbital calculations have shown that Mo_3O_{13} clusters (Figure 26(a)) should be stable for 4, 6, and 8 electrons.[78] Subsequently, 7 and 8 electron containing clusters were found for $LiZn_2Mo_3O_8$ and $Zn_3Mo_3O_8$.[72,79] Butterfly Mo_4 clusters are found in $K_2Mo_8O_{16}$, isolated octahedral Nb_6 clusters are found in $Mg_3Nb_6O_{11}$ and $Na_3Al_2Nb_{34}O_{64}$ (Figure 26(b)), while a unique cis-edge shared Mo_8 cluster (Figure 26(c)) was found in $LaMo_{7.7}O_{14}$ and subsequently in stoichiometric $LnMo_8O_{14}$ (Ln^{+3} = La, Ce, Pr, Nd, Sm, and Gd).[80,81] Here two Mo cap edge-sharing faces of a Mo_6 octahedron (Figure 32(c)) in the so-called *cis* configuration. Subsequently, it was found that the *cis*-Mo_8 cluster can exist in enantiomorphic forms as well as in the isomeric *trans* form. The result is a group of diverse, complex phases.[82]

Linear, cross-linked double chains of bonded Mo are found in $NaMo_2O_4$.[74] The fact that these chains can accommodate a variable number of electrons is shown by the fact that a series of solid solutions can be obtained for $Na_{2-x}Mo_2O_4$.[83] The conducting nature of this material coupled with easily exchangeable alkali ions makes the Li analog a promising cathode material for secondary lithium cells (see Section 5.7). The double-chain units of bonded Mo are shown in Figure 27. Hexagonal $LiMoO_2$, prepared by a solid-state reaction, also forms an extended metallic bonded system but here hexagonal

sheets of weakly bonded Mo, 2.866 Å distant, are formed by placing Mo in the interstices of a CP oxide ion lattice.[84]

Mo_6 octahedra may condense to form oligomers containing up to 6 units. Here the basic building block is an Mo_6O_{18} cluster in which the Mo_6 octahedra share trans-edges to form linear oligomeric units. $LaMo_5O_8$ contains the dimeric $Mo_{10}O_{16}$ unit with Mo–Mo bond lengths ranging from 2.676 to 2.836 Å. These cluster units are then linked to each other by two additional Mo–Mo bonds forming infinite chains. $In_{11}Mo_{40}O_{62}$ contains the 4 and 5 member oligomers, $Mo_{18}O_{28}{}^{-7}$ and $Mo_{22}O_{34}{}^{-8}$.[75–77] This compound also contains In–In metal bonds.

A variety of extended metal–metal bonded systems are also found for molybdenum and niobium based on M_6 clusters. In the case of molybdenum, the repeat motif is formed by trans-edge-sharing Mo_6 octahedra while corner-sharing Nb_6 groups form the primary mode in the niobium oxides. In $NaMo_4O_6$, infinite trans edge-sharing Mo_6O_{18} units, similar to those shown in Figure 26(b), are linked through their oxygens to form tunnels in which the Na reside.[85] The structure is shown in Figure 28. The basic repeat unit, Mo_4O_6, contains 13-d electrons delocalized in the metal–metal framework. The metal bonded chain provides for electron delocalization and the compound is a metallic conductor. Mo–Mo bonds range in length from 2.751 to 2.860 Å with an average distance of 2.801 Å, slightly longer than the 2.725 Å length found in Mo metal itself. Similar chains based are found in a variety of other compounds including $InMo_4O_6$, $Ba_{0.62}Mo_4O_6$, $Mn_{1.5}Mo_8O_{11}$, and $ZnMo_8O_{10}$.[72–74] The number of metal-cluster electrons in the Mo_4O_6 unit is between 13 and 15, which is consistent with the values estimated from bond length-bond strength calculations. Delocalization of these electrons along the chains would be expected to make these compounds metallic conductors. This has been found to be the case for the isomorphic AMo_4O_6 phases, ($A^+ = $ Na, K, In).

Layers of corner-sharing Nb_6 clusters sandwiched between perovskite-like layers formed by NbO_6 octahedra are found in $SrNb_5O_9$ and KNb_4O_6 while double layers of corner-sharing Nb_6 octahedra are found in $BaNb_7O_9$.[76] These oxides often contain more than one type of cluster. For example, $Ca_{5.45}Mo_{18}O_{32}$ contains discrete Mo_2O_{10} and Mo_3O_{13} type clusters in addition to infinite chains based on the Mo_4O_6 repeat. $BaSiNb_{10}O_{19}$ contains both octahedral Nb_6 and trigonal Nb_3 units. Most of the niobium compounds containing discrete clusters for which resistivity measurements have been made are found to be semiconductors although $NaNb_{10}O_{18}$ has been found to be metallic. Here the cluster-electron count is formally fifteen, one above the stable limit of 14 (*see* ***Electronic Structure of Clusters***), and the extra electron is expected to be delocalized through the Nb–O network.[75,86]

The niobium cluster oxides can be quite complex. For instance, $Na_3Al_2Nb_{34}O_{64}$ has a 30 layer repeat unit with four different types of Nb units. There are discrete Nb_6 clusters coordinated as Nb_6O_{18}, bonded Nb_2 clusters, Nb_3O_{13} units in which the Nb–Nb interactions are nonbonding ($d_{Nb-Nb} = 3.17$ Å), and discrete Nb, which fill octahedral holes in the oxide layers. $K_4Al_2Nb_{11}O_{21}$ contains an $Nb_{11}O_{30}$ unit in which two Nb_6 clusters share corners to form an Nb_{11} dimer. One-dimensional corner-sharing $(Nb_4)_\infty$ chains are found in $Ba_{0.2}Nb_5O_8$ while triple chains composed of 3 cross-linked Nb_6 clusters are found in $Ba_4Nb_{14}O_{23}$. In NbO,

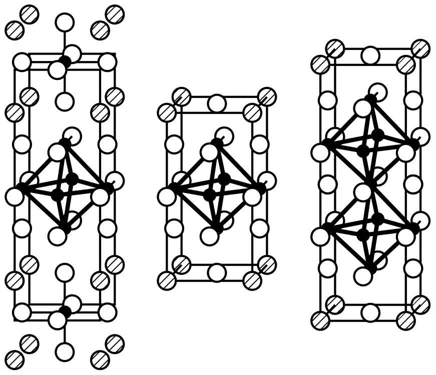

Figure 29 Unit cells of $Ba_2Nb_5O_9$ (a), $BaNb_4O_6$ (b), and $BaNb_7O_9$ (c) showing Nb_6 cluster building block

each Nb_6 cluster shares corners with similar clusters to form a three-dimensional metallic array. Layers of Nb_6 octahedra sharing four corners are found in $Ba_2Nb_5O_9$, $BaNb_4O_6$ and $BaNb_7O_9$ whose unit cells are shown in Figure 29. These structures can be considered as simple intergrowths of NbO-like layers and perovskite-like $BaNbO_3$ slabs. More complex intergrowth structures are reviewed by Kohler, Svensson, and Simon.[75] Because of the delocalized nature of the metal–metal bonding in these structures, metallic conductivity might be expected. Recent measurements of the electrical conductivity and magnetic susceptibility would seem to confirm this for $Sr_2Nb_5O_9$ while the behavior of $Ba_2Nb_5O_9$ is more complex.[87]

A number of Mo oxides containing chains are formed by two different cluster units sharing corners. In $Sr_4Al_3Mo_{26}O_{48}$, there exist chains from mono-faced-capped Mo_7 clusters and dioctahedral edge-sharing Mo_{10} clusters to form Mo_7-Mo_{10}-Mo_7 groups that repeat to form chains.[88] Mo_3, Mo_7, Mo_{13}, and Mo_{19} clusters are found in $PrMo_9O_{18}$. The Mo_7 cluster here is planar and formed by triangular Mo_3 groups sharing a central Mo. Mo_{13} and Mo_{19} groups are formed by condensation of Mo_6 octahedra. These clusters have C_{3v} symmetry and each form separate slabs in the structure.[89] $Sn_{0.4}Mo_{24}O_{38}$ contains tri-octahedral trans-edge-sharing Mo_{14} clusters as well as bioctahedral Mo_{10} clusters linked through corners to form chains.[90]

While clusters with two, three, or more metal atoms are largely confined to early transition metals, an increasing number of such clusters have been found for both late transition metals such as Re, Ru, Rh, and Ir. The typical building unit is an M_2O_9 unit built from to MO_6 octahedra by sharing a face. A rich chemistry derives from this group. The M_2O_9 unit may share may share faces to form infinite chains or finite oligimers. The oligimers may share faces with trigonal prismatic MO_6 units or share corners with one another to form infinite zig-zag chains.[91–93] The metal–metal distances in the oligimeric units can be quite short, of the order of 2.5 to 2.7 Å. However, it is clear that in some instances these are nonbonded interactions, while in others electron bonding appears likely.[94,95]

4.3 Electronic Conduction in Oxides[9,96–100]

The electrical conductivity of a solid may be defined by the following relationship

$$\sigma = ne\mu_- + pe\mu_+ \tag{4}$$

where σ is the electrical conductivity in $(\text{ohm-cm})^{-1}$. The number of charge carriers per unit volume are given by n for electrons and by p for holes while the respective carrier mobilities in cm^2/V-sec are given by μ_- and μ_+ respectively (*see* ***Semiconductors***). In oxides, the conductivity may vary from 10^{-8} $(\text{ohm-cm})^{-1}$ or less for high purity oxides containing an empty d manifold such as CaO or TiO_2 to values of the order of 10^4 to 10^5 $(\text{ohm-cm})^{-1}$ found for MoO_2, Na_xWO_3, or ReO_3, which contain one or more d electrons. Main group oxides of high purity are normally insulating but may show a modest conductance as a result of impurity doping or other defects. In the case of mixed valences, for example, In_2O_{3-x} or $Pb_xBi_{1-x}O_3$, very high conductivities may be observed.[101]

The conductivity mechanisms in many oxides are often complex and obscure. Details of the quantitative physical models will not be discussed here. There are some elementary classifications and some simple arguments based on qualitative band theory (*see* ***Semiconductors*** and ***Electronic Structure of Clusters***). Some examples that apply to transition metal oxides are discussed here. In this case, insulators are stoichiometric d^0 oxides with a large forbidden energy gap of several electron volts between the filled valence band (usually predominantly oxygen 2p in character) and the next highest empty band (conduction band) as shown in Figure 30(a). Such oxides may be made semiconducting by introducing impurities that create states that lie close to either the valence or conduction band, the latter being p-type and the former being n-type (Figures 30b,c). An example of such behavior was given in Section 3.10 for TiO_{2-x}.

A second class of semiconducting oxides are those of the late transition metals, for example, Cr_2O_3 or NiO,

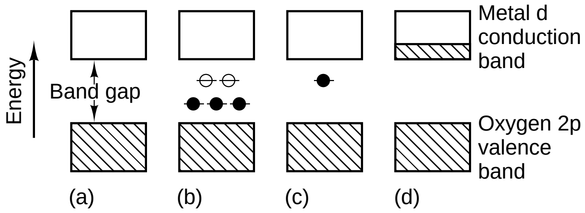

Figure 30 Simplified band diagrams. Insulator or intrinsic semiconductor (a). Extrinsic semiconductors (b) and (c). Metallic conductor (d)

which contain localized d electrons that function very much like impurity levels shown in Figure 35(c). Because these compounds have unpaired electrons, they are sometimes called as magnetic insulators. MnO is an insulator at room temperature and has a measurable semiconductivity at elevated temperatures.[102] A complex behavior is observed for samples of MnO heated between 1100–1400 °C in controlled partial pressures of oxygen formed by CO_2/O_2 mixtures. Conductivities are in the range 1 to 10^{-2} (ohm-cm)$^{-1}$. At low partial pressures of oxygen, the phase is n-type and conductivity increases with decreasing partial pressure. As the partial pressure of oxygen is increased, the conductivity goes through a minimum for a given isotherm and as the O_2 pressure is increased, the majority carriers are holes resulting from the removal of electrons by the oxidation of Mn^{+2} to form $Mn_{1-x}O$.

Semiconductors are characterized by low carrier densities 10^{16}–10^{20} carriers cm^{-3} and low mobilities, typically 10^{-5} to 1.0 V cm^{-2}-sec. Semiconductors display an increase in conductivity with increasing temperature as the result of thermal excitation of electrons located either at the top of the valence band (intrinsic carriers) or from impurity sites in the forbidden gap, or from the filling of low lying acceptor levels in the case of p-type materials. In many cases, the temperature dependence is of the Ahrrenius form

$$n = n_0 e^{-(E_a/kT)} \quad (5)$$

where E_a is the energy difference between the impurity state and the conduction band. For narrow band semiconducting oxides, E_a could represent the band gap. More often however, a more complex nonlinear behavior is found whose particular form depends upon the conductivity mechanism. These have been discussed in detail.[96–98] Metals, in contrast to semiconductors, typically have high carrier densities close to 10^{22} cm^{-3} and high mobilities. In the free electron theory, metallic electrons reside in a partially filled conduction band (delocalized) and are free to move through the lattice. Resistance to electron flow arises primarily from electron-lattice interactions, which are increased by increased vibrations of the atoms. A metal's conductivity will therefore decrease with increasing temperature. In transition metal oxides, metallic conductivity will be achieved if a means can be found to delocalize the highest energy d electrons. This occurs in a variety of compounds and usually involves either (1) the formation of a weakly bonded extended metal–metal network in which the resulting band is only partially filled or more often (2) the formation of a continuous metal d orbital-oxygen p π bonding network.

Materials that are formally insulating such as WO_3 may become semiconducting by appropriate doping; for example, Na_xWO_3 where $x < 0.3$. Upon further doping, what had been W(V) localized impurity states coalesce into a band and the bronze phase becomes metallic for $x > 0.3$.

4.3.1 *ReO_3 and Perovskite Tungsten Bronzes*

A qualitative diagram of the sigma and pi bonding for ReO_3 is given in Figure 31. In this structure, each Re is oriented so that its s, p and e_g orbitals can overlap with oxygen s and p orbitals (or sp hybridized orbitals) to form 6 strong σ bonds pointing towards the corners of an octahedron, (Figure 31(b)). Each oxygen is two coordinated by the metal. At the same time, the t_{2g} orbitals of the metal are oriented so that they can form an overlapping pi network with the p_x and p_y orbitals of oxygen (Figure 31(c)). The fillings of the electronic bands thus formed are given in the qualitative band diagram shown in Figure 32, proposed by Goodenough.[98] The low lying 12 electron σ band represents the 6σ bonds formed by each Re with six oxygens while the six electron Re–O π band is next. The lone pair on each oxygen is represented by the localized p_π levels. Because the sigma overlap is stronger than the pi overlap, the σ^* bands lie at higher energy than the π^* band.

The largely metallic 6 electron π^* band is now the conduction band and is only partially filled by the d^1 electrons of Re^{+6}. Hence, metallic conductivity is expected. The basic tenets of this simple qualitative model are confirmed by theoretical calculations.

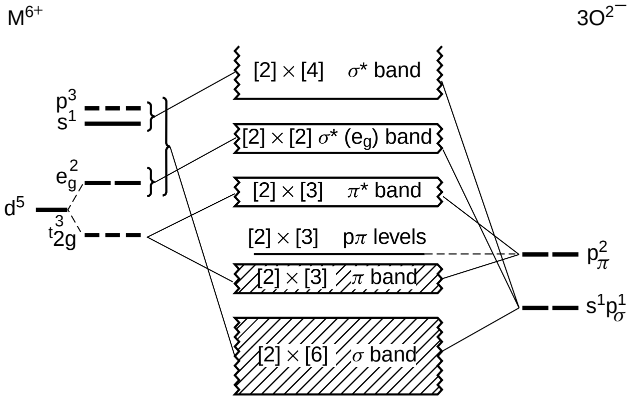

Figure 32 Qualitative band diagram for ReO_3. Electron filling indicated by shading

This diagram can also be applied to the sodium tungsten bronzes, Na_xWO_3, which adopt the cubic perovskite structure for $x > 0.3$. WO_3 is an insulator with a slightly distorted ReO_3 type structure. If a small amount of Na is added, localized electron donor sites are created having energies that lie between the π and π^* bands in Figure 32. With increasing doping, these localized impurity states coalesce into a band and the bronze phase becomes metallic for $x > 0.3$.

4.3.2 *Conduction in Rutile and Rutile Related Oxides*[103]

In rutile-type oxides, enormous differences in conductivity can occur that depend upon electronically induced distortions of the structure. The structure has been discussed previously (Section 3.2.2). Here the important thing to note are the chains of trans edge-sharing octahedra, which run parallel to the tetragonal c axis (Figures 3 and 4 (a)). In TiO_2, the metal atoms are located at the centers of the octahedra, 2.96 Å distant from one another. TiO_2, having no d electrons, is an insulator but the high-temperature form of VO_2, which also has this structure, is a metal.

Below 341 K the structure undergoes a distortion in which the V atoms move off center to form a chain with alternating long and short V–V distances (see Figure 4). The short V–V distance is 2.62 Å and corresponds to a metal–metal covalent single bond. This form is semiconducting. This behavior may also be explained by the one-electron band energy diagrams shown in Figure 33.[98] In the normal rutile structure, two of the three t_{2g} orbitals overlap oxygen p orbitals to form a metal-oxygen π band, which can contain up to 8e per V_2O_4 unit. The remaining t_{2g} orbital, which lies along the tetragonal c direction, that is, perpendicular to the edge shared oxygens, forms a nonbonding cation sublattice band. This represents the conduction band, which may also overlap the π^* band. In TiO_2 (Figure 33(a)), this band is empty and the compound is an insulator. The low lying σ and π bands represent the M–O bonding and contain 32 e with primarily O character. In the normal rutile form of VO_2, the two d electrons of a V_2O_4 unit partially fill the conduction band and the compound is a metal (Figure 33(b)). In the monoclinically distorted polymorph, the d electrons are localized in V–V bonds and the t_{2g} sublattice band is split into localized bonding and antibonding levels as shown in Figure 33(c). This compound is an insulator.

MoO_2 also has a monoclinic rutile distortion similar to that in the high-temperature form of VO_2 in which the Mo–Mo distances alternate between 2.51 and 3.11 Å. Here, one might expect that two of the four electrons per Mo_2O_4 unit would be used to form the Mo–Mo bond and the remainder occupy the conduction band and the compound would be a metal, in conformance with observation. This model can only be considered to be approximate since the observed Mo–Mo distance is more nearly that of a double bond. However, this would require the localization of all Mo d electrons, with one of the Mo t_{2g} orbitals in the ab plane being used to form metal–metal π bonds, and the compound would be a semiconductor. The true situation must be a combination of metal σ, π (and perhaps δ) contributions combined with band delocalization, a picture not easily represented in a one-electron band diagram.

In normal rutile oxides based on Figure 33(a), one might expect that elements with up to 5 d electrons would be metals and this appears to be borne out although accurate measurements of the conductivity have been limited by the quality of the samples available. In addition, CrO_2 is a ferromagnetic insulator and α-ReO_2 has a somewhat more complex distortion of the simple rutile structure. However according to the simple model, d^6 metals which can contribute 12 electrons per M_2O_4 unit would have a filled conduction band and be semiconductors. This has been shown experimentally to be the case for PtO_2.[103]

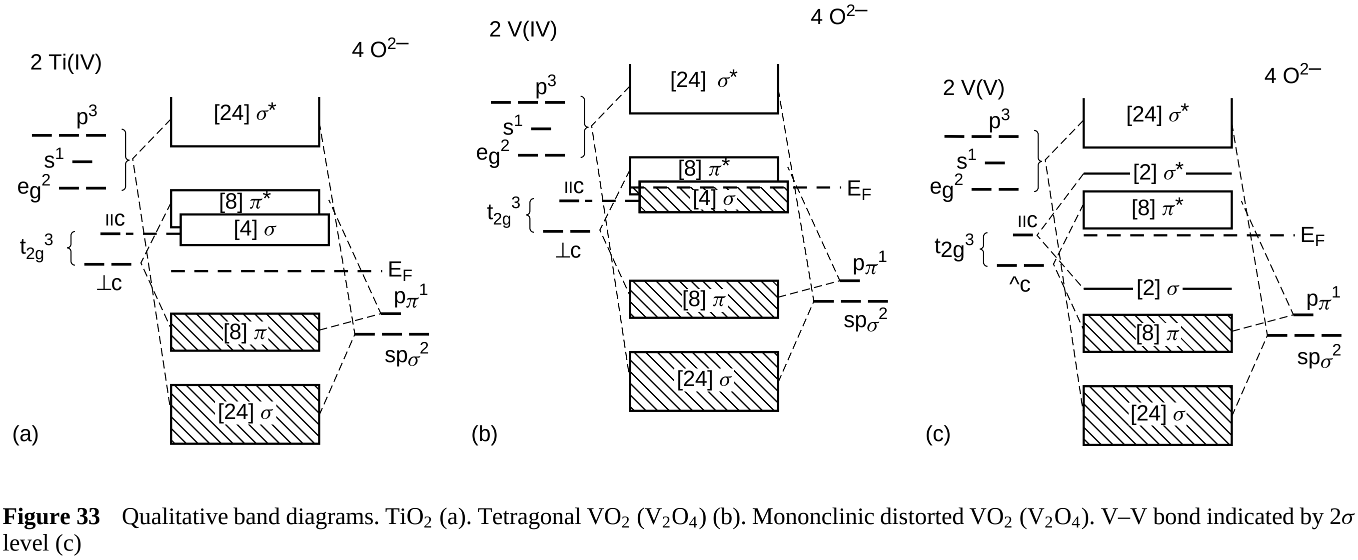

Figure 33 Qualitative band diagrams. TiO_2 (a). Tetragonal VO_2 (V_2O_4) (b). Mononclinic distorted VO_2 (V_2O_4). V–V bond indicated by 2σ level (c)

A somewhat different behavior is shown in the rutile related oxide $Y_5Mo_2O_{12}$. This compound contains chains of edge-sharing MoO_6 octahedra similar to those found in the distorted rutile type of MoO_2. In the ternary compound, the alternating long and short Mo–Mo distances are 2.496 and 3.221 Å and the chains are linear. In MoO_2 the chains are slightly puckered, the Mo–Mo–Mo angle being 173 degrees, and the Mo–Mo distances alternate between 2.511 and 3.112 Å.

The structure can be considered as containing rutile-like slabs in which certain octahedral interstices are now occupied by Y. These rutile-like planes are then interconnected by a second set of Y in sevenfold coordination. Given the mixed valence of this compound and its rutile-like nature, metallic conductivity might have been expected. Instead, the compound is a semiconductor with a room temperature resistivity of 4×10^3 ohm-cm. This is attributed to the fact that the bridging oxygens in the octahedral chains now bond to Y and are in approximate sp^3 hybridization. The p orbital that is used for Mo–O π bonding in metallic MoO_2 is no longer available and, as a result, the d electrons are localized between molybdenums and the compound is a semiconductor.[104]

4.3.3 Electronic Conduction in Rock Salt Related Oxides

TiO has a rock salt related superstructure discussed in Section 3.2.1. Here the t_{2g} orbitals of Ti can overlap to form a continuous Ti–Ti array, shown in Figure 34, leading to a partially filled t_{2g} band. The Ti–Ti distance is considerably longer than that in Ti metal but short enough to allow for electron delocalization. As one moves across a given period of divalent transition metals, the increasing effective nuclear charge tends to localize these electrons and metal–metal interactions are no longer important. VO behaves similarly to TiO while MnO and NiO have the normal rock salt structure and are insulating.

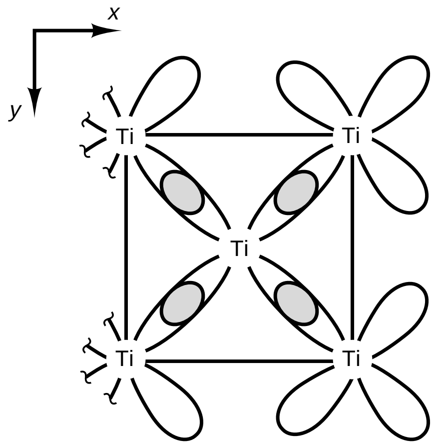

Figure 34 Diagram of sigma Ti–Ti bonding in TiO

4.4 Scheelite Based Catalysts[105,106]

Scheelite oxides are a good example of how structure-property relationships have been used to create a modern catalyst. More detailed descriptions of these and other catalysts are given in ***Oxide Catalysts***. The scheelite structure was discussed in Section 3.4.5. Scheelite based oxides are of interest as catalytic materials because of their ability to form with transition elements in high but easily reducible valence states and to form a variety of defects and defect structures that provide numerous sites for selective catalytic activity.

Molybdate based scheelites have been intensively studied in this respect, one reason being that they are found with molybdenum in both the penta- and hexavalent state. Bismuth molybdates in particular are useful catalysts for selective oxidation of propylene to acrolein, propylene ammoxidation to acrylonitrile and the oxidative dehydrogenation of butene to butadiene.

Gross cation vacancies can be introduced into a scheelite such as $PbMoO_4$ by the addition of a trivalent rare earth or bismuth to form solid solutions of the type $Pb_{1-3x}Bi_{2x}\square_xMoO_4$. When $x = 0$, no catalytic activity towards olefin oxidation is observed but for $x > 0$ increasingly significant activity is observed, reaching a maximum at about $x = 0.06$ for the oxidation of both propylene and 1-butene. Thereafter activity progressively decreases until the end member; $Bi_2(MoO4)_3$ is reached where the catalytic activity is about one-quarter of that of the optimum phase. $Bi_2(MoO4)_3$ has a distorted scheelite type structure in which 2/3 of the A cation sites are filled in an ordered fashion. The ordering of vacancies, shown in Figure 35, is believed to be the principal cause of its reduced activity.

The A cation defects in $Pb_{1-3x}Bi_2MoO_4$ are believed to function as hydrogen acceptor sites during the formation of an allyl intermediate. Oxidation of the intermediate, as established by ^{18}O studies, is accomplished through lattice oxygen at the surface, which is then replenished, by bulk lattice oxygen. This is consistent with the observation that catalytic activity is independent of oxygen partial pressure. Bismuth containing catalysts are rapidly reoxidised. Here the lone pair of electrons on Bi^{+3} are postulated to be directed towards the surface of the catalyst and behave as donor sites for the reduction of O_2 in the gas stream. The A cation defects

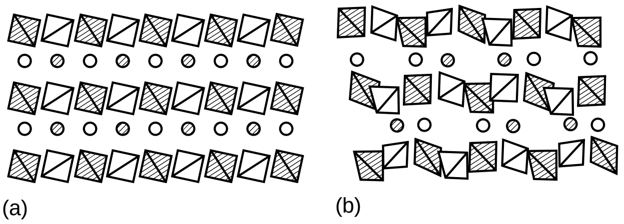

Figure 35 Structure of a regular tetragonal scheelite (a) compared with the distorted, defected structure in $Bi_2Mo_3O_{12}$ (b)

must also play a role in the high mobility of lattice oxygen and its replenishment by the gas stream.

Modern day bismuth molybdate catalysts, in addition to $A_{1-3x}Bi_{2x}MoO_4$ phases, contain other compounds such as Bi_2MoO_6 and $Bi_2Mo_2O_9$ as well as small amounts transition metal molybdates that not only increase conversion rates and selectivity but also increase catalyst lifetime and allow operation at lower temperatures.[107]

5 PREPARATIVE METHODS FOR OXIDES[9,21,50,108–111]

5.1 Direct Synthesis from the Elements

Although the majority of elements will react readily with oxygen, particularly when heated, this method is not used frequently because of the added expense of obtaining the element in a pure and usable form when compared to more convenient and less expensive alternatives. The method is also useful for those metals that do not easily form salts or whose hydrous oxides are difficult to solubilize or purify. Thus, the preferred method for the preparation of Ta_2O_5 is by burning the pure metal in oxygen. Nb_2O_5 can also be prepared in this fashion but less expensive methods are also possible. The highest valent binary oxides known are OsO_4 and RuO_4. The former is readily prepared by heating powdered osmium to red heat in the presence of oxygen. The highly toxic, volatile molecular oxide is collected as a colorless solid (mp 41 °C) in a cold trap. The stable product of the reaction of Ru with oxygen is the dioxide, the tetroxide being best prepared by passing Cl_2 through an alkaline ruthenate solution.

5.2 Decomposition Methods

Oxalates, carbonates, ammonium salts, and related materials often have the advantage that they can be obtained in high purity and the decomposition coproducts are gases. Such reactions may be carried out in air if there is no danger of mixed valency formation. The method is particularly convenient for the preparation of ZnO and CdO, trivalent rare earth oxides, and the lighter alkaline-earth oxides. High purity gallium oxide is prepared by dissolving gallium metal in hydrochloric acid, diluting the solution and adding an excess of oxalic acid to precipitate the highly crystalline gallium oxalate, which is then filtered, washed, and ignited at red heat to give pure Ga_2O_3.

Mg and Ca oxide are easily prepared by igniting the carbonates in air. However, for the Sr and Ba carbonates breaking the C–O is particularly difficult and decomposition of the carbonate is best accomplished by heating in the presence of hydrogen at temperatures above 1200 °C, thus attacking the C–O bond directly.

Decomposition of a mixture of nitrates is often a convenient method for the preparation of mixed transition metal oxides. The success of the method depends upon the fact that typically, the decomposition of the nitrates results in an intimate oxide mixture that readily reacts at higher temperatures to form a homogeneous, complex oxide. Oftentimes nitrate mixtures can be formed as precursors by dissolving a stoichiometric mixture of the oxides or carbonates in nitric acid and evaporating to dryness. This method is one of the options used to prepare the superconducting $YBa_2Cu_3O_{7-\delta}$ and isotypes.

In the case of transition metal oxides, mixed-valence compounds may result if the decomposition is carried out in air. Thus, highly pure NiO and MnO can be obtained by heating the respective carbonates in vacuo while nearly stoichiometric FeO is obtained by the decomposition of its oxalate but it will rapidly pickup oxygen when exposed to air. Conversely, decomposition of $Fe_2(Ox)_3$ yields Fe_2O_3.

More acidic acids, which form oxyanions when reacted with bases, can be prepared in high purity by the decomposition of their ammonium salts. V_2O_5, MoO_3, and WO_3 are conveniently prepared by this method. Zirconium dioxide is obtained by heating the hydrated oxychloride at 600 °C.

5.3 Precipitation Methods

Although precipitation of hydrous oxides from basic solutions might appear to be attractive such materials are often difficult to handle because of their gelatinous nature (*see* ***Sol–Gel Synthesis of Solids*** and see Section 5.5.2). In such cases, one must be sure to use highly pure reactants that yield only volatile electrolytes. High ignition temperatures may be required to obtain the pure oxide. However, there are some notable exceptions. Titanium can be isolated in pure form as $TiCl_4$ or $TiOSO_4$. The chloride reacts spontaneously with water to form hydrous titanium dioxide, which can be ignited to yield pure TiO_2 while $TiOSO_4$, which is soluble in cold water, yields gelatinous TiO_2 when its solutions are heated. Very pure, hydrous aluminum oxide can be obtained from bauxite ore by taking advantage of the amphoteric nature of Al^{+3}. This is subsequently heated to red heat to obtain the anhydrous oxide.

The adverse properties of colloidal precipitates of hydrous oxides can sometimes be avoided by using the technique of homogeneous precipitation whereby high local supersaturations are avoided by slowly generating the precipitating agent, in this case hydroxide ion, in situ. For instance, if urea is added to a solution of a soluble ion salt and the solution warmed to just below boiling, hydroxide ion is slowly generated according to the reaction

$$(NH_2)_2CO + 3H_2O = CO_2 + 2NH_4^+ + 2OH^- \qquad (6)$$

Under these conditions, the formation of the hydrous oxide takes place slowly, which results in a precipitate with an order of magnitude less volume than those formed by direct

precipitation methods. Such materials are much easier to filter and wash, thus yielding a purer product upon ignition. The method has been used successfully for the preparation of the sesquioxides of Al, Ga, Fe, and Bi, and the dioxides of Th and Sn.

Some of the more acidic oxides, such as MoO_3, WO_3, As_2O_3, As_2O_5, and Sb_2O_3 can be obtained from solution as well-defined hydrates or acids, which lose water at low heat to give the pure oxide. Similarly, the hydrous oxides of tetravalent germanium and tin can be ignited at red heat to obtain the pure oxide.

5.4 Flux and Melt Growth Methods[108,111–113]

These are techniques that are commonly used to produce high quality crystals, usually of millimeter size but sometimes several grams or hundreds of grams in weight. Flux growth usually refers to those methods in which a molten salt acts as solvent for the reactant oxides. In some cases, the flux may take part in the reaction. Melt growth usually refers to the growth of crystals from a melt of the same composition. Fluxes may be used in small amounts, for example, 1–5 percent by weight, to promote crystal growth by providing a liquid-solid interface where the crystals can form. More details of these methods can be found elsewhere.[108,109,111–113]

A desirable flux is one that can provide a significant solubility for the starting oxides, melts below 1000 °C and can be handled conveniently at temperatures up to 1500 °C. Crystallization of the desired product may result from a chemical reaction in the melt but more often will be induced by slow cooling. If the flux is volatile at the temperatures used, this property may sometimes be used to promote crystal growth. One of the problems associated with this method is that the superior solvent abilities of the flux often result in attack of refractory oxide containers, thus introducing undesirable foreign ions into the melt, which can adversely affect crystal quality. Such attack can be minimized by operating at as low a temperature as possible, consistent with other growth parameters. More often however, a noble metal crucible such a gold or platinum is used.

The flux method has been used with great success to prepare several high melting refractory oxides that are difficult to prepare by other means. For example, PbF_2 (mp 855 °C) and PbO-PbF_2 mixtures have been used to prepare large, pure α-Al_2O_3 crystals (mp ca. 2050 °C) as well as synthetic rubies and sapphires by suitable melt dopings.[114] PbO and PbO-PbF_2 mixtures have also been used to prepare crystals of many other refractory oxides such as MgO (mp 2800 °C), ZnO (mp 1975 °C), and Y_2O_3 (mp 2475 °C) as well as a variety of ternary oxides such as $BaTiO_3$, $CaMoO_4$, iron spinels of the type MFe_2O_4 (M = a divalent transition metal cation such as Mn, Ni, Fe, Zn, etc.) as well as rare earth iron and aluminum garnets, for example, YFe_5O_{12} and $GdAl_5O_{12}$. Lithium molybdate, Li_2MoO_4 with and without additions of MoO_3 has been used to grow crystals of ThO_2 (mp 3210), BeO (mp 2550 °C), and CeO_2 (mp 2600 °C). A sodium tetraborate flux, $Na_2B_4O_7$ has been used for the growth of UO_2 (mp 2870 °C), HfO_2 (mp 2780 °C), and Cr_2O_3.

One of the drawbacks to flux growth methods is that the crystals may entrap flux so it is desirable where possible to grow crystals from pure melts. Melt methods for growing single crystals were originally developed for low-melting materials (<1500 °C) where crystal growth is initiated by slow cooling of the melt, crystal pulling techniques, or liquid displacement methods. However, these techniques have been adapted so that they can be can be applied to refractory oxides as well. A few of the more important methods are described here.

One of the most widely used techniques is the Bridgeman–Stöckbarger method in which the crucible containing the melt is slowly cooled by passing it down through a vertical furnace (Figure 36(a)). In other variations of the method, the crucible may rest on a grooved pedestal that is mobile. The bottom of the crucible is tapered to a fine point to limit the number of nuclei formed in the crystallization process. The furnace is usually multizoned so that the temperature gradient may be carefully controlled and postsolidification annealing can be carried out. Although the method can be applied conveniently to the growth of such low-melting compounds as $NaNO_3$ (mp 271 °C), it can be adapted for use at much higher temperatures as well. Examples include the growth of $CaWO_4$ and $CaMoO_4$, which melt around 1500 °C, Al_2O_3, Fe_3O_4, U_3O_8, as well as stabilized zirconia single crystals.

The Verneuil method was developed in the early part of this century for the production of precious gems and other high melting oxides such as those of the rare earths. The apparatus is shown in Figure 36(b). Here, a fine powder of the starting material is dispensed from a hopper at a controlled rate and passes through an oxy-hydrogen flame at which the temperatures are in excess of 200 °C. Melting takes place in the flame and the small liquid droplets are deposited on a moving pedestal so that the top of the deposit can be kept at a fixed distance from the flame. Often a seed crystal is used whose top is slightly melted in the process. The introduction of more powerful heat sources, such as the electric arc, arc imaging devices, plasma emission sources, and laser imaging devices, has increased the temperatures available so that it is now possible to produce single crystals of such high melting compounds as CaO and HfO_2.

In the Kyropoulos method, the top of the melt is only slightly above its melting temperature and a seed crystal, which is cooled externally by attaching it to a water cooled heat sink, is placed in contact with the liquid to induce crystallization. The crystal may be rotated and continues to grow in the melt (Figures 37a and b). The size and quality of the crystal produced depends on the temperature gradient induced by the external coolant and the degree to which the temperature of the furnace can be controlled.

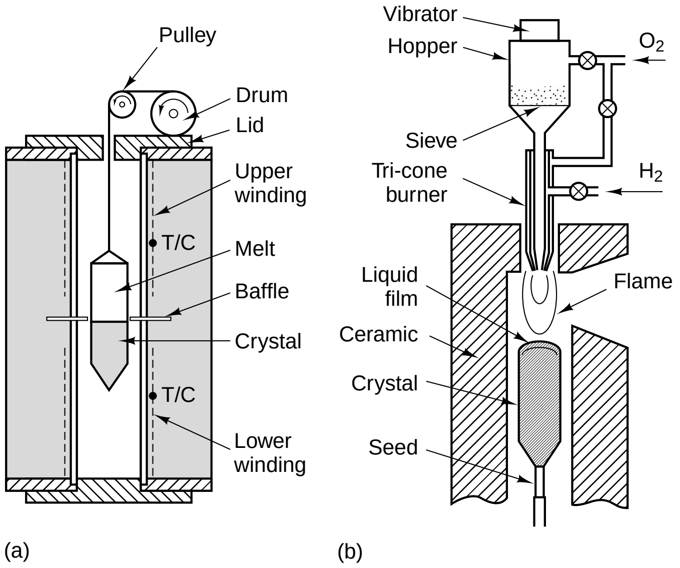

Figure 36 Schematic of the Bridgeman crystal growth method (a). Verneuil crystal growth method (b)

The Czochralski method is an adaptation of the Kyropoulos method in which the rod holding the crystal is allowed to rotate while it is slowly pulled from the melt as shown in the schematic in Figure 37. The method has been exploited for the growth of large single-crystal boules of silicon and germanium for the production of various semiconducting devices but has been applied successfully to the preparation of a variety of complex oxides including Ti_2O_3 $Ln_2Mo_3O_{12}$ (Ln = Gd, Lu), $ZnWO_4$, $Bi_{12}GeO_{20}$, $LiNbO_3$, $LiTiO_3$, $MnFe_2O_4$, $Y_3Al_5O_{12}$ and other rare earth garnets at temperatures from about 1000 °C to over 2000 °C.

For high melting oxides, where container attack is a problem, vertical zone methods have been developed where a vertically held bar of the compound is heated by a moving furnace with a very narrow temperature zone above the melting point of the sample, the liquid region being held in place by surface tension. Provision is made for rotating either end of the sample. For materials melting above 1500 °C, radiation focusing or induction methods may be employed. The former method is preferred for highly resistive materials such as alumina and Ga_2O_3. In some apparatus, provision is also made for pulling the upper portion of the boule. Other 'crucibleless' methods make provisions for the sample itself to serve as the container. One is the so-called skull method where the sample, contained in a water cooled copper vessel is heated by a high intensity radio frequency field such that only the interior of the sample is melted while a thick, solid coating is maintained on the walls of the container. Temperatures up to 3330 °C have been obtained by this method, permitting the growth of single crystals of ThO_2, ZrO_2.[115] Growth can be carried out in reducing atmospheres to produce lower valent binary and mixed-metal oxide crystals.

5.5 Precursor Methods

5.5.1 *Mixed Crystal Method*

One of the difficulties with the classical solid-state reaction is that mechanical mixing methods are relatively ineffective in bringing the solid reactants in contact with one another. Diffusion lengths, on an atomic scale, are still enormous and the temperatures required may preclude the formation of phases that might be stable at intermediate temperatures. One method, called a precursor method, involves the formation of a mixed-metal salt of a volatile organic oxyanion such as oxalate by wet chemical methods, which result in mixing essentially on the atomic level. The salt is then ignited at relatively low temperatures to form the mixed-metal oxide. The method has been applied successfully to the preparation of a number of ternary transition metal oxides with the spinel structure.[109]

5.5.2 *Sol–Gel Methods*[110–112,116–119]

Sol–gel methods are those in which a semirigid gel is formed either by the polymerization of a partially hydrolyzed organometallic compounds such as aluminum alkoxide or by the formation of a colloidal sol, which is then induced to form a gel where the colloidal particles randomly cross-link with one another and entrap great quantities of solvent in the process. The gel product may be a polymer or an amorphous material with particle sizes on the nanometer scale offering numerous advantages provided no foreign ions are present. A popular method, called the citrate or Pecini method has been used to prepare a variety of fine particle sized transition metal oxides containing two or more metal ions. A mixture of citric acid and ethylene glycol is rapidly stirred into a solution of

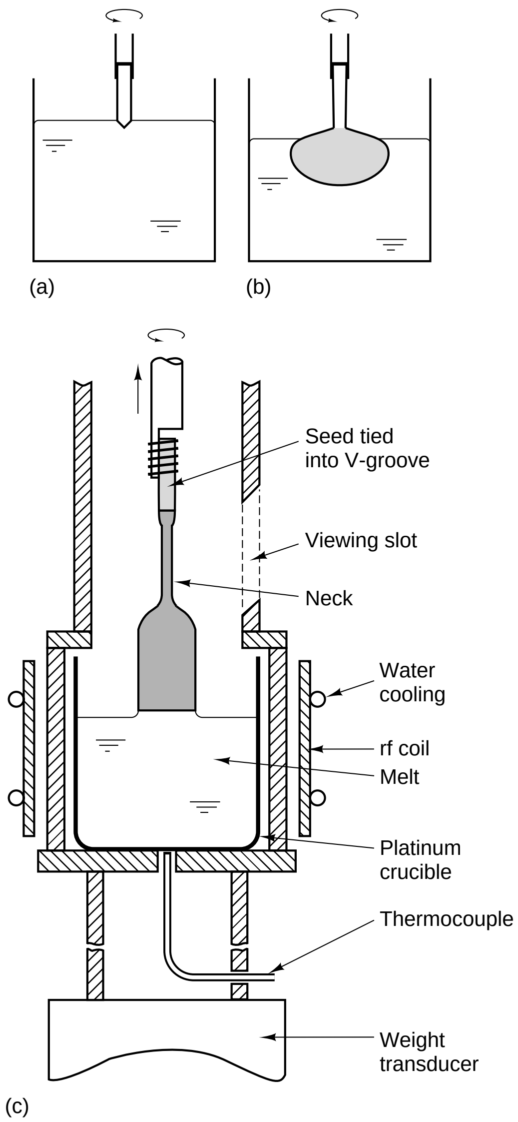

Figure 37 Kyropolis crystal growth method (a), (b). Czochralski crystal growth method (c)

the metal nitrates and lightly heated to dispel nitrogen oxides and to form a gel. The dried material is a complex polymeric material that contains uniform mixture of metal ions. This is then fired at higher temperatures to produce the desired solid.

Typically, much lower firing temperatures can be used to produce a crystalline material than is the case where the starting materials have particles sizes of several microns or more and are mechanically mixed. Since lower temperatures are required to induce reactions, new, metastable phases may be formed that might not form at higher temperatures. A low-temperature route to high density materials offers a route to low defect, high strength ceramics that are inherently impossible to prepare by standard high-temperature methods. Further, the fact that the gels may be spun into wires or precasted into shapes before firing offers a whole host of engineering possibilities (see Section 5.6). A comprehensive description of sol–gel methods for a variety of chemical systems is given in ***Sol–Gel Synthesis of Solids***, while the discussion here is limited to a few examples involving oxide systems.

An important application of the polymerized alkoxide precursor process is the formation of silica gels, carried out in water-ethyl alcohol solutions to which tetraethylorthosilicate Tetraethylorthosilicate TEOS, is added. A small amount of a mineral acid such as HCl or HNO_3 serves as a catalyst for the reaction that involves the formation of hydroxy-orthosilicate intermediate.

$$Si(OC_2H_5)_4 + xH_2O = Si(OC_2H_5)_{4-x}(OH)_x + xC_2H_5OH \qquad (7)$$

The partially hydrolyzed species then condense to form a $(SiO_2)_n$ polymer in the form of a gel along with the elimination of ethyl alcohol. By varying the relative amounts of TEOS, water, and alcohols, different gels may be produced, and they may be spinable, useful for coatings, or able to form monoliths.[117] Silica glasses useful for optical applications are prepared by sintering such gels at 1150 °C. These glasses are relatively free of impurities such as Al, Fe, Cl, or OH as compared to conventional fused quartz prepared at 2000 °C. It is these impurities that limit the transparency and homogeneity of the material.

Transparent, porous semicrystalline aluminium oxide has been prepared by this method as well as coatings of a variety of binary oxides including TiO_2, ZrO_2, Y_2O_3, and SnO_2. The alkoxide method has also been used to prepare such mixed oxides as the fast ion conductor $Na_3Zr_2Si_2PO_{12}$, the ferroelectrics $LiNbO_3$, $BaTiO_3$, and $Sr_xBa_{1-x}Nb_2O_6$ as well as a variety of other perovskite and perovskite based oxides. WO_3 gels may be prepared from sodium tungstate solutions by passing them through an acidified cation-exchange resin. After standing for several hours, a polymeric species of high molecular weight is formed. Thin films of WO_3 have interesting photo- and electrochromic properties that make them attractive candidates for large area display devices. The sol–gel process offers a cheap, rapid, and convenient alternative to vacuum deposition for their preparation.

Colloidal sols of certain transition and inner transition metal hydroxides can be formed by peptization of the precipitated hydroxide by washing it with distilled water to break up the electrical double layer that holds the coagulated colloidal precipitate together. These sols are then concentrated and added dropwise into an alcohol that partially dehydrates them and causes gellation of the droplet. This process has been used, for example, as a precusor to form small spheres of Pr_6O_{11} with 100% theoretical density and for the formation of easily sinterable, finely divided powders of $PbZrO_3$. Dispersed colloidal particles of ThO_2 are treated with a solution of $UO_2(NO_3)_2$ to which ammonia is added slowly, forming a uranium oxide coating on the ThO_2 colloid. This then can be processed to form highly dense nuclear fuel fragments.

Sol–gel methods are used to prepare a heterogeneous, nanometer composite of calcium zirconium phosphate and strontium zirconium phosphate, $Ca_{0.5}Sr_{0.5}Zr_6O_{13}$. In this composite, individual domains both expand and contract upon heating, leading to a material with virtually zero thermal expansion over the range 0–500 °C.

5.6 Intercalation in Oxides[15,111]

Intercalation reactions involve the reversible insertion of foreign ions or molecules into a host species in which, ideally, the basic structure of the host is not disrupted. As the name implies such reactions were once considered to be confined to layered structures where the guest species was inserted into the van der Waals gap. However, modern intercalation chemistry includes numerous examples of three-dimensional host structures flexible enough to accommodate the guest.[119–122]

Intercalation is usually carried out under mild conditions and at relatively lowtemperatures (0–300 °C). Thus, the process offers the opportunity to synthesize new phases that might not be stable at the temperatures required for classical solid-state reactions in oxide systems. Because of the reversible nature of the process, intercalated oxides have also attracted attention for use as reversible electrodes in high energy density batteries (Lithium batteries) and as catalysts for a variety of reactions where selective organic chemistry can be carried out within the host. Intercalation has also been found to induce superconductivity in layered materials or increase T_c where it already existed.[15,122] For example, the intercalation of *Chevrel Phases* has led to a new class of superconductors. Indeed, some look upon the formation of superconducting $YBa_2Cu_3O_7$ and related phases to be the result of the intercalation of oxygen into the insulating phase $YBa_2Cu_3O_6$. For a more general discussion of intercalation and intercalates, (*see* ***Intercalation Chemistry***).

Alkali metal intercalation reactions have been intensively studied for systems involving lithium. Host oxides are those of elements in high oxidation states that possess lower valence states that are also stable in oxides. Lithium intercalation may be carried out by LiI solutions for easily reducible systems, for example,

$$xLiI + V_2O_5 = Li_xV_2O_5 + I_2 \qquad (8)$$

while more difficultly reducible oxides will require treatment with lithium organics, the typical choice being n-butyl lithium (n-BuLi)

$$2x(n\text{-BuLi}) + 2WO_2 = 2Li_xWO_2 + xC_8H_{18} \qquad (9)$$

The reactions are carried in an organic solvent such as hexane using controlled amounts of the lithiating agent.

Crystalline V_2O_5 is somewhat difficult to intercalate but a gel form can be intercalated easily. On the other hand, crystalline $VOPO_4$ has a structure that is more clearly two dimensional than V_2O_5 and forms a variety of intercalates. As in V_2O_5, the V are well off center in the octahedra and their coordination is more square pyramidal than octahedral. This and related compounds of the type $MOXO_4$ (M = V, Nb, Ta, Mo; X = P, As, S) undergo a variety of intercalation reactions under soft conditions with the larger alkali and alkaline earths as well as a variety of organic molecules with electron donors such as long chain alcohols and heterocyclic amines.[120]

$LiBH_4$ has been used for the intercalation of MoO_2 while ReO_3 also undergoes a complex series of intercalation and deintercalation reactions with Li. Other types of intercalations are also possible. MoO_3 has been intercalated successfully to form new hydrogen oxide bronzes H_xMoO_3 with four distinct solid solution ranges for $0.23 \le x \le 1.72$ as well as a phase with the composition $H_{1.99}MoO_3$. They can be prepared by electrolysis of an acidic molybdate solution or by hydrogen 'spillover' reduction with a Pt catalyst.[14] These phases are metallic. Hydrogen molybdenum bronzes may react with strong Lewis bases L, to give layered intercalation compounds $L_nH_xMo_3$.[120] Hydrogen vanadium bronzes can be prepared by similar techniques but these are amorphous semiconductors.

Electrochemical insertion of Li has been intensively studied for use in rechargeable high energy density batteries principally on transition metal disulfides (*see* ***Intercalation Chemistry***). However, the process is also important in the common MnO_2 dry cell where H^+ intercalation occurs, as well as in so-called nickel oxide batteries. Manthiram and Kim have reviewed insertion materials for lithiated batteries and the current status of lithiated batteries is discussed by Takamura.[122,123]

Quasi-layered oxides of the type AMO_2 (A = Li, Na; M = trivalent Ti, V, Cr, Mn, Fe, Co, Ni) prepared by high-temperature solid-state reactions have also been studied as possible cathodes since these materials undergo loss of alkali metal upon treatment with I_2 or Br_2 in acetonitrile. Of these, $LiCoO_2$ is the material of choice in the current generation of lithium batteries. A practical problem here is the expense of Co. However, $LiNiO_2$ doped with 10–30 mole% $LiCoO_2$ shows promise as a replacement.[123]

5.7 Ion Exchange

Ion-exchange methods are those in which a compound containing a mobile ion, usually a cation, is placed in contact with a solution containing a high concentration of another ion of similar size or charge, which is exchanged for an ion in the original solid.

Such reactions can be carried out with those solid-state systems that have large tunnels in them established by the crystallographic architecture or layer compounds in which covalently bound layers are linked to one another by ions inserted between them (*see* ***Intercalation Chemistry***).

β-aluminas such as $Na_2Al_{16}O_{25}$ contain exchangeable sodium ions between weakly connected Al–O slabs. Exchange can be achieved by placing the compound in molten salt baths containing cations such as Li^+, K^+, Ag^+, Cu^+, $NH_4{}^+$, Mg^{+2}, Ca^{+2}, and so on.[124,125] Sodium in $Na_xMo_2O_4$ may be completely exchanged for Li by treatment with excess LiI at 340 °C.[126] This compound is of interest as a possible cathode material for rechargeable lithium batteries. Layered α-$Zr(HPO_4)\cdot 2H_2O$ and related compounds will exchange their phosphate hydrogens for alkali metals by titration with MCl–MOH mixtures.[127,128]

An interesting variation of ion exchange was reported recently where nanometer sized particles of γ-Fe_2O_3 were obtained embedded in a sulfonated polystyrene resin. The resin in its hydrogen form was exchanged with an aqueous solution of Fe, which was subsequently soaked for several hours in a strongly basic NaOH solution. The composite formed is magnetic and transparent. Its magnetization is more than an order of magnitude higher than other known transparent magnetic materials and could find application in magnetic inks for photocopiers, information storage, and magnetic refrigeration.[129]

5.8 Solid-state Reactions

This method is the most common one used for the preparation of mixed-metal oxides. Accurately weighed, stoichiometric amounts of the constituent binary oxides are intimately mixed by grinding or ball milling and heated at high temperatures in refractory containers for several hours or days to produce the desired product. Since the reactions take place by a diffusion mechanism, intimate contact between reactant particles is essential. Reactivity will also be promoted by using finely divided powders with large surface areas. Typically, it is necessary to make intermittent regrindings of the products to promote homogeneity among the particles of any unreacted or partially reacted starting materials since the reactions take place by diffusion. Often, the reactants are pressed into pellets to promote internal reaction and to minimize contact with the container. Ternary oxides such as $BaZrO_3$, $MgAl_2O_4$, $LiNbO_3$, garnets, and so on are prepared in this fashion as are the high-temperature superconductors $YBa_2Cu_3O_{7-x}$ but here the oxygen stoichiometry depends upon the temperature and partial pressure of oxygen.

5.9 Chemical Vapor Transport Methods[21,130,131]

This is one of several specialized methods designed to obtain small quantities of well-formed single crystals of a few tenths to several millimeters in largest dimension. Typically, a charge of polycrystalline material, either the desired material itself or a mixture of oxides, is sealed off in an evacuated silica tube along with a small amount of a volatile transporting agent such as $TeCl_4$, NH_4Cl, Cl_2, I_2, O_2, or water vapor. In some cases, the transporting agent promotes a reaction such as

$$Ru(s) + O_2(g) = RuO_2(s) \tag{10}$$

The tube is heated in a two or three zone furnace, the charge being placed in the hottest zone. The transporting agent reacts with the charge to form one or more gaseous species that then diffuse to the colder end of the tube where decomposition takes place to form the desired compound. Considerable experimentation is often required to determine the optimum parameters for growth. The method has been applied successfully to the preparation of binary oxides such as MoO_2, NbO_2, RuO_2, IrO_2, V_2O_3, Fe_3O_4, ReO_3, Nb_2O_5, and Mo_4O_{11}. In certain circumstances, crystals have been grown of mixed-metal oxides such as $MgTiO_3$, $A_2Mo_3O_8$ (A^{+2} = Zn, Mn, Ni, Fe), ATa_2O_6 (A^{+2} = Mg, Mn, Co, Ni), AWO_4 (A^{+2} = Mg, Mn, Fe, Co, Ni, Zn), ACr_2O_4, and AFe_2O_4 (A^{+2} = Mn, Co, Ni, Fe). In some cases, more than one transporting agent is used.

A primary advantage of this method is that it produces extremely well-formed crystals and, because the transport action is also a method of purification, the products are often of high purity. The principal disadvantages are that the crystals are usually no larger than a few millimeters in largest dimension and the yields are small. The success of the method depends on optimizing the partial pressure of the transport agent and rigorous control of the gradient temperatures to insure stability of growth conditions at the solid-vapor interface.

5.10 Deposition as Thin Films[112]

The deposition of oxides in the form of thin films is essential for the manufacture of electronic devices. These take the form of either physical or chemical methods. Physical methods include evaporation and sputtering either by a plasma discharge, reactive magnetron sputtering or by laser ablation. Sputtering methods are used to make coatings of group 4 and group 5 refractory transition metal oxides for use in optical communication filters.[132] Chemical vapor deposition involves the decomposition of a gas to form a thin-film layer. An example is the decomposition of silane to form a layer of Si, which then can be oxidized to form a thin film of SiO_2. MOCVD methods use volatile organometallic compounds to accomplish the same purpose.[133,134] Numerous oxide films have been prepared by this method including ZrO_2, HfO_2, V_2O_5, superconducting $YBa_2Cu_3O_7$, Lead zirconium titanate PZT, Strontium Bismuth Tantalate SBT ferroelectrics, and conducting ZnO.

5.11 Electrochemical Reduction

Electrochemical reduction of high-temperature solvents to which solute compounds have been added has long been an

important method for the large scale commercial preparation of aluminum, the lighter alkali metals, the alkaline earths, and lanthanides. It is also used to prepare crystal specimens of a variety of low-valent transition metal oxides that cannot be prepared easily by other means. The method is applied with great success to the preparation of reduced, mixed, nonstoichiometric oxides of tungsten with the alkali metals, known as tungsten bronzes, because of their bright colors, metallic luster, and high electrical conductivity. The bronzes have the general formula Na_xWO_3 where $O < x < 1$ and the color depends on the value of x. Typically, WO_3 is added to Na_2WO_4 to form a melt at 700–900 °C in a high density alumina or noble metal crucible. The electrolysis is carried out for several days at low current densities (typically $<10\,\text{ma cm}^{-2}$) using platinum electrodes. The crystals grow on the cathode and single crystals, usually of cubic habit, up to several grams in size can be obtained. The stoichiometry of the crystals obtained depends upon the melt composition. The method has been extended to other tungsten bronze systems and to the related molybdenum oxide bronzes such as $K_{0.30}MoO_3$, $A_{0.9}Mo6O_{17}$, ($A^+ = $ Li, Na, K, Tl) and $K_{0.33}MoO_3$. A more detailed description of electrochemical oxide bronze preparation by this method has been given by Wold and coworkers.[135] In more recent years, the method has been applied successfully to the preparation of a wide variety of low-valent ternary transition metal oxides including vanadium bronzes of the type $Na_xV_2O_5$, a number of vanadium spinel-type oxides, MV_2O_4 ($M^{+2} = $ Mg, Mn, Fe, Co, Zn, Cd), some nonstoichiometric rhenium oxides such as $Na_{0.6}ReO_3$ and $K_{0.3}ReO_3$ as well as stoichiometric $LiReO_3$ and Li_2ReO_3. In addition, a variety of apparently stoichiometric, low-valent molybdenum oxides containing strong metal–metal bonds including $Y_5Mo_2O_{12}$, $La_2Mo_2O_7$, $La_5Mo_4O_{16}$, and $LaMo_8O_{14}$ have been prepared by this method. A more general review of oxide prepared by fused salt electrolysis is given by DeRoy and Besse;[136] (*see also **Intercalation Chemistry***).

Examples of electrochemical oxidation for oxide synthesis are far less numerous than its reductive counterpart. However, the method is regularly used for the production of commercial grade lead dioxide, PbO_2, and for the tough oxide coating found on aluminum siding. It has been used successfully to prepare α-Mn_2O_3, Co_3O_4 as well as Na and Sr doped Colossal magnetoresistance (CMR) oxomanganates phases using a M_2MoO_4-MoO_3 ($M = $ Na, Cs) solvents.[137,138] Well-formed crystals of superconducting ($T_c = 18$ K) $K_xBa_{1-x}BiO_3$, $0.6 \le x \le 0.8$, have been prepared from KOH melts containing Bi_2O_3 as a solute.[139]

5.12 Hydrothermal Methods[21,50,140–142]

Hydrothermal methods provide a specialized synthesis technique where aqueous solutions are placed in a sealed system and then heated above the normal boiling point of water, often near or slightly above the critical temperature of the solvent (374 °C). Usually, the charge has a low solubility in water that sometimes can be enhanced by adjusting the pH. The success of the method hinges upon establishing a suitable temperature gradient, usually between 10 and 50 °C with the cold end being the growth region, over which mass transfer and growth can take place. Seed crystals are normally used to initiate growth. For oxide systems, strongly basic solutions are usually preferred but weakly basic mineralizers such as KF and NH_4Cl have been used for the preparation of $PbTiO_3$ and $NiFe_2O_4$ respectively.

Hydrothermal synthesis methods have been in use for over 150 years to prepare a wide variety of compounds including oxides, sulfates, carbonates, sulfides, and oxyhalides. The primary use of hydrothermal synthesis is to produce good quality single crystals of few millimeters in size but it is also used for the preparation of large amounts of polycrystalline powders. However, considerably larger crystals may also be grown. Without a doubt its most spectacular application has been in the production of high quality single-crystal quartz required for a variety of electronic and optical device applications. Here large autoclaves are used in which single crystals a kilogram or more in weight are produced over a several week period. For other oxides, the results are less spectacular in terms of crystal size and its use is largely limited to laboratory scale preparations, the notable exceptions being the commercial production of zinc oxide and certain zeolitic materials.

Other examples of the types of phases produced include TiO_2, Fe_3O_4, spinels such as $NiFe_2O_4$ and $ZnFe_2O_4$, the ferrimagnetic garnet $Y_5Fe_3O_{12}$, semiprecious stones such as zircon ($ZrSiO_4$) and tourmaline, and such ternary oxides as $AlPO_4$ and $AlAsO_4$.[140,141] A variety of scheelite and wolframite based molybdates and tungstates of the transition metals and rare earths have also been prepared.[143] Although hydrothermal methods are usually considered as a means for the preparation of high-valent oxides, there have been numerous reports of the synthesis of reduced oxides also, such as V_2O_3, V_2O_4, LiV_2O_4, and $K_2Mo_8O_{16}$.[140,144]

One of the problems with the method is that growth rates are extremely slow, often between a 0.01 and 0.1 mm per day (quartz is an exception where rates of $1\,\text{mm day}^{-1}$ are obtained). However, the slow rates are usually offset by the quality of the materials obtained, which in turn is a consequence of the slow growth rate.

Details of the synthesis of zeolites and quartz are given below as examples of two important commercial methods. Large crystals of quartz may be grown hydrothermally from a solution 1 molar in NaOH in which the charge region is held at 400 °C while the growth region is at 360 °C. Pressures of the order of 1.7 kbar are developed. The quartz charge dissolves in the hot region and is transported to the colder region where its solubility is lowered by the convection currents set up by the temperature gradient. The silica then deposits on a high quality single-crystal seeds placed in the cold region.[141,142]

Zeolites are normally prepared under alkaline conditions using a charge of silica, alumina, and a base, typically

an alkali metal hydroxide or organic base that have been prereacted to form a gel. The reactions are carried out at fairly low temperatures, rarely approaching 200 °C and sometimes less than 100 °C. Precipitation methods are often used to prepare large quantities of commercially important zeolites. In a typical zeolite A synthesis, hydrated alumina is dissolved in a concentrated sodium hydroxide solution and upon cooling, a measured amount of sodium metasilicate solution, $Na_2SiO_3{\cdot}9H_2O$, is added to give the desired ratio of Na, Al, and Si such as $2.1Na_2O{\cdot}Al_2O_3{\cdot}2.1SiO_2{\cdot}60H_20$. The mixture reacts to form a white gel, which is then collected and sealed in a plastic bottle, which is then heated for several hours at around 90 °C to induce crystallization. If the heating is allowed to go on for a longer period of time, the zeolitic structure may break down and other materials will be produced. The use of different bases, both inorganic and organic, and different ratios of reactants lead to different classes of zeolites.[143]

Hydrothermal autoclaves are usually placed in a furnace where a temperature gradient can be established between the charge or nutrient region and the growth area. A baffle between the two regions restricts convective flow and sharpens the temperature gradient. Provision may be made to allow adjustments in baffle openings. Seed crystals may or may not be used. Design of the autoclave depends on the internal pressures that are generated, most being made for operation below 600 atm. The typical laboratory autoclave has a working volume of about 100 cm^3 or less but those designed for commercial operations may have diameters of 1 m and heights of 2 m or more. The reaction chamber may be lined with an inert material such as Teflon, gold, or platinum.

5.13 High-Pressure Methods

High-pressure methods are discussed in detail under ***High Pressure Synthesis of Solids***. Hydrothermal methods are discussed in the previous Section. A few examples relative to oxide synthesis are given here. Descriptions of the equipment used are given by Rao and Gopalkrishnan and by Rooymans.[145,146]

An important use of high mechanical pressures is to force solids to assume crystal structures and coordination numbers in which they are normally unstable. Thus, four-coordinate Si in SiO_2, typified by quartz or trydimite, can be forced to assume the six-coordinate rutile structure under very high pressures. Once formed, these structures are kinetically stable. The high-pressure polymorph of silica, called stishovite is found terrestrially as the result of meteor impact.

The same principles can be applied in the laboratory. Goodenough, Longo, and Kafalas have described the application of high pressure to obtain mixed oxides with high coordination numbers.[147] Thus, wurtzite-like $NaAlO_2$ is transformed to a spinel at high pressures while the olivine types phases Ca_2GeO_4 and Sr_2CrO_4, where the transition metal is in fourfold coordination, adopt the K_2NiF_4 structure. $PbRuO_3$ and $BiScO_3$, which have defect pyrochlore structures at atmospheric pressure, adopt the denser perovskite structure at 90 and 70 kbars respectively.

Novel oxidation states can also be achieved by the use of high pressures. The apparently stoichiometric oxides $Sr_{0.5}La_{1.5}Li_{0.5}Fe_{0.5}O_4$ and La_2LiFeO_6 can be prepared under 60 Kbar pressure. These remarkable oxides contain tetravalent and pentavalent iron in an unexpected sixfold coordination with oxygen.[148] Pentavalent chromium, which is extremely difficult to stabilize, is prepared in mixed-valence oxides of the type A_xCrO_3, ($A^+ = $ Na, K, Rb) by heating under 25–65 kbar pressure. These nonperovskite type phases contain both tetrahedral and octahedrally coordinated Cr with an apparent site preference of Cr^{+5} for the octahedral sites.[147]

Tetravalent chromium oxides are not easily prepared at atmospheric pressures but form readily under pressure. Examples include the cubic perovskites $SrCrO_3$, a metal and $PbCrO_3$, a semiconductor. $BaCrO_3$ forms a perovskite related hexagonal phases in several different polytypic intergrowth forms. Cubic alkali molybdenum oxide bronzes, similar to those of tungsten, can only be prepared at high pressures.[149]

High gas pressures of oxygen are used where high oxidation states are difficult to achieve and in systems where the normal pressure phase is substoichiometric with respect to oxygen. These include several alkaline and rare earth oxides of iron, cobalt, nickel, and copper. For instance, $NdNiO_3$ and several other rare earth isotypes were prepared at 950 °C under 60 Kbar of oxygen generated in situ by the decomposition of $KClO_3$ while others have used 150–200 bars of oxygen at 1000 °C with several intermittent regrinding and repelleting steps.[149]

5.14 Chemical Oxidation/Reduction Methods

Many elements form oxides in a number of different valence states whose synthesis requires the use of oxidizing or reducing conditions. Low-valent oxides can often be obtained by heating a higher valent oxide in hydrogen. Careful attention must be paid to the purity of the gas, the temperature, and partial pressure of water vapor. Otherwise a mixture of oxides may result or reduction to the metal takes place. Thus, MoO_2 is produced by hydrogen reduction of MoO_3 at 600–650 °C but Mo metal is the product at 800 °C. Below 600 °C, one gets a variety of mixed-valence oxides. Reduction with carbon can be used for the preparation of many transition metal oxides but the products are usually contaminated with various amounts of carbide, unreacted carbon, or mixed oxides. CO has been used successfully for the preparation of various di- and trivalent oxides of the first period of transition metals.

A common method for preparation of small quantities of reduced oxides is a solid-state reaction of stoichiometric quantities of a higher valent oxide and a lower valent oxide or the metal. The reaction is carried out in an evacuated sealed container, which may be glass, quartz, or metal, but dynamic vacuums or inert gas blankets are also used. The latter

method is especially useful in the preparation of intermediate phases where careful control of the oxygen partial pressure is necessary. The sealed capsule method is one of the more reliable means of obtaining a pure product providing complete reaction can be obtained. Since this requires careful mixing of reactants, usually by grinding, the method is usually limited to the preparation of small quantities.

Often, the highest valent oxide cannot be obtained by the direct combination of the elements and special methods must be used. A general rule of thumb is that basic conditions tend to stabilize high oxidation states. Thus, potassium permanganate is prepared by fusion of MnO_2 in KOH while the unusual 4 and 6 valence states of iron are stabilized by ternary oxide formation in basic media. Potassium nitrate is often used to assist the oxidation. Thus, the hexavalent ferrate K_2FeO_4 is prepared by heating Fe_2O_3 with a mixture of K_2O_2 and KNO_3.

Higher valent oxides of nickel with Ba can be made by basic fusion of NiO to which sodium or barium peroxide has been added. Excess oxygen can be added to $LaNiO_3$ by high-pressure oxygenation. Holland has reported the preparation of $Sr_5Ni_4O_{11}$ by reaction of $SrCO_3$ and NiO in KOH at 700 °C.[150] Low-melting NaOH/KOH mixtures have been used recently to prepare superconducting $La_{(2-x)}Sr_xCuO_4$.[151] These caustic mixtures are saturated with H_2O and melt at temperatures below 200 °C, thus offering a low-temperature route to the synthesis of metastable phases.

5.15 Synthesis of Multiple Perovskites by Metathesis

Several oxides with a double, triple, and even quadrupled perovskite formula units, $(AA')_n(BB')_nO3_n$ ($n = 2$, 3 and 4), have been known for some time. In the ideal formulation, the B and B′ cations, of necessity, should be ordered although the degree of ordering may vary depending on the synthetic conditions, oxide ion defects, and chemical compatibility between the B-site ions. In the absence of an ordered B-site sublattice, these compounds should be regarded as simple perovskites. In general, the ordering of B-site ions is rock-salt-like although there are examples showing a layered-order. An excellent compilation of the work carried out up to 1970 detailing the structure and properties of multiple perovskites is available in the literature.[152] A critical survey of nearly 300 oxides with double perovskite structure has illustrated the importance of chemical, geometrical, and valence factors that influence the ordering of the B and B′ cations.[153]

An interesting aspect of the multiple perovskites is their ability to accommodate mono- and divalent cations at the B-site, which is not possible with a simple perovskite formulation.

In the last decade, study of double perovskites has accelerated with the discovery of tunneling magnetoresistive (TMR) effects in $Sr_2FeMoO_{6.156}N$. Both the magnetism and transport in these oxides is strongly influenced by the cationic nature and the order/disorder of the ions at the B-site. Ferromagnetism and half-metallic properties are often observed in the $A_2BB'O_6$ oxides with $BB' = CrW$, CrRe, FeMo, or FeRe and $A = Ca$, Sr or Ba. The simultaneous presence of magnetism and transport also make these materials attractive for spintronics applications.

Recently, the synthesis of truly triple and quadruple perovskites has been reported in the literature by way of metathesis reactions. The low temperatures routes are necessary to realize the formation of otherwise meta-stable phases. Articles describing the utility of topotactic methods for the synthesis of several perovskite and related phases can be found elsewhere.[154,155,156]

6 SOME APPLICATIONS OF OXIDES[157–159]

Oxides are among the most useful compounds known and find a wide variety of applications in all walks of life from heavy construction to microelectronic circuits. Oxide based minerals along with sulfides are often the primary source of most metallic elements and their compounds but, for the most part, their extraction and purification will not be a part of this discussion. Other high volume oxides such as Al_2O_3, CaO, and TiO_2, and particularly SiO_2 have important applications in their own right.[157]

6.1 Applications of Magnetic Oxides

The useful properties of magnetic materials depend upon the existence of a net magnetic moment beyond that predicted by the Curie–Weiss Law (*see Curie Constant*) as the result of spin interactions between ions with unpaired electrons. For a discussion of the origins and types of cooperative magnetic effects observed in oxide systems, *see* ***Magnetic Oxides*** and ***Magnetism of Extended Arrays in Inorganic Solids***.

Most commercially useful magnetic oxides are (*see Ferrimagnetism*) often called ‘ferrites’ and contain Fe^{+3} as a major component. A notable exception is ferromagnetic CrO_2, which is used in high quality magnetic tapes (*see Ferrimagnetism*). Ferrites can be divided into three main classifications: (1) Spinel-type oxides (Section 3.4.2); (2) Hexagonal ferrites based on the magnetoplumbite structure (Section 3.11); and (3) Rare earth ion garnets (Section 3.4.3). These phases are particularly useful because, unlike most conventional magnetic materials, they can be prepared with very high electrical resistances, resulting in low-energy loss properties. Rare earth iron garnets can be prepared with resistivities exceeding 10^{12} ohm-cm, making them particularly valuable for high frequency (microwave) applications.

Most spinel ferrites used in device applications are not simple ternary oxides but rather contain proprietary mixtures of several different magnetic ions tailor made for specific applications.[160] So-called (Mn, Zn) ferrites of general formula $Zn^{+2}{}_x\ Fe^{+3}{}_{1-x}[Mn^{+2}{}_{1-xF}\ ]O_4$ and related (Ni, Zn) ferrites

are used as cores for inductors or transformers and in TV deflector yokes. (Mg, Mn) ferrites and yttrium iron garnets including those partially substituted by Al or Gd find numerous applications in microwave circuitry.[161]

One of the biggest applications of magnetic oxides is for information storage. Computer memories typically utilize (Mn, Mg) based spinels. Hexagonal barium ferrites are used in floppy discs. Fe_3O_4 is used as a magnetic toner in photocopiers and as a magnetic printing ink while the defect spinel γ-Fe_2O_3 and γ-Fe_2O_3/Fe_3O_4 mixtures compete with ferromagnetic CrO_2 for the audio and video magnetic tape market.[162] In addition to composition, the shape and size of the particles plays a crucial role in the quality and performance of the tape. In this respect CrO_2 is superior because of its normal, needle-like crystal habit.

6.2 Oxide Sensors

Sensors are materials that produce a reversible and reproducible electrical response to various physical or chemical changes that can be used to automatically control a given process. There is an expanding list of processes that could be controlled with inexpensive microprocessors if the right sensor was available. There exist a variety of oxides with sensitive responses to changes in temperature, pressure, or gas ambient.[160] A few examples will be given here.

Temperature sensors include thermistors such as doped $BaTiO_3$ and $Ni_{0.6}Mn_{2.4}O_4$ that have large temperature coefficients of resistance. $BaTiO_3$ and $PbZrO_3$-$PbTiO_3$ solid solutions (PZT) show anomalously large changes in resistivity as their ferroelectric-paraelectric transition is approached, which makes them useful as switches. Switching temperatures can be adjusted by varying the solid solution composition and by the addition of other dopants (*see Ferroelectricity*). Stabilized, cubic zirconia acts as an oxygen sensor since changes in O_2 partial pressure affect its ionic conductivity. Ti^{+4} doped $MgCr_2O_4$ (a p-type semiconductor) acts as a humidity sensor. Suitably doped SnO_2 responds to the presence of hydrocarbon gases. Piezoelectric materials, such as lead zirconate $PbZrO_3$, PZT, and α-quartz, are substances that produce an electrical signal under pressure. Long established as acoustical pickups in hydrophones and phonographs, they now find application as micromechanical positioners, ultrasonic cleaners, small high quality loud speakers ('piezo speakers'), gas igniters, sensors in automobile suspension systems, transformers, and filters.[163]

6.3 Luminescent Materials[164]

Luminescent oxides (or phosphors) play an important role in television receivers and other cathode ray tube (CRT) applications, fluorescent lamps, scintillation counters, and information display devices including CRT and flat panel display (FPD) as well as the emerging plasma display panels (PDP). Although some materials exhibit intrinsic luminescence, most phosphors are obtained by doping suitable hosts with small amounts of a foreign substance (called the activator), which provides the necessary defect levels to produce luminescence when stimulated by shorter wavelength light (photoluminescence) or by bombardment with electrons in vacuo (cathodoluminescence). The mechanisms of these interactions are discussed in ***Luminescence***.

Production of good phosphors requires rigorous attention to synthesis or activation conditions. Careful control of activator concentrations, usually measured in parts per million, is essential. Multiple activators may be necessary to achieve the desired color, brightness, response or decay times. Virtually unmeasurable, trace amounts of unwanted substances may have such severe deleterious effects on phosphor performance that the materials are usually produced under clean room conditions rivaling those used in the production of silicon based integrated circuits.[164]

Some examples of commercial luminescent oxides are Mn doped willemite, Zn_2SiO_4:Mn, a standard green phosphor with wide application, $CaSiO_3$:Pb, Mn, an orange phosphor used in radar screens because of its long persistence, $Ca_2MgSi_2O_7$:Ce, an ultraviolet emitting phosphor used in flying spot scanners and photography, and $Zn_3(PO_4)_2$:Mn, an old, standard red phosphor for color TV. Other red phosphors developed specifically for color TV include YVO_4, Y_2O_3 and Gd_2O_3 as well as the oxysulfides R_2O_2S (R^{+3} = Y, La, Gd), all of which must be doped with small amounts of europium. A very short persistence yellow–green phosphor can be obtained by doping the yttrium aluminum garnet $Y_3Al_5O_{12}$ with cerium.[165]

In fluorescent lamps, an electrical discharge produces UV emission, which stimulates the emission of visible light from a phosphor coated on the walls of the tube. Early 'white' lamps used Mn doped willemite resulting in an orange cast and were replaced by a heavily Be^{+2} doped material. The highly toxic nature of beryllium salts eventually led to their replacement by materials such as the halophosphate $Ca_5(PO_4)_3X$:Mn,Sb (X^- = Cl, F). In these multiply activated phosphors, the color balance may be varied by changing the relative amount of each activator. Other important host materials include $CaWO_4$, YVO_4, $Cd_2B_2O_5$, and $MgGa_2O_4$.

A relatively new class of luminescent materials are the β''-aluminas. Sodium β'' alumina when doped with approximately 10^{19} Cu^{+2} cm^{-3} has a visible emission in the green, which can be tuned from the blue to the red by the addition of codopants such as Ca^{+2}, Ba^{+2}, or Ag^{+}.[166]

Europium doped barium aluminates of the type $Ba_{1-x}Eu_xMg_2Al_{16}O_{27}$ are used as a blue component in fluorescent lamps, and are also being investigated for possible use in flat panel displays.[167] The crystal structure of this material is characterized by an intergrowth of spinel and magnetoplumbite units (See 3.4.2 and 3.11).

A historical review of the development of luminescent materials is given by Chen and Lockwood.[168]

6.4 Colossal Magnetoresistive Perovskites

Lanthanide oxomanganates attracted renewed attention in the 1990s because of the discovery of an anomalously high magnetoresistance in several of these perovskite related phases, referred to as colossal magnetoresistance (CMR).[169,170] The phenomenon of magnetoresistance, a change in the resistance of a material in the presence of a magnetic field, forms the basis for current devices used in data retrieval and recording technology such phase are potentially of great practical interest provided certain processing problems related to mass production can be overcome.

$LaMnO_3$ is a prototype for a wide range of rare earth oxomanganates whose physical properties can be radically altered by partial substitution of alkaline earths for La or by similar replacement of Mn by a 3d or other small to medium sized cation. $La_{1-x}A_xMnO3$ (A = Ca, Sr, Ba) constitutes one of the more interesting systems for CMR applications. Pure stoichiometric $LaMnO_3$ is an insulator that orders antiferromagnetically at 135 K and it is only by introducing a critical amount of Mn^{+4} into the structure that the CMR effect can be observed. Thus, some comment about the nature of the defect chemistry of $LaMnO_3$ is in order.

The actual stoichiometry of nominal $LaMnO_3$ is strongly dependant upon the method of preparation. Samples can be made by solid-state reactions of constituent oxides but sol–gel or other precursor precipitation reactions are preferred where the products are subsequently fired at high temperatures in atmospheres having various partial pressures of oxygen.[170–172] As mentioned in Section 3.11, the variable oxygen stoichiometry of $LaMnO_3$ is often represented by a chemical formula such as $LaMnO_{3+\delta}$ implying an ‘excess’ of oxygen where, in fact, the actual vacancies are on the cation sites. Unfortunately, the simplicity of the oxygen excess formula has resulted in its continued use in spite of its incorrect implications. However, defect stoichiometries in lanthanide oxomanganates are not limited to oxygen. Indeed, $LaMnO_3$ could fairly be called ‘Daltons nightmare’ since nonstoichiometry can exist not only on the oxygen sites but also on the La and Mn sites as well. In fact, all three may simultaneously exist in the same compound at the same time. Thus, to produce materials with the desired properties, careful control of synthesis conditions is essential.

The effects of firing conditions on samples whose La:Mn ratio is fixed at 1 is illustrated by the following data reported by Hauback and coworkers.[170] If the sample is fired in Ar at 1000 °C, it has the composition $LaMnO_{3.00}$ and a structure that is an orthorhombic distortion of the cubic perovskite. If the sample is heated in air at 750 °C, a sample with a rhombohedral perovskite structure results that becomes ferromagnetic at low temperatures before transforming at 9 K to the ORTH 1 variant of the $GdFeO_3$ structure. On the other hand if the firing temperature is lowered to 900 °C, δ increases to 0.09 and a phase with a rhombohedral modification of perovskite is formed. If the La/Mn ratio is lowered to 0.88, firing at 750 °C results in a rhombohedral phase with $\delta = -0.08$ that becomes ferromagnetic at 248 K. Ferromagnetism is believed to occur in these systems via the so-called double exchange mechanism, which requires that a critical amount of Mn^{+3} be replaced by Mn^{+4}, the amount of which also affects the critical temperature, T_c, at which the transition occurs.

While CMR is observed at low temperatures in metal deficient $LaMnO_3$, the highest T_c observed is only around 250 K for phases with compositions $La_{0.94}Mn_{0.98}O_3$ and $La_{0.90}MnO_{3-\delta}$. However, partial replacement of La by Sr in $La_{1-x}A_xMnO_3$ in bulk samples with $x = 0.20–0.30$ results in a material that is ferromagnetic at room temperature and above. It typically displays MR values between 30 and 45%, depending upon the method of preparation, in 5 to 7 tesla fields. These samples have rhombohedral structures are essentially stoichiometric with respect to oxygen.[171,172] Near room temperature CMR can also be achieved by doping $LaMnO_3$ with approximately 10 mole% Na.[137] The crystal chemistry and properties of $Ln_{1-x}A_xMnO_3$ materials are described by Raveau and coworkers.[173] In order for CMR materials to be useful for device applications, they must be able to be prepared reproducibly in the form of thin films. Various techniques for such thin-film deposition have been explored such as molecular beam epitaxy (MBE), pulsed laser deposition (PLD), and metal organic chemical vapor deposition.[174] So-called charge ordering, where Mn^{+3} and Mn^{+4} order on crystallographic sites, is prevalent in $La_{1-x}A_xMnO_3$ phases and can have dramatic effects on CMR properties.[175,176]

The observation of room temperature CMR in the ordered double perovskite Sr_2FeMoO_6 has sparked renewed interest in this class of compounds.[177] Similar effects are seen when Fe is replaced by Fe, Co or Mn, or Mo partially replaced by W.[178,179]

6.5 Materials for Solid Oxide Fuel Cells[180]

There is great interest in fuel cells since they offer the possibility of nonpolluting power sources of high efficiency that use methane, or preferably, hydrogen as a fuel.

One of the more important fuel cells is the solid oxide fuel cell Solid oxide fuel cell (SOFC), since they offer a realistic opportunity for use in electric utility operations. A schematic of a fuel cell is shown in Figure 38. These can be developed in stacks having 5–10 kW capacity that would be suitable for both stationary and mobile power units.

The basic elements of a SOFC are (1) a cathode, typically a rare earth transition metal perovskite oxide, where oxygen from air is reduced to oxide ions, which then migrate through a solid electrolyte (2) into the anode, (3) where they combine electrochemically with to produce water if hydrogen is the fuel or water and carbon dioxide if methane is used. Carbon monoxide may also be used as a fuel. The solid electrolyte is typically a yttrium or calcium stabilized zirconia fast oxide ion conductor. However, in order to achieve acceptable anion mobility, the cell must be operated at about 1000 °C. This requirement is the main drawback to SOFCs. The standard anode is a Nickel–Zirconia cermet.

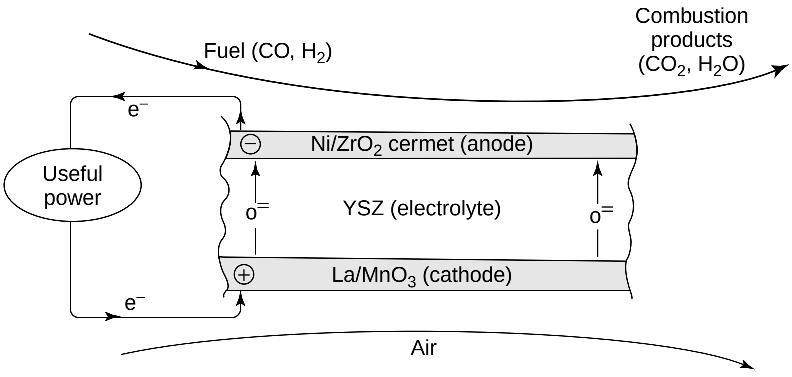

Figure 38 Schematic of a Solid Oxide Fuel Cell

Strontium substituted lanthanum oxomanganates, $La_{1-x}Sr_x MnO_3$ ($x = 0.1-0.3$) (LSM) are the current cathode materials of for choice in SOFCs. These phases have excellent electronic conductivity but their ionic conductivity is poor even at 1000 °C so that attempts to operate at lower temperatures give unacceptably high resistive effects. This can, in part, be ameliorated by forming a composite with yttrium stabilized zirconia, but even these cannot operate below 800 °C. Other perovskite oxides that have higher ionic conductivities are strontium doped lanthanum oxocobaltates and oxoferrates, which have conductivities 2 to 3 order of magnitude higher than LSM. Unfortunately, cobaltates react with the zirconia electrolytes and the electronic conductivity of the ferrate based materials is too low. However, the use of gadolinium doped CeO_2 electrolyte in combination with a Sr and Fe doped lanthanum cobaltate is being explored, which may overcome these problems.[181]

The interconnecting material used in building a stack of fuel cells must have a high electrical conductivity and a coefficient of expansion similar to that of the electrolyte. The perovskite oxide $LaCrO_3$ meets these requirements nicely and is widely used although ferritic stainless steels have been used successfully in certain fuel cell geometries.[182,183]

6.6 Ferroelectric Materials[184–186]

Ferroelectrics are high dielectric materials that are easily polarized in an electric field and can remain polarized to some degree after the field is removed. Such properties make them ideal candidates for computer memory applications and they have been used in the form of thin films as ferroelectric random access memories (FeRAMs) and as high permittivity dielectrics for Dynamic Random Access Memory DRAMs. They have also been looked at as a replacement for silicon dioxide in certain MOS applications.

Materials of particular interest are the perovskite oxides $BaTiO_3$-$SrTiO_3$ (BST) and $PbZrO_3$-$PbTiO_3$ (PZT) solid solutions as well as the layered perovskites based upon $SrBi_2Ta_2O_9$ (SBT). Since the ferroelectric effect requires a lack of a center of symmetry, all of these phases must necessarily have a structure that is distorted from the ideal cubic structure described previously. No one material has the ideal properties and current research centers on achieving optimal performance by modifying existing materials while also search for new ones. To be useful for memory applications, the materials must be prepared in the form of thin films. This appears to be well worked out for PZT where the chemical vapor deposition method is routinely used.

Films with 47 mole% $PbTiO_3$ have optimal properties. BST containing about 70 mole% $BaTiO_3$ appears to be the an attractive material for DRAMs where large dielectric constants can be achieved that are necessary for high storage capacities, provided a satisfactory method for preparing thin films can be found. SBT is of interest because of its remarkably high resistance to polarization fatigue. In addition, lead-free SBT also offers an environmentally friendly alternative to PZT but its efficacy remains to be proved.

6.7 Optical Materials

While silicate-based glasses and quartz still play an important role in the optics industry, there has been a dramatic growth in the use of Nonlinear Optical (NLO) materials for use with high intensity beams of radiation generated by laser sources (*see* ***Noncrystalline Solids***; and Section 6.5). NLO materials provide an effective means of doubling the frequency of an incident light beam and electronically processing optical signals of high intensity such as those generated by lasers. NLO materials play an important role in the development of optically based computers.

Nonlinear optical oxides are typically d^0, acentric compounds. Useful materials include $LiIO_3$, KH_2PO_4, $KB_5O_8 \cdot 4H0$, and $KTiOPO_4$, which are used as harmonic generators, frequency mixers, and parametric oscillators in the UV, visible and near IR regions. Another class of oxides is the so-called electro-optic materials in which electric fields may be used to control light beams.[187] Such materials need not be acentric but they often are. La doped lead lanthanum zirconium

titanates (PLZT) are transparent electro-optic materials for the 0.4 to 6 µm region. Other electro-optic oxides are $K(Ta,Nb)O_3$, $LiTaO_3$ and $BaNaNb_5O_{15}$. $LiNbO_3$ finds many uses in optical communications. Its primary use is as an optical modulator but it can also be used as a laser, waveguide, or light emitting diode.[188] SiO_2 coatings doped with refractory oxides such as HfO_2 or Nb_2O_5 are an important material for optical communication filters.[132]

Oxide lasers include the Cr doped Al_2O_3 ruby laser, Nd doped Yttrium iron garnet (Nd:YAG), and the Nd doped silicate and phosphate glass lasers. Nd:YAG lasers have high radiant power outputs and are used for pumping tunable dye lasers. SiO_2 coatings doped with refractory oxides such as HfO_2 or Nb_2O_5 are an important material for optical communication flters.[132]

6.8 Dilute Magnetic Semiconductors

Materials that exhibit ferromagnetism and semiconductivity simultaneously at room temperature are important for magneto-optoelectronics and spintronics applications.[189,190] The rationale here seems to integrate the functionality of the magnetic storage and semiconductor driven processor technologies into one single material. Although there are many materials that are either ferromagnetic or semiconducting, there are very few that display both. Until recently, the study of DMS has been limited to III to IV pnictides doped with transition metals such as Mn. However, currently the search has been extended to oxides and led to the development of Co doped anatase form of TiO_2 and Mn doped ZnO.[191,192] In the Co doped TiO_2, the question of whether the magnetism is intrinsic (carrier-induced) or due to elemental cobalt atom-clustering has not been resolved unambiguously. In the case of Mn doped ZnO, ferromagnetic ordering seems to be intrinsic although the exact composition of this phase is unclear. While the precise origin of ferromagnetism is currently debated, the hope for discovering new oxide systems however remains high.

6.9 Other Electronic Applications of Oxides

By this term, we mean other uses of oxides such as insulating substrates, capacitors, resistors, and conductors in electronic circuits. Insulating oxides are used in electrical circuits for such jobs as the separation of conductors, mechanical supports, heat sinks, and capacitor materials. Classical materials include naturally occurring minerals or manufactured composites such as zircon, steatite, mica, quartz, porcelain, and glass. The latter was particularly useful in low stress situations because of its low cost and the ease of forming it into desired shapes.

While these materials still find some application, such materials as alumina, beryllia, and single-crystal corundum find increasing use in high-power applications for heat dissipation because of their relatively high thermal conductivity. Classical ceramic capacitors with dielectric constants of the order of 10 largely have been replaced by $BaTiO_3$ based materials that can have combined dielectric constants of a 1000 or more (10^5 in composite, grain boundary barrier layer capacitors) and exceptionally low dielectric loss. Useful composites include $(Ba,Mg)(Ti,Sn)O_3$, $(Ba,Sr,Ca)TiO_3$ and $BaTiO_3/Bi_2(SnO_3)_3$. $BaTiO_3$ shows a large increase in its resistance near 130 °C, which allows it to function as a surge protector in electrical devices. $Ba_2Ti_9O_{20}$ finds use as a microwave filter for radio communications networks.[193]

Certain semiconductor device fabrication methods require the formation of a single-crystal deposit of the semiconductor on an insulating substrate. In epitaxial methods, the semiconductor is deposited on a single-crystal piece of substrate chosen, in part, on the basis of the match of the lattice parameters, thermal expansion coefficients and chemical compatibility of the substrate and deposit. Single-crystal substrates include those of Al_2O_3, $MgAl_2O_4$, α-quartz and $ZrSiO_4$.[194]

ZnO varistors are high resistance, semiconducting devices that, because of their highly nonlinear current-voltage characteristics, are used to mitigate power surges in electronic circuits and electric power transmission lines by providing an emergency conduit to ground. Their electrical behavior appears to be determined by grain boundary effects. Optimum characteristics are obtained by the addition of small amount of various transition metal and main group oxides.[195,196]

Conducting RuO_2 and the pyrochlore $BiRu_2O_7$ are used in the formation of conductive thick films on substrates where conventional conductors would be destroyed under the conditions required to achieve suitable bonding between the two. RuO_2, IrO_2, Tl_2O_3, $Bi_2Ru_2O_7$, and $Pb_2Ru_2O_6$ are also in the preparation of glass composite resistors.

Transparent, conducting, tin oxide coatings are used in applications where light must pass through the substrate in order to strike the active element such as a photoconductive or photoelectric material. Chemically deposited films of silicon dioxide serve as masks on semiconductor materials for selective doping in the preparation of integrated circuits that can later be removed by chemical etching.

6.10 Ceramics and Refractories[197]

These areas represent another huge market for oxide based materials. Traditional silicate-based materials are those stable to about 1000–1100 °C and that are used for porcelain chinas, dishware, electric insulators, and other low stress industrial applications.

More specialized ceramics include refractory silicates such as mullite, $Al_6Si_2O_{13}$, or binary oxides such as MgO, Al_2O_3, TiO_2, or stabilized zirconia, which are fired and sintered, sometimes under pressure at 1500–2000 °C. A great deal of this refractory production involves the fabrication of low and medium density fire-bricks for ovens and furnaces.

These include inexpensive, high silica content fire clay bricks produced from silica and clays used in glass making furnaces and alumina-rich bricks ranging from 50 to 85% Al_2O_3 that are used as furnace linings for making steel. Because of their resistance to basic slags, they are also employed in certain cement and glassmaking operations. Sintered magnesia bricks containing up to 80% MgO, and fosterite bricks (approximately 50% fosterite, $(Mg, Fe)_2SiO_4$ and 50% MgO) are used as liners in steel making furnaces and in nonferrous metallurgy.[197]

High purity binary oxides such as BeO, MgO, Al_2O_3, TiO_2, And stabilized zirconia are sintered under pressure to produce high density ceramic ware, particularly crucibles and other containers for use in nonferrous metallurgy and other specialized applications where temperature resistance and corrosion are a problem. Titania is also formed in honeycomb arrays for use as catalyst supports.

In all of these materials, the ceramic consists of grains or crystallites having dimensions of 10^2 to 10^4 nm. It is in the grain boundary regions where impurity phases, formed at high temperatures, tend to congregate and form a glass-like binder. It is this type of defect that gives the classical ceramics their notorious brittleness and poor mechanical properties that limit their usefulness.

Modern ceramic materials with microstructures in the 1–100 nm region are precast into desired shapes as sol–gel precursors (see Section 5.5) and then crystallized at high temperatures. Alternatively, the gel may be prepared as a low-temperature glass and machined or spun into wires or fibres. These are then crystallized by firing at higher temperatures. Because of the small particle size of the colloidal precursor, grain size is greatly reduced and much lower firing temperatures are possible, reducing or even eliminating grain boundary problems and yielding materials with superior mechanical properties. Applications already exist in the production of flaw-free optical materials and fuel-efficient ceramic prototype engines have been made for operation at high temperatures. Glass ceramic techniques show some promise for the preparation of flexible wires of the new high-temperature superconducting cuprate oxides.

6.11 Miscellaneous Specialized Applications[157,187]

In addition to its use as a specialized refractory, great quantities of CaO are used for the fabrication of construction materials and the manufacture of concrete also serves as a trap for desulfurization of flue gases. CaO is obtained by the decomposition of calcite, $CaCO_3$, at 1000 °C. Much of it is converted to slaked lime, $Ca(OH)_2{\cdot}2H2_O$. Slaked lime is used as a whitewash for buildings. BeO is used as an admixture in nuclear fuels because of its superior properties as a neutron moderator.

Yttria and the rare earths find a variety of specialized applications. Y_2O_3 is used to produce yttria stabilized zirconia ceramics. Cerium, neodynium, and didymium oxides (a mixture of the heavier rare earth oxides) are used to reduce discoloration in glass screens of color television sets caused by small amounts of iron(III) oxide. Ceric oxide is also used as an opacifier in white porcelain enamels and as a optical polishing agent. Other rare earths are used as core materials for arc carbons to increase luminosity and spectral balance. A number are used as coloring agents in ceramics, the more notable being praseodymium oxide, which imparts a brilliant yellow to zirconium silicate glazes. Small amounts are used in the manufacture of rare earth iron garnet magnets. There is also some demand for rare earth-borate glasses because of their high refractive indices. Certain rare earth transition metal oxides are used as hosts for luminescent materials (see Section 6.3).[198]

A large multibillion dollar market ($2.5 billion in the United States alone in 2002) exists for inorganic metal oxides for use as pigments for paints and coatings, printing inks, and coloring agents for plastics, enamels, and ceramics. Most pigments produced today are synthetic, tailor made to meet exacting standards with respect to color, application, and weathering. Natural pigments, mainly iron oxides, account for only about 3% of world production. White titanium dioxide accounts for over 2/3 of the pigment market world wide, while iron based pigments account for another 1/6 of the market. The latter are relatively cheap and are used in construction where color is secondary. White zinc oxide is used as a colorant and antifungal agent in polymer composites. Other important colored oxide pigments are Cr_2O_3 (green), $PbCrO_4$ (chrome yellow), $Pb(Cr,Mo,S)O_4$ (molybdate red), $(Fe_{1-x}Mn_x)_2O_3$ (black to red–brown), and $CoAl_2O_4$ (cobalt blue).[157] Mica is an important component in the production of the currently popular bright, pearlescent coatings. Ultramarines, particularly the blue often found in fine porcelain china, are valued by artists for their bright, vivid hues.[198]

TiO_2, beyond its use in paints and coatings, is also used as an additive for the production of glossy paper. Doped with group 5 and 6 oxides it serves as an effective ceramic substrate for the catalytic removal of NO_x from flue gases.

The worldwide production of bauxite (unrefined alumina) in 1999 was 127 million tons. Approximately 85% was used for the production of the metal. The remainder was used in the fabrication of refractory materials, abrasives, 'hard' concretes, aluminum-based chemicals and as a filler for plastics and toothpaste. Activated alumina is used as a desiccant, filtering media, chromatographic column packing, and as an inert support for finely divided catalytic materials. Many applications exist for boron oxide, B_2O_3, such as in the manufacture of borosilicate glasses, welding and soldering fluxes, water softeners, and detergents. It is the product of ignition of boric acid, obtained by the addition of strong acids to borates, principally sodium tetraborate (borax) found in large natural deposits (*see* ***Borates: Solid-state Chemistry***).

Pure vitreous silica has important laboratory applications as containers in the 1000–1300 °C range and is used for

optics in the ultraviolet region. The grades may vary widely depending upon the method of preparation. Silica glasses made by flame fusion may contain significant amounts of hydroxyl impurity, which has a deleterious effect on its optical properties. The sol–gel method of synthesis (Section 5.5.2) offers a means of overcoming impurity and structural problems associated with high-temperature processing. Quartz is valued for its piezoelectric properties and finds use in quartz crystal oscillators and various electro-mechanical transducers. Amorphous silicas are used as drying agents, catalyst supports, fillers, binders, and stiffeners in waxes and fibers. So-called food grade silica may be used as an additive but finely divided crystalline silica dusts are a lethal hazard and are cited as the main cause of the lung disease known as silicosis. Sodium silicates are used for detergents. Their solutions are important precursors for the synthesis of zeolites.

Many oxides and oxide mixtures are used as catalysts and catalyst supports (*see* ***Oxide Catalysts in Solid-state Chemistry***).

1 INTRODUCTION

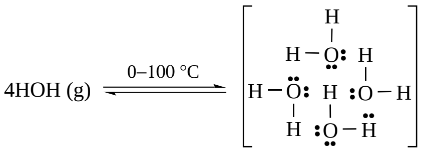
Dioxygen, produced by photosynthetic bacteria more than two billion years ago, makes up 21% of the atmosphere of the earth. Oxygen is ubiquitous both in inorganic minerals and in all living things, where it is a key component of proteins and carbohydrates, for example. Unlike any other molecule in the atmosphere, oxygen, in its ozone allotrope protects the earth by filtering out harmful UV-C and UV-B radiation. The many disparate uses for oxygen rely on the fact that the molecule is reactive and can be converted into many other reactive oxygen species. This review will describe how these additional oxygen species are formed, give some basic chemical information, and offer a brief description of the important reactions these species participate in.

1.1 Water

The HOH molecule (oxygenated hydrogen) is the most important oxygen-containing molecule and is fundamental to the realm of oxygen chemistry. It possesses exceptional ruggedness and thermal stability by virtue of strong chemical bonds (equation 1).

$$\mathrm{HOH\,(g)} \longrightarrow \mathrm{H\bullet\,(g)} + \mathrm{HO\bullet (g)} \longrightarrow \mathrm{H\bullet} + \bullet\mathrm{O}\bullet$$
$$\Delta H_{\mathrm{DBE}} = 119\ \mathrm{kcal\ mol^{-1}} \qquad \Delta H_{\mathrm{DBE}} = 103\ \mathrm{kcal\ mol^{-1}} \qquad (1)$$

DBE = dissociative bond energy



(2)

Thus, 222 kcal mol^{-1} must be transferred to HOH to produce atomic oxygen, which is a measure of the deactivation and stabilization of atomic oxygen in the formation of a water molecule. Another important and unique characteristic of water molecules is their tendency to cluster through intermolecular *hydrogen bonds* (more properly hydrogen–oxygen bonds) (equation 2). In contrast, for ambient conditions, BH_3, CH_4, NH_3, and HF are monomeric gas molecules (as are CO, CO_2, H_2S, and SO_2).

Liquid water also has exceptional solvation energies for small ions and thereby promotes the dissolution and heterolytic dissociation (ionization) of salt, acid, and base molecules, for example, NaCl (s), HCl (g), and NaOH (s) (equation 3).

This ability to interact strongly with positively and negatively charged ions is consistent with water's unique amphoteric (acid–base) properties, and is why it is fundamental to the Brønsted acid–base theory (equations 4 and 5).

$$\mathrm{NaCl(s)} \xrightarrow{H_2O} \underset{[\mathrm{Na^+(aq)}]}{[\mathrm{Na(OH_2)_{4-6}}]^+} + \underset{[\mathrm{Cl^-(aq)}]}{[\mathrm{Cl(H_2O)_{4-6}}]^-} \qquad (3)$$

$$\mathrm{HCl(g)} + \mathrm{H_2O(l)} \xrightarrow{H_2O} \mathrm{H_3O^+(aq)} + \mathrm{Cl^-(aq)} \qquad (4)$$

$$\mathrm{Na_2O(s)} + \mathrm{H_2O(l)} \xrightarrow{H_2O} \mathrm{2Na^+(aq)} + \mathrm{2HO^-(aq)} \qquad (5)$$

$$\mathrm{Cl_2(aq)} + \mathrm{2H_2O(l)} \xrightleftharpoons{H_2O} \mathrm{HOCl(aq)} + \mathrm{H_3O^+(aq)} + \mathrm{Cl^-(aq)} \qquad (6)$$

$$\mathrm{SO_3(g)} + \mathrm{2H_2O(l)} \xrightleftharpoons{H_2O} \mathrm{H_3O^+(aq)} + \mathrm{HOSO_2O^-(aq)} \qquad (7)$$

$$\mathrm{2Na(s)} + \mathrm{2H_2O} \longrightarrow \mathrm{H_2(g)} + \mathrm{2Na^+(aq)} + \mathrm{2HO^-(aq)} \qquad (8)$$

$$\mathrm{e^-(aq)} + \mathrm{H_2O} \longrightarrow \mathrm{H\bullet(g)} + \mathrm{HO^-(aq)}, \quad \mathrm{H\bullet(g)} \longrightarrow \mathrm{1/2\ H_2\,(g)} \qquad (9)$$

Although the water molecule is exceptionally rugged, it is a reductant (nucleophile) of strong oxidants (electrophiles) (equations 6 and 7) and an oxidant (electrophile) of strong reductants (nucleophiles) (equations 8 and 9).

Water is the essential matrix for (C, N, O, H)-based life. Thus, all living biopolymers have a water–carbohydrate surface component with hydrogen–oxygen bonding. The

inter- and intracellular aqueous phases are essential for the dissolution and transport of sugars, salts, nutrients, and some enzymes and cofactors for homogeneous, solution-phase metabolism and respiration.

1.2 Metals and Nonmetals

When the Earth first formed from a condensed cloud of gases and dust, those elements and molecules that are unstable in the presence of water reacted to form oxygenated products through the reduction of water to molecular hydrogen (equations 10–14).

$$Ca(g) + H_2O(g) \longrightarrow H_2(g) + (CaO)_n(s) \xrightarrow{H_2O(l)} Ca^{2+}(aq) + 2HO^-(aq) \quad (10)$$

$$2Al(g) + 3H_2O(g) \longrightarrow 3H_2(g) + (Al_2O_3)_n(s) \quad (11)$$

$$Fe(g) + H_2O(g) \longrightarrow H_2(g) + FeO(s) \xrightarrow{H_2O(l)} Fe^{2+}(aq) + 2HO^-(aq) \quad (12)$$

$$2P(g) + 6H_2O(g) \longrightarrow 3H_2(g) + 2HPO(OH)_2(aq) \quad (13)$$

$$n\,Si(g) + 2nH_2O(g) \longrightarrow 2nH_2(g) + (SiO_2)_n(s) \quad (14)$$

The transformation of the Earth's atmosphere to an oxidizing environment through the photosynthetic oxidation of water to dioxygen (O_2) (photosystem II of green plants; *see Photosystem I*) resulted in the autoxidation of the reduced forms of the molecules of the Earth's crust, oceans, and atmosphere (over a period of about 750 million years) (equations 15–19).[1–3]

$$4FeO(s) + O_2 \longrightarrow 2Fe_2O_3(s) \xrightarrow{FeO} Fe_3O_4(s) \quad (15)$$

$$2HPO(OH)_2(aq) + O_2 \xrightarrow{H_2O} 2(HO)_3PO(aq) \quad (16)$$

$$2Cu(s) + O_2 \longrightarrow 2CuO(s) \quad (17)$$

$$2C + O_2 \longrightarrow 2CO \xrightarrow{O_2} 2CO_2 \quad (18)$$

$$4NH_3 + 3O_2 \longrightarrow 2N_2 + 6H_2O \quad (19)$$

Another unique characteristic of oxygen-containing molecules is their exceptionally strong X–O bonds. For example, the gas-phase enthalpies for homolytic bond dissociation (ΔH_{DBE}) are: H–O•, 103 kcal mol^{-1}; HO–H, 119 kcal mol^{-1}; CO, 257 kcal mol^{-1}; BaO, 134 kcal mol^{-1}; FeO, 93 kcal mol^{-1}.

1.3 Dioxygen

The discovery and isolation of molecular oxygen (dioxygen, O_2) was first reported in 1774 by Joseph Priestley, but was independently codiscovered by Scheele in Sweden, who gave it the name *fire air* (reported in 1777).[1] Because it did not support combustion in a manner equivalent to other fuels, Priestley named the substance 'dephlogisticated air' ('air that does not burn'). He also discovered that green plants generate dioxygen. In 1777, Antoine L. Lavoisier identified dioxygen as a component of air, and named it *oxygen* on the basis that its reaction with other elements generated oxy acids (his alternative designation was *vital air*). He established that dioxygen is the oxidant of fuels in combustion, and that it is the essential oxidant for biological respiration. Because science was a hobby rather than a vocation with Lavoisier, his contributions were limited by available time and by a foreshortened life. Prior to the French Revolution, he made a living as a tax collector. He was beheaded during the French revolution. Scheele observed that pure dioxygen (1 atm) is toxic to plants; Priestley made similar observations.[1]

Thus, in the late 18th century, Priestley, Scheele, and Lavoisier had established that dioxygen comprises about 21% (by volume) of the Earth's atmosphere, that it is essential for aerobic life and toxic to plant life at high concentrations, and that it is the essential oxidant for the combustion of organic molecules (fuels). Priestley also noted that nitric oxide reacts with O_2 to produce NO_2 and N_2O_4, which react with water to form HON(O) and HON(O)$_2$ (nitrous acid and nitric acid).

About 2.5 billion years before dioxygen was chemically identified and characterized, it was added to the Earth's atmosphere as a natural product through photosynthetic oxidation of water by primitive green plants (blue–green algae). Life, which evolved on Earth in the absence of dioxygen some 3.5 billion years ago, was restricted to hydrogen sulfide as a source of hydrogen atoms for bacterial photosynthetic energy transfer.[2,3] With the development of blue–green algae and photosystem II some one billion years later, water replaced hydrogen sulfide as a source of reducing equivalents with dioxygen a by-product. Prior to the development of these primitive marine plants, photosynthetic life was limited to bacteria that could avail themselves of hydrogen sulfide from marine sources. Although extensive production of dioxygen occurred with the appearance of blue–green algae, biological utilization of dioxygen (aerobic life and oxidative metabolism) had to await another 750 million years for significant quantities of dioxygen to become available. This amount of time was required to produce sufficient dioxygen to titrate the immense amount of reduced iron (Fe^{II}) present in the Earth's oceans. Until this was precipitated as iron(III) oxide, the atmospheric concentration of oxygen was less than 1%. Thus, about 1.7 billion years ago there was an almost instant transformation of the atmosphere to 17–21% dioxygen.[2] Until then, life was restricted to the aquatic environment of the ocean. The absence of atmospheric oxygen precluded the photosynthetic production of ozone,

which is the essential shield from the solar UV radiation that is sufficiently energetic to break the chemical bonds of organic compounds.

1.4 Biosynthesis of Dioxygen

Green-plant photosynthesis utilizes water as a source of reducing equivalents (hydrogen atoms). As a result, there is a parallel evolution of dioxygen from the plant cells (chloroplasts) with the photosynthetic 'fixing' of carbon dioxide as carbohydrate. The conventional wisdom for the mechanism of photosynthesis includes two independent photosystems that pump reducing equivalents from water (photosystem II)[4–7] through a cascade of steps controlled by enzymes to a CO_2 reduction center (photosystem I).[8] The essential components for the dehydrogenation of water include manganese,[4–6] chloride ion, calcium ion, and bicarbonate ion. Green plants that are deprived of manganese in the chloroplast cells of the leaves cease to evolve oxygen. Full photosynthetic activity and oxygen evolution can be restored by the administration of manganese.

Photosystem II (PS II) within higher plants represents a solar-energy-driven process that removes hydrogen atoms from water to form molecular oxygen (O_2, dioxygen) through an overall four-electron transfer reaction (equation 20),[9–12]

$$2H_2O \longrightarrow O_2 + 4[H^+ + e^- \equiv H] \qquad (20)$$
$$E^{\circ\prime}(\text{pH } 5) = +0.93 \text{ V vs. NHE}$$

where NHE is the normal hydrogen electrode. The mechanistic sequence that facilitates this reaction involves an initial photoactivation process in which light is trapped and converted to chemical energy. This energy is subsequently transferred to other protein complexes within the lipoprotein membrane, where the chemical transformation of water to dioxygen occurs. The almost instantaneous increase in the concentration of dioxygen in the oceans had revolutionary consequences for the existent anaerobic life. The vast majority of species could not adapt rapidly enough and were destroyed (or retreated to an oxygen-free environment). Some species adapted and others evolved to oxygen-utilizing aerobes. With dioxygen present in the atmosphere, solar radiation transformed a small fraction of it to ozone and thereby provided a protective shield against short-wavelength UV light (equation 21).

$$3O_2 \xrightarrow{h\nu} 2O_3 \qquad (21)$$

In turn, this made it possible for the newly evolved aerobes to leave the marine environment and establish terrestrial life, and the subsequent evolutionary development of higher forms of life. Aerobic life had to develop and make effective use of dioxygen as an energy source through oxidation of organic molecules. This required the biosynthesis of a series of metalloproteins to facilitate the transport and the selective reactivity of dioxygen and its activated forms ($O_2^{-}\cdot$, HOO•, HOOH, HOO^-, and HO•) in respiration, metabolic, and detoxification processes. Although dioxygen is vital for biological oxidations and oxygenation reactions, the mechanisms and energetics for its reduction, and for the interconversion of the various dioxygen species, have been characterized to a reasonable degree only during the past two decades.

In the chemical realm, the dioxygen molecule (•O• triplet ground state) is a unique reagent with two unpaired electrons (biradical) and a bond order of two. With its introduction into the oceans of the planet as a by-product of green-plant photosynthesis, the transformation of the reducing environment into an oxidized state began. Those transition metals that were present autoxidized ($Fe^{II} \rightarrow Fe_2O_3$ (s), Fe_3O_4 (s); $Mn^{II} \rightarrow MnO_2$ (s), etc.) and, in most cases, precipitated as metal oxides. The same was true for the reduced forms of organic molecules (MeCH(O) $\rightarrow$ MeC(O)OH, RSH $\rightarrow$ RSSR, $H_2S \rightarrow S_8$, etc.).

Aerobic life makes use of dioxygen as an oxidant in all of its respiration and oxidative metabolic processes. These are processes whereby the reducing equivalents of food (carbohydrates, fats, and proteins) are oxidized by dioxygen to give water, carbon dioxide, and urea. Although the transformation is equivalent to combustion, biology uses catalysts known as enzymes and cofactors (*see Enzyme* and *Coenzyme*) to control the reaction pathway in specific steps that release and/or store energy. Combustion is a radical autoxidation process that requires a high-temperature initiation step. For example, the efficient transformation of the oxidizing energy of dioxygen into heat and stored chemical energy is accomplished in eukaryotic cells with a protein known as **Cytochrome Oxidase**.[13,14] This system contains two iron–porphyrin (heme) groups and at least two copper atoms, and is able to transform about 80% of the redox energy stored in dioxygen (chemists and engineers have not been able to achieve a comparable efficiency with synthetic catalysts). Aerobic life also makes use of a vast array of metalloproteins for the selective catalysis of processes that produce useful biomolecules from the reaction of dioxygen and hydrogen peroxide with specific substrates.[15] In most cases, these biological catalysts include one or more transition metals (iron, copper, manganese, and molybdenum) at their active sites. Although oxidases and peroxidases accomplish their chemistry by hydrogen-atom transfer (or electron–proton transfer), there are other catalysts (oxygenases) that transform substrates by the addition of one or two oxygen atoms from the dioxygen molecule.

1.5 Activation and Reactivity of Dioxygen Species (•O_2•, HOO•, $O_2^{-}\cdot$, HOOH)

Because the ground state of dioxygen is a triplet with two unpaired electrons with parallel spins, its reactivity with organic molecules in the singlet state is severely

restricted, particularly at room temperature. Dioxygen's limited reactivity as a product is undoubtedly an essential feature of biosynthetic processes. A product with high reactivity would have destroyed the 'maker'. Although dioxygen is a strong oxidant at pH 7 when utilized as a concerted four-electron transfer agent, it is an extremely weak one-electron oxidant ($O_2 + e^- \rightarrow O_2^{-}\cdot$; $E°$, −0.16 V vs. NHE (unit molarity for standard states)).

Because approximately 15% of the O_2 that is respired by mammals appears to go through the superoxide state, the biochemistry and reaction chemistry of this species is of interest to those concerned with oxygen toxicity, carcinogenesis, and aging.[16] The most general and universal property of $O_2^{-}\cdot$ is its tendency to act as a strong Brønsted base. Although the acidity of hydroperoxy radical (HOO•) in water (pK_a 4.9) is the same as acetic acid, the strong proton affinity of $O_2^{-}\cdot$ is due to its redox-driven propensity to be O_2 and HOOH (equation 22).

$$2O_2^{-}\cdot + H_2O \rightleftharpoons O_2 + HOO^- + HO^- \qquad (22)$$
$$K = 2.5 \times 10^8 \text{atm}$$

Thus, two superoxide ions plus a water molecule are converted to two strong bases. This strong proton affinity manifests itself in any media and is exemplified by the ability of $O_2^{-}\cdot$ to deprotonate butanol.

The existence of proteins such as *Superoxide Dismutase*[17] and *Catalase*[18,19] in aerobes often is cited in support of the conclusion that $O_2^{-}\cdot$ and HOOH are biological toxins. The present understanding of the biological utilization of hydrogen peroxide includes enzyme-facilitated processes that involve its disproportionation, the dehydrogenation of organic molecules, and the production of hypochlorous acid in neutrophils (equations 23–25).

$$HOOH + HOOH \xrightarrow{\text{catalase}} O_2 + 2H_2O \qquad (23)$$

$$RCH_2OH + HOOH \xrightarrow{\text{peroxidase}} RCHO + 2H_2O \qquad (24)$$

$$HCl + HOOH \xrightarrow{\text{myeloperoxidase}} HOCl + H_2O \qquad (25)$$

Given that the myeloperoxidase enzyme[20] (*see Peroxidases*) within the neutrophils produces hypochlorous acid, an intriguing possibility is that it may combine with another hydrogen peroxide molecule. Such a reaction in the laboratory produces a stoichiometric quantity of singlet dioxygen ($^1O_2$), which is selectively reactive with conjugated polyenes.

Although the introduction of O_2 into the Earth's atmosphere revolutionized biology and gave birth to oxidative metabolism and the associated biochemistry (oxidases, peroxidases, superoxide dismutases, monooxygenases, dioxygenases, lipid peroxidation and autoxidation, and antioxidants (ascorbic acid, α-tocopherol, glutathione, and thiols)), the chemistry of dioxygen and hydrogen peroxide has not enjoyed the attention of most chemists. However, process engineers appreciate an essentially free reagent (air) and have developed major processes that are based on the catalytic activation of O_2:

1. Sulfuric acid production from H_2S and SO_2 with V_2O_5 (s) as the catalyst;
2. Ethylene oxide production from ethylene with supported Ag (s) as the catalyst;
3. Cyclohexanol and cyclohexanone from cyclohexane with supported Co (s) as the catalyst.
4. Catalysis with transition-metal complexes.[21]

Likewise, hydrogen peroxide, perborates, and peracids are used as bleaches and decolorizing agents, disinfectants, and general oxidizing agents. There is increasing interest in the use of ozone (O_3) for water purification (in place of chlorine), and as a clean oxygenating reagent. Nature for the past 1.7 billion years has devised highly selective catalysts for the constructive use of dioxygen and hydrogen peroxide to synthesize molecules. Through an understanding of the chemistry for these biological oxygen-activation processes, new catalyst systems can be designed.

2 REDOX THERMODYNAMICS FOR OXYGEN SPECIES (O_2, O_3, HOO•, $O_2^{-}\cdot$, HOOH, HOO^-, O, AND HO•)

The reaction thermodynamics for oxygen species are influenced by the solution matrix and its acidity. Thus, the redox thermodynamics of O_2 are directly dependent upon hydronium ion activity,

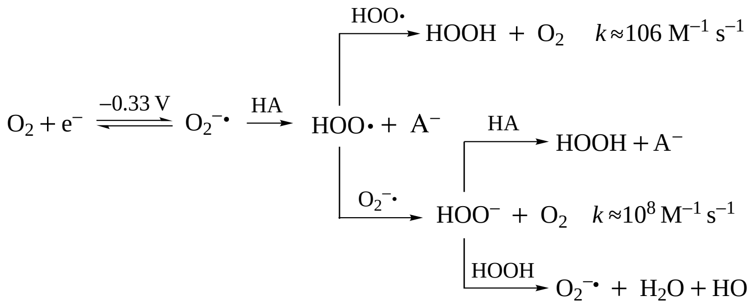
$$O_2 + 4H_3O^+ + 4e^- \longrightarrow 6H_2O \qquad (26)$$

which, in turn, depends upon the reaction matrix. In acetonitrile, the activity values for pK_a' range from −8.8 for $(H_3O)ClO_4$ to 30.4 for H_2O.[22] This means that the formal potential ($E°'$) for equation (26) in acetonitrile (MeCN) is +1.79 V versus NHE in the presence of 1 M $(H_3O)ClO_4$ and −0.53 V in the presence of 1 M $(Bu_4N)OH$.

Another limiting factor with respect to chemical energy flux for oxidative metabolism and respiration is the solubility of O_2. Because of its nonpolar character, dioxygen is much more soluble in organic solvents than in H_2O.

The reduction potentials for O_2 and various intermediate species in H_2O at pH 0, 7, and 14 are summarized in Table 1;[23–26] similar data for O_2 in MeCN at pH −8.8, 10.0, and 30.4 are presented in Table 2.[27–29] Potentials for the reduction of ozone (O_3) in aqueous and acetonitrile solutions are presented in Table 3.[26,28]

The reduction manifolds for O_2 (Tables 1 and 2) indicate that the limiting step (in terms of reduction potential) is the first electron transfer to O_2, and that an electron source



Scheme 1 Formation and degradation of the superoxide ion ($O_2{}^{-}\bullet$)

adequate for the reduction of O_2 will produce all of the other reduced forms of dioxygen ($O_2{}^{-}\bullet$, HOO•, HOOH, HOO^-, •OH) through reduction, hydrolysis, and disproportionation steps (Scheme 1).[30,31] Thus, the most direct means to activate O_2 is the addition of an electron (or hydrogen atom), which results in significant fluxes of several reactive oxygen species.

The dominant characteristic of $O_2{}^{-}\bullet$ in any medium is its ability to act as a strong Brønsted base to form HOO•,[32,33] which reacts with itself or a second $O_2{}^{-}\bullet$ (Scheme 1). Within water, superoxide ion is rapidly converted to dioxygen and peroxide (equation 27).

$$2O_2{}^{-}\bullet + H_2O \rightleftharpoons O_2 + HOO^- + HO^- \quad (27)$$

$$K \approx 2.5 \times 10^8 \text{atm}$$

$$(DMF)^+Fe^{III}TPP + O_2{}^{-}\bullet \longrightarrow Fe^{II}TPP + O_2 \quad (28)$$

$$\Delta E = +0.7\ \text{V}$$

Such a proton-driven disproportionation process means that $O_2{}^{-}\bullet$ can deprotonate acids much weaker than water (up to $pK_a \sim 23$).[34] The data of Tables 1 and 2 indicate that $O_2{}^{-}\bullet$ is a moderate one-electron reducing agent. Thus, cytochrome *c* (Fe^{III}) is reduced in H_2O[35,36] and iron(III) porphyrins in DMF (equation 28).

Superoxide ion reacts with proton sources to form HOO•, which disproportionates through a second $O_2{}^{-}\bullet$ or itself (Scheme 1). However, with limiting fluxes of protons to control the rate of HOO• formation from $O_2{}^{-}\bullet$, the rate of decay of HOO• is enhanced by reaction with the allylic hydrogens of excess 1,4-cyclohexadiene (1,4-CHD).[37] Because HOO• disproportionation is a second-order process, low concentrations favor hydrogen-atom abstraction from 1,4-CHD. This is especially so for Me_2SO, in which the rate of disproportionation for HOO• is the slowest (PhCl > MeCN > H_2O > DMF > DMSO).[37]

2.1 Atomic Oxygen

The electron-transfer potentials for the reduction of ground-state atomic oxygen in water and in acetonitrile are directly related to hydronium ion concentration (equations 29–31).[23,24,38]

$$O(g) + H_3O^+ + e^- \longrightarrow HO\bullet + H_2O \quad (29)$$

$$(E^\circ)_{H_2O} = +2.14\ \text{V},\ (E^\circ)_{MeCN} = +2.66\ \text{V}$$

$$HO\bullet + H_3O^+ + e^- \longrightarrow 2H_2O \quad (30)$$

$$(E^\circ)_{H_2O} = +2.72\ \text{V},\ (E^\circ)_{MeCN} = +3.24\ \text{V}$$

$$O(g) + 2H_3O^+ + 2e^- \longrightarrow 3H_2O \quad (31)$$

$$(E^\circ)_{H_2O} = +2.43\ \text{V vs. NHE},\ (E^\circ)_{MeCN} = +2.95\ \text{V}$$

$$2H_3O^+ + 2e^- \longrightarrow 2H\bullet + 2H_2O \quad (32)$$

$$E^\circ = -2.10\ \text{V vs. NHE}$$

Because the oxygen atom in a water molecule is essentially without charge, these reduction processes represent the facilitated reduction of hydronium ions by stabilization of the product H atom through strong covalent bond formation with atomic oxygen. Thus, the standard state reduction of protons to hydrogen atoms (equation 32) is shifted to a much more favored process in the presence of atomic oxygen (equation 31).

3 CHEMICAL BONDS FOR OXYGEN

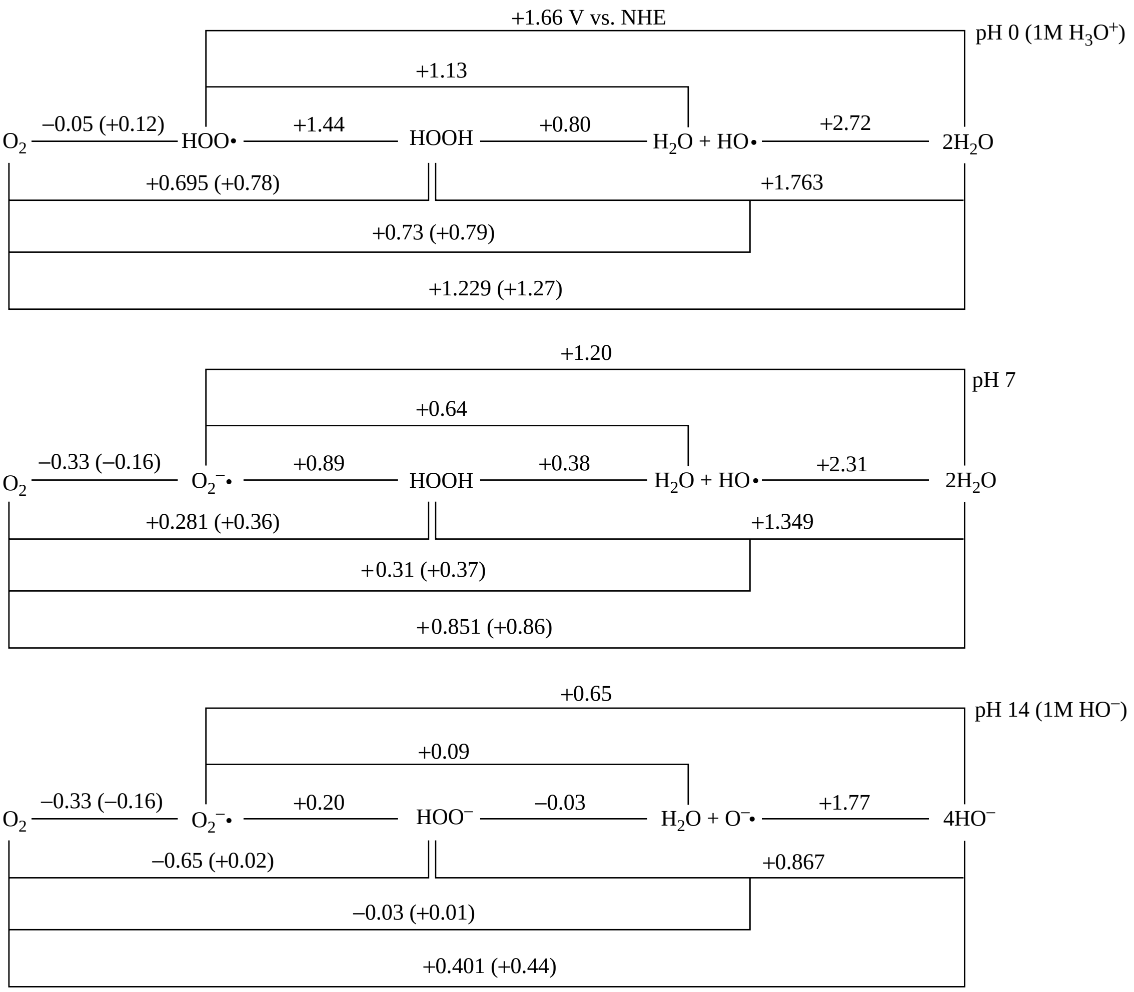
The bonding for oxygen atoms in heteratomic molecules is viewed as essentially covalent (*see Covalent Bonds*) (e.g. MeOH, $Me_2C{=}O$, MeCHO, and MeC(O)OOH) and similar to that for carbon, nitrogen, and chlorine atoms. In contrast, a Lewis acid–base formalism often is used for metal–oxygen compounds with ionic interactions by dianionic oxo groups (e.g. $[Ba^{2+}\ O^{2-}]$, $[Fe^{6+}\ (O^{2-})_4]^{2-}$, $[Mn^{7+}\ (O^{2-})_4]^-$, and $[(Cu^+)_2O^{2-}]$). This results from the thermodynamic relations for ionic solution equilibria, and the inference that the combination of ions results in molecules and complexes held together by electrostatic interactions (equations 33–35).

$$H_3O^+ + HO^- \rightleftharpoons 2H_2O \quad K_f = 10^{14} \quad (33)$$

$$Zn^{2+} + 4HO^- \rightleftharpoons Zn(OH)_4{}^{2-} \quad K_f = 10^1 \quad (34)$$

$$Fe^{3+} + 3HO^- \rightleftharpoons Fe(OH)_3(s) \quad K_f = 10^{36} \quad (35)$$

Table 1 Standard reduction potentials for dioxygen species in water[a]



[a]O_2, 1 atm (1.0 mM). Formal potentials for O_2 at unit activity in parentheses.

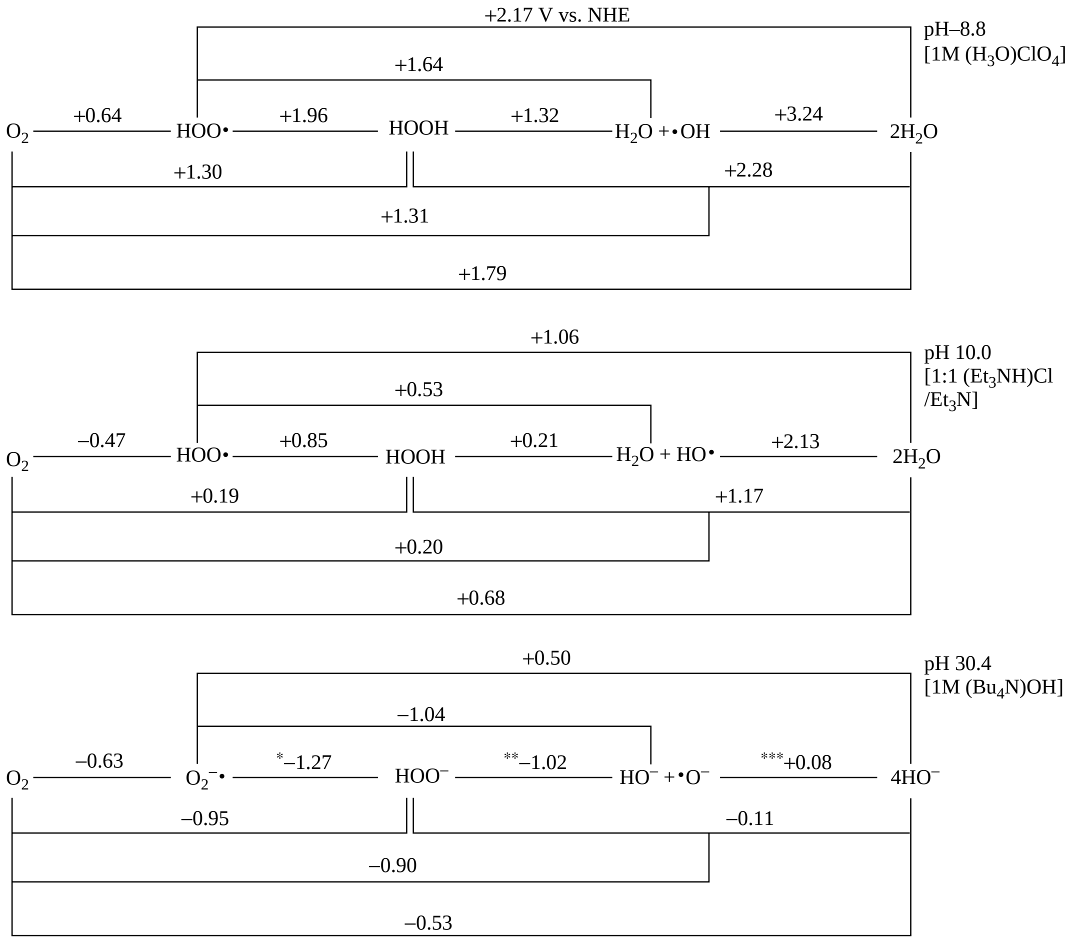
However, the bonding in the H_2O molecule is essentially covalent [H–OH (1s−2p)] with a charge excess of 0.12+ per hydrogen atom (0.25− for oxygen), and *not* [$H^{+-}OH$].[39,40] The same is true for all of the molecular products in equations (33−35).

Thus, the bonding in metal compounds and complexes has traditionally been viewed as ionic, with a positive metal center interacting with negative ions, such as HO^-, O^{2-}, Cl^-, AcO^-, and coordinate donor, Lewis acid−base interactions with a positive metal center interacting with negative ions and electron-pair Lewis bases, such as :NH_3, :PPh_3, H$\ddot{O}$H. Examples of ionic versus covalent bonding illustrate the tradition: H^+Cl^- versus H–Cl (1s−3p), $C^{4+}(Cl^-)_4$ versus $C(–Cl)_4$ [$2sp^3–(3p)_4$], $Fe^{3+}(Cl^-)_3$ versus $Fe(–Cl)_3$ [$3d^5sp^2–(3p)_3$], $H^{+-}OH$ versus H–OH (1s−2p), $C^{4+}(O^{2-})_2$ versus O=C=O [$2sp^3–(2p^2)_2$], and $Fe^{2+}(O^{2-})$ versus Fe=O [$3d^6sp–(2p^2)$]. Such ionic formulations for these molecules in an inert matrix are not consistent with their physical and chemical properties. For example, ferrate ion (FeO_4^{2-}) is formulated as an ionic salt $Fe^{6+}(O_2^{2-})_4$ ($3d^2$, $S = 2/2$, tetrahedral). This is in spite of the fact that O^{2-} is unattainable with electron beams in a vacuum, which would make it a stronger reducing agent than the electron (electrons transform all oxidized iron to Fe^0 or Fe^-).

3.1 Covalent Bonding in Oxygen-containing Molecules

With simple organic compounds, covalent bonds result from the combination of the four unpaired electrons in the sp^3 hybridized orbitals of carbon with the unpaired electrons of hydrogen or oxygen (equations 36 and 37). Likewise, atomic hydrogen forms covalent bonds with atomic oxygen (without charge transfer) (equations 38 and 39). An additional electron, added to HOH or HO•, goes to the atom with the greatest electron affinity (O, 1.46 eV and H, 0.75 eV) (equations 40 and 41).

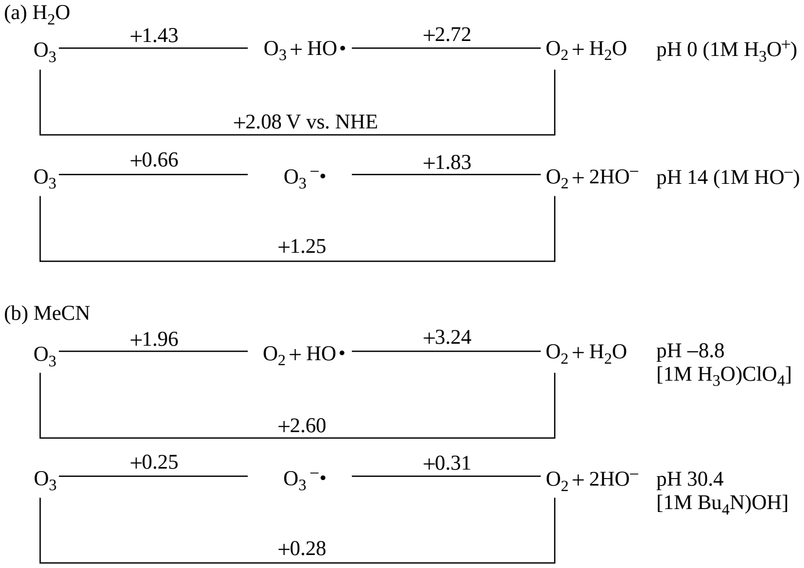
Table 2 Formal reduction potentials for dioxygen species in acetonitrile[a]



*($O_2^{-}\bullet \xrightarrow{-1.51}$ HOOH) **(HOOH $\xrightarrow{-0.90}$ HO^{-} + OH•) ***(HO• $\xrightarrow{+0.92}$ HO^{-})

[a]O_2, 1 atm (8.1 mM).

Table 3 Standard reduction potentials for ozone in water and in acetonitrile



$$\cdot\ddot{C}\cdot + 4H\cdot \longrightarrow CH_4\ \text{(H–C–H with H above and below)}\quad (4\sigma\text{bonds}) \tag{36}$$

$$\cdot\dot{C}\cdot + 2\cdot O\cdot \longrightarrow O{=}C{=}O\ \ (2\sigma \text{ bonds and } 2\pi \text{ bonds}) \tag{37}$$

$$2H\cdot + \cdot O\cdot \longrightarrow \text{H–O–H} \tag{38}$$

$$H\cdot + \cdot O\cdot \longrightarrow \text{H–O}\cdot \tag{39}$$

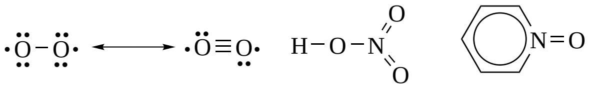
$$HOH + e^- \longrightarrow HO^- + H\cdot \tag{40}$$

$$E^\circ = -2.9\ \text{V vs. NHE}$$

$$HO\cdot + e^- \longrightarrow HO^- \tag{41}$$

$$E^\circ = +1.9\ \text{V vs. NHE}$$

The covalent bonding of atomic oxygen (•O•, $2s^2p^4$) with carbon and hydrogen is representative of its bonding to all elements. In neutral molecules without an oxygen-centered radical (HO• and MeO•), the covalence of oxygen is two (e.g. H–O–H, H–O–O–H, •N=O, H–O–Cl, O=C=O, Me–O–H). In contrast, the covalence of oxygen in the hydronium ion (H_3O^+) is three, and in hydroxide ion (HO^-) is one. The valence bond approach can be extended to molecular oxygen (dioxygen, $\cdot O_2\cdot$, **1**), which has a bond order of two, nitric acid (**2**), pyridine *N*-oxide (**3**), and carbon dioxide (O=C=O).



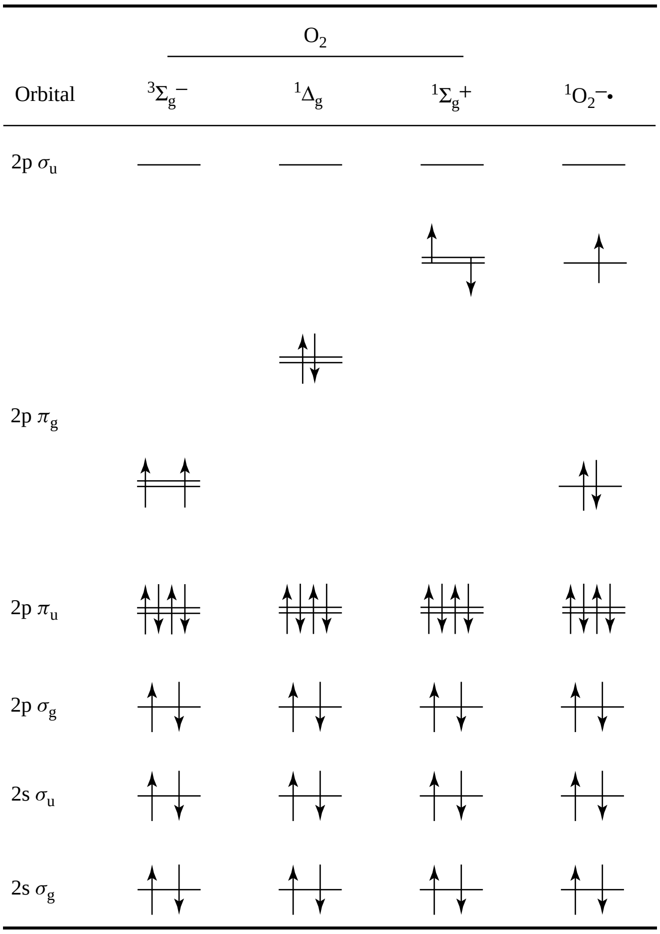
(**1**) (**2**) (**3**)

The C–O bond energy (ΔH_{DBE}) in CO_2 is 130 kcal mol^{-1}, and the N–N bond energy in N≡N is 227 kcal mol^{-1}. Hence, the bond energy for CO (isoelectronic with N_2), 257 kcal mol^{-1}, prompts the formulation of an eight-electron covalent bond (C≡O: or two three-electron bonds plus a σ bond).

The bond orders for ground-state molecular oxygen (dioxygen, $^3O_2$), for superoxide ion ($O_2^{-}\cdot$), and for (HOOH) are 2, 1.5, and 1, respectively. Table 4 provides molecular orbital diagrams for dioxygen ($^3\Sigma_g^-$, $^1\Delta_g$, and $^1\Sigma_g^+$) and superoxide ion, which illustrates the biradical character of $^3O_2$ ($\cdot O_2\cdot$) and the delocalized spin density of $O_2^{-}\cdot$ (one-half spin per oxygen).

The bonding of an oxygen atom in a water molecule H–$\ddot{\underset{\cdot\cdot}{O}}$–H involves an octet of electrons about the oxygen atoms (closed valence-electron shell) with two covalent sigma (σ) H–O bonds ($1s-2p_{x,y}$) at a dihedral angle of 104° (≈90° for the $p_{x,y}$ orbital geometry of ground-state atomic oxygen (•O•)). This bivalent bond order for oxygen is general in its compounds with nonmetals and metals. The addition of covalently bonded Na^I_2O (s) to water results in the transfer of an electron from each sodium atom to the oxygen of a water molecule and internally to the oxygen atom (equation 42). Likewise, the

Table 4 Molecular orbital diagrams for O_2 and $O_2^{-}\cdot$



reaction of Na^I_2O (s) with CO_2 (s) yields covalently bonded sodium carbonate, which dissociates heterolytically in aqueous solutions (equation 43). Metal–oxygen compounds can be directly synthesized by atom–atom reactions, especially when sources of atomic oxygen are utilize (equations 44–48).

$$Na^I_2O(s) + HOH \xrightarrow{H_2O} 2Na^+(aq) + 2HO^-(aq) \tag{42}$$

$$Na^I_2O\ (s) + CO_2\ (g) \longrightarrow Na^I{-}O{-}C({=}O){-}O{-}Na^I\ (s) \xrightarrow{H_2O} 2Na^+\ (aq) + CO_3^{2-}\ (aq) \tag{43}$$

$$m\text{-}ClC_6H_4C(O)OOH \longrightarrow m\text{-}ClC_6H_4CO_2H + [O] \tag{44}$$

$$HOOH \longrightarrow HOH + [O] \tag{45}$$

$$O_3 \longrightarrow O_2 + [O] \tag{46}$$

$$HOCl \longrightarrow HCl + [O] \tag{47}$$

$$HOIO_3 \longrightarrow HOIO_2 + [O] \tag{48}$$

The dissolution and oxidation of the elemental manganese in steel alloys to permanganate ($HOMn^{VII}O_3$) by $HOIO_3$

illustrates such oxygen-atom transfer chemistry and the associated increase in the covalence of Mn (equations 49 and 50).

$$Mn(s) + [O] \longrightarrow Mn^{II}{=}O(s) \xrightarrow{[O]} O{=}Mn^{IV}{=}O(s) \quad (49)$$

$$2Mn^{IV}O_2(s) + 3[O] \longrightarrow O_3Mn^{VII}OMn^{VII}O_3 \xrightarrow{H_2O} 2H_3O^+(aq) + 2O_3Mn^{VII}O^-\ (aq) \quad (50)$$

3.2 Covalent Bond Energies for Oxygen in Molecules

Although the gas-phase dissociative X–O bond energies (ΔH_{DBE}) are known for many diatomic and nonmetallic molecules (see Table 5 for illustrative examples),[41] the metal–oxygen bond energetics for transition-metal complexes, organometallics, and metalloproteins in the condensed phase are not understood. With the latter systems, the traditional thermochemical methods of evaluation are tedious and imprecise.

The need for quantitative bond energy data for oxygen-containing molecules in the condensed phase has prompted the development of an evaluation procedure that is based on electron-transfer thermodynamics. The approach is illustrated for H–O bonds and for Fe–O bonds, but is applicable to any X–O bond for which appropriate electron-transfer potentials are available. Table 6(a) summarizes the one-electron standard reduction potentials for H_3O^+, HO•, HOH, O_2, HOO•, O_2^-•, •O•, and O^-• in aqueous solutions (see Table 1).

Combination of the appropriate electron-transfer half-reactions (Table 6a) provides an expression for the free energy of bond formation [$-\Delta G_{BF} = nF(\Delta E°)_{reac}$]. For example, in the case of the H–OH bond the energetics for the reduction of a hydronium ion in the absence and presence of HO• are given by (equations 51 and 52). Subtraction of equation (51) from equation (52) gives equation (53). This provides a measure of the H–OH bond energy (equation 54).

Table 5 Gas-phase dissociative bond energies for oxygen-containing molecules

$$HO\bullet + H_3O^+ + e^- \longrightarrow 2H\text{–}OH \quad (52)$$
$$E° = +2.72 \text{ V}$$
$$HO\bullet + H\bullet \longrightarrow H\text{–}OH \quad (53)$$
$$(\Delta E°)_{reac} = +4.82 \text{ V}$$
$$-\Delta G_{BF} = nF(\Delta E°)_{reac} = [(4.82)][23.1 \text{ kcal mol}^{-1}(\text{eV})^{-1}] = 111 \text{ kcal mol}^{-1} \quad (54)$$

Analogous arguments are used to evaluate the free energies

Table 6 Standard aqueous reduction potentials for protons, water, and oxygen species; and the free energy of bond formation for several hydrogen – oxygen species

(a) Reduction potentials in H_2O (standard states, unit molality) Redox couple	$E°$ (V vs. NHE)	Redox couple	$E°$ (V vs. NHE)
HO• + H_3O^+ + e^- → H–OH + H_2O	+2.72	•O^- + HOH + e^- → H–O^- + HO^-	+1.77

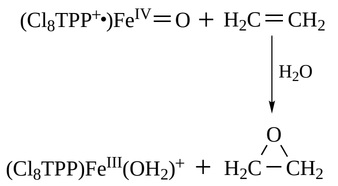
of bond formation ($-\Delta G_{BF}$) for the H–O•, H–O$^-$, H–OOH, H–OO$^-$, and H–OO• bonds, which are summarized in Table 6(b).

An equivalent approach has been used to evaluate metal–ligand covalent bond-formation free energies ($-\Delta G_{BF}$) for metal complexes (ML_n)[42] and metal–oxygen compounds.[43] Thus, for ML_3 complexes the differential redox potentials ($\Delta E^{\circ\prime} = E^{\circ\prime}{}_{\cdot L/L^-} - E^{\circ\prime}{}_{ML3/ML3^-}$) of their ligand-centered electron-transfer processes provide a measure of the L_2M–L bond energy ($-\Delta G_{BF} = (\Delta E^{\circ\prime})23.1\,\mathrm{kcal\,mol^{-1}}$).[42] Table 7 illustrates such an approach for iron complexes and summarizes their apparent free energies of covalent bond formation (M–L, $-\Delta G_{BF}$).[26,42–44]

Although the uncharged tris(3,5-di-*t*-butylcatecholate) complex of iron [Fe(DTBC)$_3$] has been extensively studied,[44–46] the proposed bonding in these reports is unclear. The most common formulation is as an ionic salt between iron(III) and three semiquinone anion radicals, $Fe^{3+}(DTBSQ^{-}\bullet)_3$. However, the magnetic moment is 2.9 BM (consistent with an $S = 2/2$ spin state)[44,46] and the electrochemistry indicates a ligand-centered reduction.[29] Both of these characteristics are analogous to ferrate dianion, $Fe^{VI}(O)_4{}^{2-}$ (d^5sp^2; $S = 2/2$; covalence, 6). Thus, the iron center (d^5sp^2, eight unpaired electrons) forms six covalent Fe–O bonds with three catechols (equivalent to the six H–O bonds in three $DTBCH_2$ molecules), which leaves two unpaired electrons at the iron center ($S = 2/2$) (Table 7).

Additional X–O dissociative bond energies (ΔH_{DBE}; XO $\rightarrow$ X + O) for oxygen-containing molecules are summarized in Table 8.[26,41] These provide a thermodynamic measure of the propensity for oxygen-atom transfer. For example, the dissociative bond energies (ΔH_{DBE}) of the oxygen atom in the compound I model [($Cl_8TPP^{+}\bullet$)Fe^{IV}=O] and in ethylene oxide (CH_2–CH_2O) are 54 and 84 kcal mol^{-1}, respectively. Hence, the transfer of an oxygen atom from compound I to ethylene is an exothermic process ($-\Delta H_{reac} = 30\,\mathrm{kcal\,mol^{-1}}$) (equation 55).



(55)

In summary, the bond energies for atomic oxygen (•O•) and dioxygen (•O$_2$•) with transition metals are much smaller than with either carbon or hydrogen (Tables 5–8), and hereby provide the means to stabilize active forms of oxygen [•O• $\rightarrow$ MO; •O$_2$• $\rightarrow$ M(O$_2$); •O$_2$• $\rightarrow$ MOOM]. Although the weak metal–oxygen bonds attenuate the reactivity of atomic oxygen, this is more than compensated by its increased lifetime in condensed phase reactors (the reaction of equation (55) is a good example). In some cases, the stabilization by transition metals can enhance the reactivity through a change in the spin state of atomic oxygen (•O• $\rightarrow$ MO) (equation 56). This appears to be the approach that has been utilized by Nature for the activation of •O$_2$• and HOOH for the dehydrogenation, monooxygenation, and dioxygenation of organic substrates.

4 REACTIVITY AND ACTIVATION OF HYDROGEN PEROXIDE (HOOH) AND HYDROPEROXIDES (ROOH)

The reactivity of hydroperoxides is primarily dependent upon their unique bond energies (e.g. H–OOH, 90 kcal mol^{-1}; HO–OH, 51 kcal mol^{-1}; H–OOBu-t, 91 kcal mol^{-1}, HO–OBu-t, 47 kcal mol^{-1}),[41] which allow low-energy rearrangements to give (HO•) and (•O•) (equations 57–60).[43]

$$HOOH \longrightarrow HOH + [O] \qquad -\Delta H = 39\ \text{kcal mol}^{-1} \tag{57}$$

$$HOOH + Fe^{II}L_2 \longrightarrow L_2Fe^{III}\text{–}OH + HO\bullet \qquad \Delta H_{H_2O} = -2\ \text{kcal mol}^{-1} \tag{58}$$

$$m\text{-}ClC_6H_4C(O)OOH \longrightarrow m\text{-}ClC_6H_4CO_2H + [O] \qquad \Delta H = 31\ \text{kcal mol}^{-1} \tag{59}$$

$$HOOH \xrightarrow{Fe^{III}Cl_3} HOH + [Cl_3Fe{=}O] \qquad \Delta H_{MeCN} = -11\ \text{kcal mol}^{-1} \tag{60}$$

Thus, m-$ClC_6H_4C(O)OOH$ in acetonitrile will epoxidize alkenes without a catalyst, but the presence of an iron complex accelerates the process by several orders of magnitude.[47]

In water, the Brønsted acidity of HOOH and HO• are essentially the same (pK_a = 11.8 and 11.9, respectively). Electrochemical reduction of HOOH in acetronitrile yields molecular hydrogen (rather than cleavage of the HO–OH bond) (equation 61)[29] and oxidation of HOOH yields hydroperoxyl radical (HOO•) (equation 62).

$$HOOH + e^- \xrightarrow[\text{GC, MeCN}]{-1.7\ \text{V vs. SCE}} \tfrac{1}{2}H_2 + HOO^- \tag{61}$$

$$HOOH + HOH \xrightarrow[\text{GC, MeCN}]{+2.1\ \text{V vs. SCE}} HOO\bullet + H^+ + e^- \tag{62}$$

Hydrogen peroxide is formed from (a) the dimerization of hydroxyl radicals (equation 63), (b) the proton-induced decomposition of superoxide ions (equation 64), (c) the reductive electrolysis of O_2 in acidic media (equation 65), and (d) the base-induced reduction of O_2 by 1,2-disubstituted hydrazines (equation 66).[48]

$$2HO\bullet \longrightarrow HOOH \qquad k = 1 \times 10^9 M^{-1}s^{-1} \tag{63}$$

$$2O_2^{-}\bullet + 2H_3O^+ \longrightarrow HOOH + O_2 \tag{64}$$

$$O_2 + H_3O^+ + 2e^- \xrightarrow[\text{MeCN, Pt}]{+0.4\ \text{V vs. SCE}} HOOH + 2H_2O \tag{65}$$

$$O_2 + PhNHNHPh \xrightarrow{:B} HOOH + PhN{=}NPh \tag{66}$$

Hydrogen peroxide is produced industrially by (a) the base/anthraquinone-catalyzed chemical reduction of O_2 by water and (b) the palladium-catalyzed hydrogenation of O_2. In aerobic biology, many oxidases (dehydrogenases) produce HOOH as a by-product along with oxidized substrate (e.g. glucose oxidase, O_2 + glucose → gluconic acid + HOOH; xanthine oxidase, O_2 + xanthine → uric acid + HOOH (*see Oxidoreductase*)). Alkyl hydroperoxides and peroxy acids are formed via the reaction of HOOH with alkyl halides and acid chlorides, respectively.

4.1 Elementary Reaction Chemistry

Hydrogen peroxide is (a) a modest electron-transfer oxidant that requires a one-electron catalyst (usually iron or copper) (equation 67) and (b) a weak two-equivalent reductant that also requires a one-electron catalyst (equation 68).

$$HOOH + 2I^- + 2HA \xrightarrow{\text{cat}} I_2 + 2HOH + 2A^- \tag{67}$$

$$2Mn^{VII}O_4^- + 5HOOH + 6H_3O^+ \xrightarrow{\text{cat}} 5O_2 + 2Mn^{II}(OH_2)_6^{2+} + 2HOH \tag{68}$$

The hydroperoxide ion (HOO^-) in aprotic media is an effective nucleophile that (a) oxygenates sulfoxides (equation 69),[49] (b) hydrolyzes nitriles and amides (equations 70–71) and (c) reacts with HOOH to form superoxide ions and hydroxyl radicals (equations 72 and 73).[31]

$$HOO^- + Me_2SO \longrightarrow Me_2SO_2 + HO^- \tag{69}$$

$$HOO^- + MeC{\equiv}N \xrightarrow{2HOH} Me{-}C(NH_2)(OH)(O^-) + HOOH \quad (70)$$

$$HOO^- + Me_2NCHO \xrightarrow{HOH} Me_2NH + HCO_2^- + HOOH \quad (71)$$

$$HOO^- + HOOH \longrightarrow O_2^{-}{\bullet} + HOH + HO{\bullet} \quad (72)$$

$$2HOO^- + HOOH \longrightarrow 2O_2^{-}{\bullet} + 2HOH \quad (73)$$

4.2 Fenton Chemistry

Although the activation of hydrogen peroxide by reduced transition metals has been known for almost 100 years as Fenton chemistry (equations 74–77)[50] there is uncertainty as to whether this chemistry produces free hydroxyl radicals (HO•). There is clear kinetic evidence[51,52] that free HO• is not the dominant reactive intermediate in Fenton chemistry, but rather an $HOOH/Fe^{II}L$ adduct that results from nucleophilic addition.[53,54]

$$HOOH + LFe^{II} \xrightarrow{pH\ 2} LFe^{III}OH + HO{\bullet} \quad (74)$$
$$k = {\sim}100\ M^{-1}s^{-1}$$

$$HO{\bullet} + LFe^{II} \longrightarrow LFe^{III}OH \quad (75)$$
$$k = 3 \times 10^8 M^{-1}s^{-1}$$

$$HO{\bullet} + RH \longrightarrow R{\bullet} + H_2O \quad (76)$$
$$k = 10^7 - 10^{10} M^{-1}s^{-1}$$

$$HO{\bullet} + HOOH \longrightarrow HOO{\bullet} + H_2O \quad (77)$$
$$k = 1 \times 10^7 M^{-1}s^{-1}$$

The bis(picolinate)iron(II) complex $[Fe^{II}(PA)_2$; PAH = picolinic acid, 2-pyridinecarboxylic acid] in combination with hydrogen peroxide (HOOH) is an effective Fenton reagent for organic substrates, and has reactivities and product profiles that are closely similar to those for traditional aqueous Fenton reagents.[55] This system reacts with hydrocarbon substrates ($c\text{-}C_6H_{12}$) via an intermediate that results from the nucleophilic addition by HOOH to the electrophilic $Fe^{II}(PA)_2$ center (equation 78).[56]

$$Fe^{II}(PA)_2 + HOOH \underset{(py)_2HOAc}{\overset{k = 2\times10^3 M^{-1}s^{-1}}{\rightleftharpoons}} [(PA)_2\text{-}Fe^{II}OOH + pyH^+] \ (\mathbf{4})$$
$$\downarrow c\text{-}C_6H_{12} \quad (78)$$
$$c\text{-}C_6H_{11}(py) + 2H_2O + Fe^{II}(PA)_2$$
$$KIE = 1.7$$
$$(\text{in MeCN, } c\text{-}C_6H_{11}OH)$$

The resulting adduct (**4**) is the reactive intermediate for this Fenton system and reacts directly with substrates (the observed kinetic isotope effect (KIE, $k_{c-C_6H_{12}}/k_{c-C_6D_{12}}$) is 1.7; aqueous Fenton systems produce $c\text{-}C_6H_{11}OH$ with a KIE of 1.1[51] and free HO• (pulse radiolysis) produces $c\text{-}C_6H_{11}{\bullet}$ with a KIE of 1.0).

4.3 Nucleophilic Character of HOOH

Because the HO–OH bond in hydrogen peroxide is weak ($\Delta H_{DBE} = 51\ kcal\ mol^{-1}$ vs. $90\ kcal\ mol^{-1}$ for the H–OOH bond), there has been a tendency to assume homolytic cleavage in the reactivity and activation of HOOH. However, a pioneering study[57] established that sulfur dioxide is converted to sulfuric acid through a nucleophilic addition mechanism (equation 79).

$$HO^*O^*H + SO_2 \longrightarrow [HO^*O^*S(O)OH] \longrightarrow HO^*S(O^*)(O)OH \quad (79)$$

A subsequent investigation[58] of this system with anhydrous HOOH in dry MeCN demonstrated that there is no net reaction in the absence of H_2O. The reaction is first order with respect to H_2O up to a 100 mM concentration, and becomes second and third order at higher concentrations. The reactivity of *t*-BuOOH and SO_2 also exhibits a similar first-order dependence on H_2O concentration, but *t*-BuOOBu-*t* is unreactive under all conditions (the *t*-BuO–OBu-*t* bond energy is essentially the same as that for the HO–OH bond). Thus, water induces HOOH ($pK_a = 11.8$) to act as a nucleophile towards SO_2 ($pK_a = 1.9$) with the reaction rate fastest at pH 1.9 (equation 80).

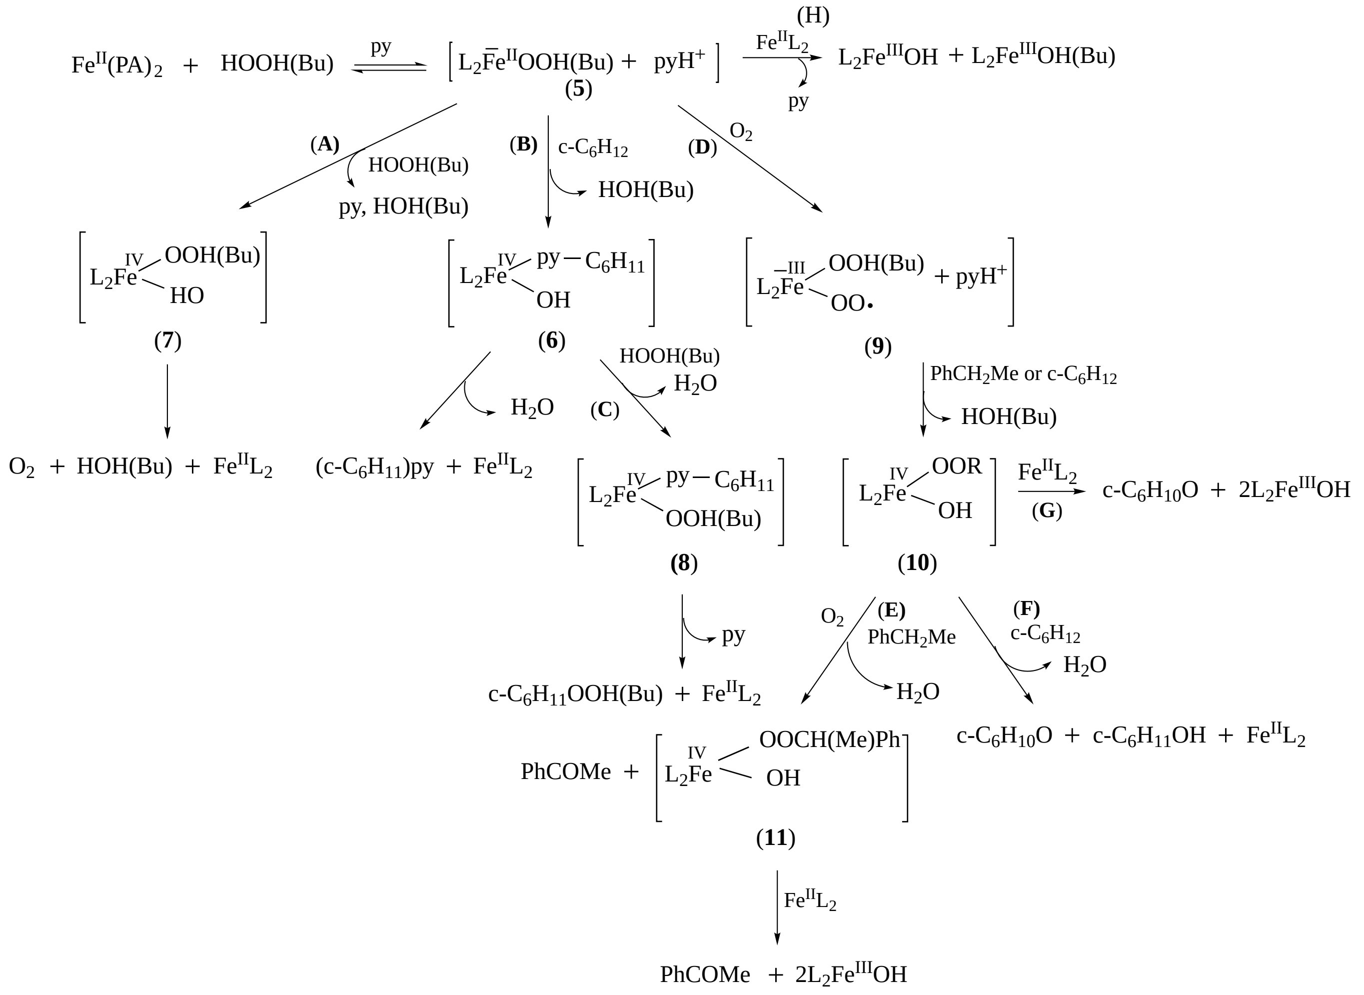
$$HOOH + SO_2 + H_2O \longrightarrow [HOOS(O)O^- + H_3O^+] \longrightarrow$$
$$(HO)_2S(O)_2{\bullet}H_2O \longrightarrow HOS(O)_2O^- + H_3O^+ \quad (80)$$

If HOOH can act as a nucleophile in aqueous solutions at pH 1.9, then stronger bases in aprotic media (e.g. pyridine (py) in $py_2(HOAc)$ and MeCN solvents) should facilitate similar pathways. Hence, the Fenton process in H_2O (at pH 2–10) and in aprotic media $[py_2(HOAc)]$ must involve nucleophilic addition to the iron(II) center (equation 81).

$$Fe^{II}(OH_2)_6^{2+} + HOOH \underset{pH\ 2}{\xrightarrow{H_2O}} [(H_2O)_5^+Fe^{II}OOH + H_3O^+]$$
$$\downarrow RH \ | \ k_H/k_D \quad (81)$$
$$ROH + H_2O + Fe^{II}(OH_2)_6^{2+}$$

4.4 Hydroperoxide Adducts of Copper(I) and Iron(II) Activate Dioxygen

In acetonitrile/pyridine, bis(bipyridine)copper(I) $[Cu^I(bipy)_2^+]$ activates HOOH and *t*-BuOOH for the selective ketonization of methylenic carbons.[59,60] With 5 mM $Cu^I(bipy)_2^+$/100 mM HOOH(Bu), the conversion efficiencies [product per 2 HOOH(Bu)] for $c\text{-}C_6H_{12}$ are 31% (HOOH) and 59% (*t*-BuOOH, argon atmosphere), and for $PhCH_2Me$ are 24% (HOOH) and 64% (*t*-BuOOH, argon). With 5 mM $Cu^I(bipy)_2$ and 10 mM *t*-BuOOH under argon, the conversion efficiency for $c\text{-}C_6H_{12}$ is 10% and for $PhCH_2Me$ is 140%. However, in the presence of O_2 (1 atm, 7 mM) the conversion efficiency for $c\text{-}C_6H_{12}$ increases to 67%, and for $PhCH_2Me$ to 440% [all PhCOMe (22 mM)], respectively. The latter result



Scheme 2 Iron/HOOH(t-Bu) induced activation of dioxygen (O_2) for the oxygenation of hydrocarbons

represents a $Cu^I(bipy)_2/t$-BuOOH induced autooxygenation with at least 2.2 O_2/catalyst turnovers. The first-formed intermediate is a one-to-one adduct $[(bipy)_2Cu^IOOBu$-$t + pyH^+]$, which reacts with (a) excess $Cu^I(bipy)_2{}^+$ to give 2 $(bipy)_2{}^+Cu^{II}OH$, (b) excess t-BuOOH to give O_2 and t-BuOH, (c) excess c-C_6H_{12} to give c-$C_6H_{11}OH$, (d) excess c-C_6H_{12} and excess t-BuOOH to give c-$C_6H_{11}OOBu$-t, and (e) O_2 to form an adduct $[(bipy)_2Cu^{III}(O_2)(OOBu$-$t) + pyH^+]$ that reacts with (i) c-C_6H_{12} to give c-$C_6H_{10}O$ and c-$C_6H_{11}OH$ and (ii) $PhCH_2Me$ to give PhCOMe.

Via closely similar pathways, iron complexes $[Fe^{II}(PA)_2$ (PA = picolinate), $Fe^{II}(bipy)_2{}^{2+}$, $Fe^{II}(OPPh_3)_4{}^{2+}$, $Fe^{II}(MeCN)_4{}^{2+}$, $(Cl_8TPP)Fe^{II}(py)_2$ (Cl_8TPP = tetrakis(2,6-dichlorophenyl)porphyrin), and $Fe^{III}Cl_3]$ in combination with HOOH or t-BuOOH in MeCN, $(MeCN)_4py$, or $(py)_2HOAc$ solution matrices catalytically activate O_2 to oxygenate hydrocarbons {e.g c-C_6H_{12} → c-$C_6H_{10}O$ [9O_2 turnovers per $Fe^{II}(PA)_2$ or $Fe^{II}(bipy)_2{}^{2+}$, and 13 per $(Cl_8TPP)Fe^{II}(py)_2$]; $PhCH_2Me$ → PhCOMe (up to 25O_2 turnovers per FeL_x); c-C_6H_{10} → c-C_6H_8O (up to 9O_2 turnovers per FeL_x); $PhCHMe_2$ → PhCOMe, $PhCMe_2OH$, and Ph(Me)C=CH_2 (up to 5O_2 turnovers per FeL_x); and *cis*-PhCH=CHPh → 2 PhCHO (up to 2O_2 turnovers per FeL_x)}.[61] With large t-BuOOH (or HOOH)/FeL_x ratios, spontaneous decomposition occurs to give free O_2 that is incorporated into the substrates. The product profiles for the various FeL_x/t-BuOOH, O_2/RH systems and their electrochemical characterization during steady-state turnover confirm that the first-formed intermediate is a one-to-one t-BuOOH/FeL_x adduct (e.g. $[(PA)_2Fe^{II}OOBu$-t (**5**) $+pyH^+]$) (Scheme 2), which reacts with (a) excess t-BuOOH to give O_2 and t-BuOH (path A), (b) excess $Fe^{II}(PA)_2$ to give $(PA)_2Fe^{III}OH(Bu$-$t)$ (path H), (c) excess c-C_6H_{12} to give (c-C_6H_{11})py (path C, Fenton chemistry) (kinetic isotope effect, [KIE] $= k_{c-C_6H_{12}}/k_{c-C_6D_{12}}$, 4.6 with t-BuOOH and 1.7 with HOOH), and (d) O_2 to form an adduct (path D) $[(PA)_2{}^-Fe^{III}(O_2)(OOBu$-$t)$ (**9**) $+pyH^+]$, that reacts with c-C_6H_{12} to form c-$C_6H_{10}O$ (paths F and G), [KIE] = 8.7. When $PhCH_2Me$ or c-C_6H_{10} are the substrates (RH), (**9**) reacts to form $[(PA)_2Fe^{IV}(OH)(OOR)]$ (**10**), which in turn reacts with RH and O_2 in a catalytic cycle to give

PhCOMe or c-C_6H_8O (path E) (up to 7 O_2 turnovers per iron with $Fe^{II}(OPPh_3)_4{}^{2+}$).

4.5 Activation of HOOH by Lewis Acids

In a rigorously nonbasic solution matrix (e.g. dry acetonitrile), reduced iron without basic ligands (e.g. $[Fe^{II}(MeCN)_4](ClO_4)_2$) is not oxidized by hydroperoxides (HOOH, *t*-BuOOH, or *m*-$ClC_6H_4C(O)OOH$). Table 9 summarizes the reactivity and products from the combination of iron(II) and hydrogen peroxide in MeCN with a series of organic substrates.[62,63] Whereas Fenton chemistry in aqueous solutions produces a diverse group of products through the radical processes that are induced by (**5**, Scheme 2), the products in a nonbasic matrix such as acetonitrile are characteristic of dehydrogenations, monooxygenations, and dioxygenations. That traditional Fenton chemistry does not occur is confirmed by the complete retention of the reduced oxidation state for iron.

The slow addition of dilute HOOH [pure HOOH (98%) in dry acetonitrile (MeCN)], *t*-BuOOH, or *m*-$ClC_6H_4C(O)OOH$ to a solution that contains $[Fe^{II}(MeCN)_4](ClO_4)_2$ and an organic substrate (RH) in dry MeCN (<0.004% H_2O) results in the dehydrogenation (oxidation) or monooxygenation of RH. The net reactions and the conversion efficiencies (moles of substrate per mole of HOOH) for 1:0.5:0.5 RH/Fe^{II}/HOOH combinations of several organic substrates are summarized in Table 10. The results from studies with *t*-BuOH and *m*-$ClC_6H_4C(O)OOH$ as the oxidant in place of HOOH also are included. In sharp contrast to aqueous Fe^{II}/HOOH radical chemistry, the products from the RH/Fe^{II}/ROH combination in dry acetonitrile are characteristic of oxidase (dehydrogenation) and monooxygenation reactions. The total absence of products from (HO•) radical chemistry, and of any Fe^{III} in the product solutions, confirms that classical Fenton chemistry does not occur.

In the absence of substrate, the combination of Fe^{II} and HOOH in dry MeCN results in the latter's rapid disproportionation to O_2 and H_2O, but the Fe^{II} remains unoxidized. Similar combinations of Fe^{II} and *t*-BuOOH or *m*-$ClC_6H_4C(O)OOH$ do not promote their rapid disproportionation, but facilitate a slow hydrolysis process (ROOH + H_2O → ROH + HOOH, assayed by ROH). Because all of the HOOH is consumed in the experiments of Table 10, the reaction efficiency for the Fe^{II}–HOOH system represents a crude measure of the relative rate of reaction for the adduct with substrate and HOOH. Scheme 3 outlines an activation cycle that is based on the argument that within an aprotic matrix the iron(II) center is a strong Lewis acid that weakens the O–O bond of HOOH.

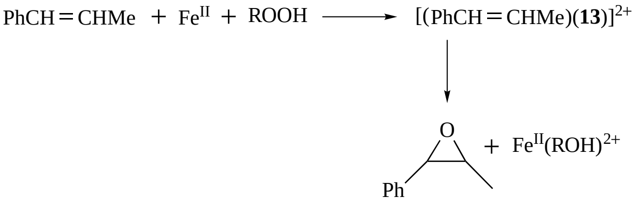
The results of Table 10 confirm that the $Fe^{II}(ROOH)^{2+}$ adducts are effective dehydrogenation agents for substrates such as cyclohexadienes, substituted hydrazines, catechols, and thiols. For PhNHNHPh and 3,5-*t*-Bu_2-1,2-$(OH)_2C_6H_2$, the reaction efficiencies are comparable for HOOH and *m*-$ClC_6H_4C(O)OOH$ as the oxidant but somewhat reduced for *t*-BuOOH. This may indicate that the oxene complex (**13**, Scheme 3) is the dominant reactive form and that *t*-BuOOH is hindered from assuming this configuration. Thus, the end-on configuration (**13**) with its oxene character is favored for HOOH and *m*-$ClC_6H_4C(O)OOH$.

1,4-Cyclohexadiene yields only benzene for the three $Fe^{II}(ROOH)^{2+}$ adducts. Either the bound substrate induces the homolytic scission of the RO–OH bond to give bound RO• and •OH (**12**, Scheme 3) for the concerted removal of two H atoms from the substrate or the oxene-like character of the end-on configuration (**13**) results in the same concerted removal of two H atoms. Although H_2S is oxygenated to H_2SO_4 by the $Fe^{II}(HOOH)^{2+}$ adduct (four HOOH molecules per H_2S), thiols (both aromatic and aliphatic) are dehydrogenated by the $Fe^{II}(ROOH)^{2+}$ complex to give disulfides as the only product. The reaction stoichiometry of two RSH molecules per ROOH is the same as for the dimerization of 1,3-c-C_6H_8; a similar bis adduct for the reaction complex probably is formed (equation 82).

$$2RSH + Fe^{II} + ROOH \longrightarrow [(RSH)_2(\mathbf{12})]^{2+} \longrightarrow RSSR + Fe^{II}(H_2O)(ROH)^{2+} \quad (82)$$

Because the side-on configuration (**12**) of the $Fe^{II}(ROOH)^{2+}$ adduct appears to be the reactive form, the lower yields for the *m*-$ClC_6H_4C(O)OOH$ oxidant indicate that the oxene configuration (**13**) is dominant for the peroxy acid.

The monooxygenation of methylstyrene (PhCH=CHMe) to form the epoxide (Table 9) appears to involve an O-atom transfer from the end-on configuration (**13**) of the $Fe^{II}(ROOH)^{2+}$ complex (equation 83).



(83)

However, a significant fraction of the products from this substrate (75% for HOOH and 80% for *t*-BuOOH, Table 10) is the result of a dioxygenation to give PhCHO and MeCHO. When *m*-$ClC_6H_4C(O)OOH$ is the oxidant, only 10% of the PhCH=CHMe that reacts is dioxygenated. These results are consistent with the proposition that the end-on configuration of the $Fe^{II}[m\text{-}ClC_6H_4C(O)OOH]^{2+}$ adduct has the most oxene character and favors O-atom transfer to PhCH=CHMe and that the $Fe^{II}(HOOH)^{2+}$ and $Fe^{II}(t\text{-}BuOOH)^{2+}$ adducts react via a biradical mechanism (**12**, Scheme 3).

The formulations of Scheme 3 for the reactive forms of the $Fe^{II}(ROOH)^{2+}$ adducts represent unique electrophilic centers that are consistent with reasonable dehydrogenase (**12**), monooxygenase (**12** and **13**), and dioxygenase (**14**) reaction

Table 9 Products from the iron(II)-induced monooxygenation, dehydrogenation, and dioxygenation of organic substances (RH) by HOOH in dry acetonitrile[a]

Substrate	Reaction efficiency (%)[b]	Products
Monooxygenation		
Blank (H_2O_2)	100	O_2, H_2O, Fe^{II}
PPh_3	100	PPh_3O
Me_2SO	100	Me_2SO_2
Ph_2SO	100	Ph_2SO_2
EtOH	70	MeCHO (90%), $MeCO_2H$ (10%), O_2
$PhCH_2OH$	100	PhCHO
Cyclohexanol	47	Cyclohexanone, O_2
MeCHO	20	$MeCO_2H$, O_2
Me_2CO	NR	O_2
PhCHO	28	$PhCO_2H$, O_2
Dehydrogenation and oxidation		
Cyclohexane	NR	O_2
1,4-c-C_6H_8	59	PhH, O_2
PhNHNHPh	100[c]	PhN=NPh
H_2S	100	H_2SO_4

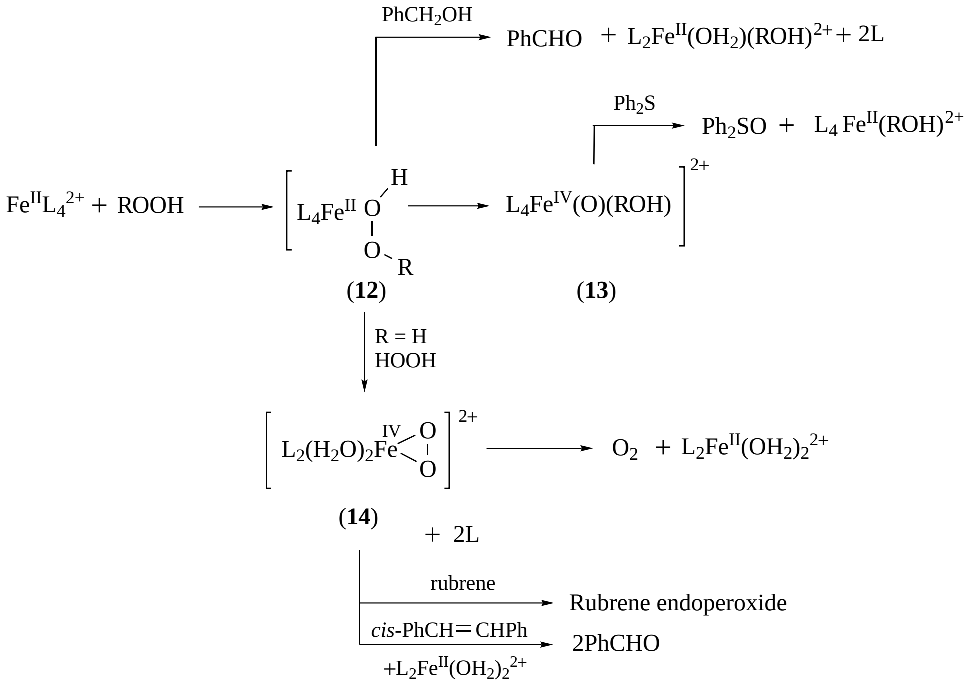
Ph_3P → Ph_3PO	100	100	47

[a]To 1.0 mmol of substrate and 0.5 mmol of $[Fe^{II}(MeCN)_4](ClO_4)_2$ in 10 mL of MeCN was added slowly 0.5 mmol of hydroperoxide (1 M ROOH in MeCN). Reaction time and temperature: 23 °C for 5 min (1,4-c-C_6H_8, 1,3-c-C_6H_8, PhNHNHPh, $PhCH_2SH$, PhSH, c-$C_6H_{11}OH$, MeCHO, PhCHO, $PhCH_3$, Ph_2SO and Ph_3P); 5 °C for 10 min (3,5-*t*-Bu_2-1,2-$(OH)_2C_6H_2$, $MeCH_2OH$). [b]100% represents one substrate dehydrogenation or oxygenation per ROOH. [c]Product ratio.



Scheme 3 Activation of ROOH by Iron(II) Lewis acids

mechanisms. The monooxygenase formulations also are consistent with the redox stoichiometry of the cytochrome P-450 cycle[64] and represent a form of oxygen activation that promotes electrophilic abstraction of a hydrogen atom (or O-atom transfer) to give radical (or oxene) activated intermediates[65] and the monooxygenation of cytochrome P-450 substrates (Table 10).[66]

In the presence of excess HOOH, the $Fe^{II}(MeCN)_4{}^{2+}$ catalyst forms a reactive adduct (**14**) that reacts with diphenylbenzofuran, arylalkenes, 9,10-diphenylanthracene, or rubrene to form exclusively dioxygenated products (Table 9). Such reactivities parallel those of dioxygenases with this group of substrates.

In a base-free medium (dry MeCN), $Fe^{III}Cl_3$ activates HOOH to form a reactive intermediate that oxygenates alkanes, alkenes, and thioethers, and dehydrogenates alcohols and aldehydes.[67] Table 11 summarizes the conversion efficiencies and product distributions for a series of alkene substrates subjected to the $Fe^{III}Cl_3$/HOOH/MeCN system. The extent of the $Fe^{III}Cl_3$-induced monooxygenations is enhanced by higher reaction temperatures and increased concentrations of the reactants (substrate, $Fe^{III}Cl_3$, and HOOH). For 1-hexene (representative of all of the alkenes), a substantial fraction of the product is the dimer of 1-hexene oxide, a disubstituted dioxane. With other organic substrates (RH), $Fe^{III}Cl_3$ activates HOOH for their monooxygenation; the reaction efficiencies and product distributions are summarized in Tables 11(b). In the case of alcohols, ethers, and cyclohexane, a substantial fraction of the product is the alkyl chloride, and with aldehydes, for example, PhCHO, the acid chloride represents one-half of the product. In the absence of substrate the $Fe^{III}Cl_3$/MeCN system catalyzes the rapid disproportionation of HOOH to O_2 and H_2O.

Because $Fe^{III}Cl_3$ is an exceptionally strong Lewis acid and electrophilic center, it activates HOOH (which acts as a nucleophile) for the dehydrogenation of a second HOOH. On the basis of the disproportionation process, as well as the monooxygenation and dehydrogenation reactions of Table 11, the activation of HOOH by $Fe^{III}Cl_3$ probably involves the initial formation of at least two reactive forms (**15** and **16**) of an $Fe^{III}Cl_3$(HOOH) adduct (Scheme 4).

The disproportionation of HOOH occurs via a concerted transfer of the two hydrogen atoms from a second HOOH to the $Fe^{III}Cl_3$(HOOH) adduct. This dehydrogenation of HOOH is a competitive process with the $Fe^{III}Cl_3$/substrate/HOOH reactions. The controlled introduction of dilute HOOH into the $Fe^{III}Cl_3$/substrate solution limits the concentration of HOOH and ensures that the substrate/HOOH reaction can be competitive with the second-order disproportionation process. The substrate reaction efficiencies in Table 11 are proportional to the relative rates of reaction (k_{RH}/k_{HOOH}). The mode of activation of HOOH by $Fe^{III}Cl_3$ is analogous to that of $Fe^{II}(MeCN)_4{}^{2+}$; both are strong electrophiles in ligand-free dry MeCN and induce HOOH to monooxygenate organic substrates.

The epoxidation of alkenes (Table 11(a)) appears to involve an O-atom transfer from the oxene configuration of the $Fe^{III}Cl_3$(HOOH) adduct (**16**). The resulting epoxides are rapidly dimerized to dioxanes. Hence, the complete conversion of an alkene to its epoxide is precluded; the more complete the conversion, the higher the fraction of dioxane in the product mixture.

The results in Table 11 indicate that the $Fe^{III}Cl_3$(HOOH) adduct monooxygenates alkanes, alcohols, and aldehydes. A mechanism that is consistent with this involves the homolytic scission of the HO–OH bond in the side-on configuration (**15**), induced by the bound substrate, and the subsequent abstraction by one •OH of an H atom from the α-carbon and addition of the second •OH to the resulting carbon radical (Scheme 4). An analogous process appears to occur for the oxygenation of benzaldehyde by the $Fe^{III}Cl_3$(HOOH) adduct, but 50% of the product is the acid chloride. Occurrence of the latter indicates that the activated side-on complex (**15**) has some hypochlorous acid (HOCl) character and can add a chlorine atom to the carbon radical that results from the H-atom abstraction by the •OH group. This also occurs with alkanes, alcohols, and ethers (Table 11). Such chemistry is similar to the activation of chloride ion and HOOH to HOCl by heme-centered myeloperoxidase.[68,69] Phosphines, dialkyl sulfides, and sulfoxides are monooxygenated by the $Fe^{III}Cl_3$(HOOH) adduct in a manner that appears to be analogous to that for the epoxidation of alkenes via species (**16**).

Anhydrous $Fe^{III}Cl_3$ catalyzes the stereospecific epoxidation of norbornene, the demethylation of *N*,*N*-dimethylaniline, and the oxidative cleavage of PhCMe(OH)CMe(OH)Ph (and other α-diols) by hydrogen peroxide (Table 11 and Scheme 4).[67] For each class of substrate, the products parallel those that result from their enzymatic oxidation by cytochrome P-450. The close congruence of the products indicates that the reactive oxygen in the $Fe^{III}Cl_3$/HOOH model system and in the active form of cytochrome P-450 is essentially the same, with strong electrophilic oxene character (stabilized singlet atomic oxygen).

4.6 Formation and Reactivity of Atomic Oxygen from Hydroperoxides [HOOH, ROOH, R′C(O)OOH]

The function of peroxidase enzymes is the activation of HOOH to provide two oxidizing equivalents for the oxidation of a variety of substrates. The interaction of horseradish peroxidase (HRP, an iron(III) heme that has a proximal imidazole) with HOOH results in the formation of a green reactive intermediate known as Compound I. It is reduced by one electron to give a red reactive intermediate, Compound II.[70] Both of these intermediates contain a single oxygen atom from HOOH, and Compound I is two oxidizing equivalents above the iron(III)−heme state with a magnetic moment equivalent to three unpaired electrons ($S = 3/2$). A recent extended X-ray-absorption fine-structure (EXAFS) study[71] summarizes the physical data in support of $(por^{+}\bullet)Fe^{IV}{=}O$ as a

Table 11 Products and conversion efficiencies for the $Fe^{III}Cl_3$ induced oxygenation–dehydrogenation of alkenes and organic substrates (RH) by HOOH in dry acetonitrile[a]

Substrate	Reaction efficiency (%)[b]	Products[c]
(a) Alkenes (−5 °C, 10 min reaction times)		
Blank (HOOH)	100	O_2, H_2O

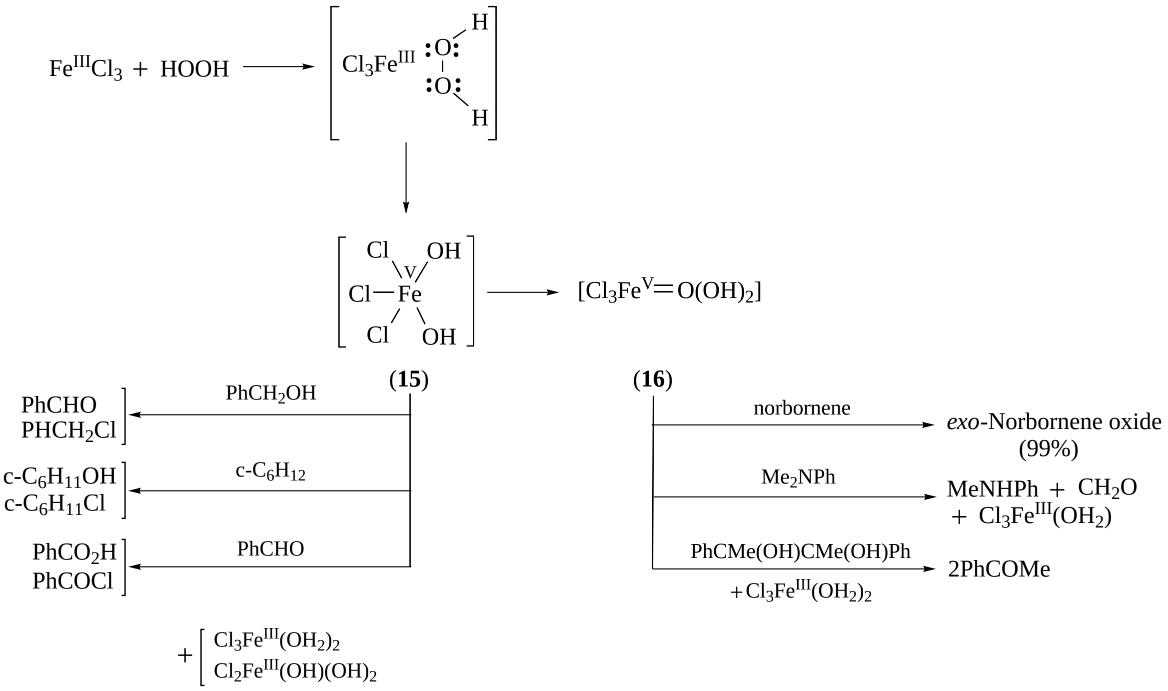
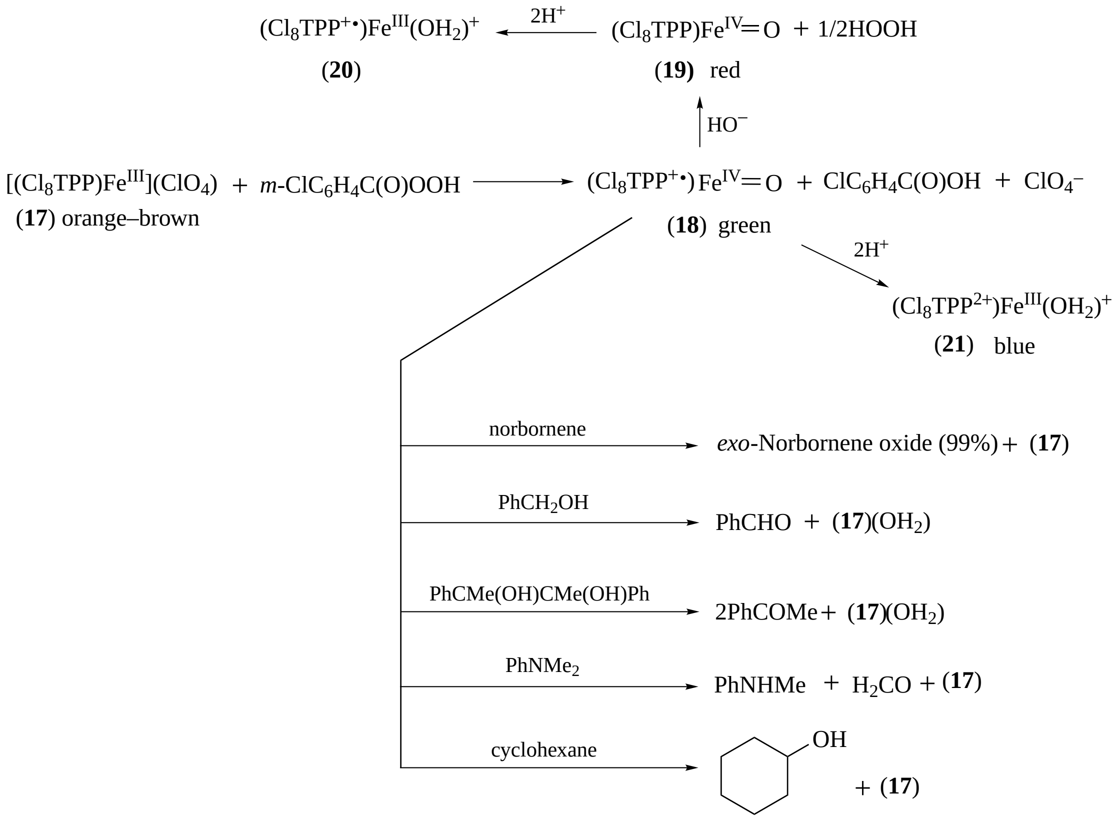
[a]RH and $Fe^{III}Cl_3$ (1.0 mmol of each) combined in 10–20 mL of dry MeCN, followed by the slow addition of 1 mmol HOOH (1 M HOOH (98%) in MeCN). [b]Percentage of substrate converted to products. [c]After the indicated reaction time, the product solution was quenched with water, extracted with diethyl ether, and analyzed by capillary gas chromatography and GC–MS.



Scheme 4 Proposed pathways for activation of HOOH by $Fe^{III}Cl_3$in MeCN



Scheme 5 Model for Compounds I and II horseradish peroxidase

formulation for Compound I, and (por)Fe^{IV}=O for Compound II, and concludes that both species contain an oxene–ferryl group (Fe=O) with a bond length of 1.64 Å.

Model systems provide compelling evidence that stabilized atomic oxygen is present in Compound I and Compound II of HRP.[47] Thus, the combination of tetrakis(2,6-dichlorophenyl)porphinatoiron(III) perchlorate (**17**, Scheme 5) with pentafluoroiodosobenzene, *m*-chloroperbenzoic acid, or ozone in acetonitrile at −35 °C yields a green porphyrin–oxene adduct (**18**). This species, which has been characterized by spectroscopic, magnetic, and electrochemical methods, cleanly and stereospecifically epoxidizes olefins (>99% *exo*-norborneneoxide). The reaction chemistry of Scheme 5 illustrates how (**18**) acts as an oxygen-atom transfer agent towards alkenes. The stereospecificity for the epoxidation of norbornene is consistent with the concerted insertion[72] of a singlet oxygen atom into the π bond which is analogous to the stereospecific transfer of a singlet oxygen atom from uncatalyzed *m*-$ClC_6H_4C(O)OOH$ to norbornene.

The spectroscopy, electrochemistry, and magnetic properties of (**18**) indicate that its iron center is equivalent to that of Compound I of HRP. The spectroscopic and electrochemical properties of (**19**), and its reduced reactivity with alkenes, indicate that the electronic structure of its iron–oxygen center is analogous to that of Compound II of HRP.

5 REACTIVITY OF OXYGEN RADICALS (HO•, RO•, HOO•, AND ROO)

Oxygen radicals are defined as those molecules that contain an oxygen atom with an unpaired, nonbonding electron (e.g. HO•). Although triplet dioxygen (•O_2•) and superoxide ion (O_2^{-}•) come under this definition, their nonradical chemistry dominates their reactivity. The hydroxyl radical (HO•) is the most reactive member of the family of oxygen radicals (HO•, RO•, •O•, HOO•, ROO•, and RC(O)O•), and is the focus of most oxygen radical research. In the gas phase, the dramatic example of oxygen-radical reactivity with hydrocarbon substrates is combustion, which is initiated by HO• (or RO• or MO•) and propagated by •O_2• and •O• (equation 84).

$$CH_4 + HO\bullet \longrightarrow HOH + Me\bullet \xrightarrow{\bullet O_2\bullet} MeOO\bullet; \quad Me\bullet \xrightarrow{\bullet O\bullet} MeO\bullet \qquad (84)$$

These initial steps are highly exothermic, which accelerates the autoxidation cycle to an explosive rate to give CO, CO_2, and H_2O as the stable products. Within biological matrices the autoxidation and peroxidation of lipids and fats from foodstuffs are important examples of oxygen radical

chemistry. In general, the initiator is HO• (or HOO•) and the autoxidation cycle is carried by $\cdot O_2\cdot$ (equation 85).

$$\underset{(\mathbf{22})}{RCH{=}CHCH_2(CH_2)_nCO_2R'} + HO\cdot \longrightarrow \underset{(\mathbf{23})}{RCH{=}CH\dot{C}H(CH_2)_nCO_2R'}$$

$$\xrightarrow{\cdot O_2\cdot} RCH{=}CHCH(OO\cdot)(CH_2)_nCO_2R'$$

$$\xrightarrow{(\mathbf{22})} (\mathbf{23})\cdot + RCH{=}CHCH(OOH)(CH_2)_nCO_2R' \qquad (85)$$

Both combustion and lipid autoxidation are initiated through the creation of a carbon radical (abstraction of a hydrogen atom by HO• from a C–H bond). The rate is inversely proportional to the C–H bond energy. The C–H bond energies of aromatic carbons are so large that the reaction of HO• with benzene usually goes by addition. Thus, conjugated systems can stabilize radicals by delocalization throughout the π-electron system. However, with saturated σ-bonded substrates the only pathway for oxygen-radical reactions is by hydrogen-atom abstraction (equation 86).

$$R–H + YO\cdot \longrightarrow YO–H + R\cdot \qquad (86)$$

The driving force for such a reaction is the difference between the free energy of bond formation for YO–H ($-\Delta G_{BF}$), and the enthalpy of bond dissociation for R–H (ΔH_{DBE}). Table 12 summarizes the YO–H bond-formation energies for oxygen radicals (YO•), as well as dissociative bond energies for several R–H substrates.[41,73] Reference to these data indicates that t-BuO• will react exothermally with toluene ($PhCH_3$), but will be essentially unreactive with methane.

5.1 Reactivity of HO•

Gas-phase HO• is generated by photolysis of HOOH and by cosmic radiation and solar radiation of O_2/H_2O in the atmosphere. The latter process is an important contributor to the atmospheric chemistry associated with organic pollutants. The gas-phase reactions of HO• with organic molecules have been exhaustively reviewed and summarized in a recent compendium.[74] In aqueous solutions, HO• is produced by radiolysis (continuous and pulsed) (equation 87),[75]

$$HOH \xrightarrow{h\nu} H\cdot + HO\cdot;\quad H\cdot \xrightarrow{N_2O} N_2 + HO\cdot \qquad (87)$$

and has been the basis for a massive compilation of reactivity data for HO• with organic and inorganic substrates.[76] Although sophisticated measuring techniques provide precise kinetic data for the primary (HO•/R–H) reaction with hydroxyl radicals generated by pulse radiolysis, the limited yields of terminal products preclude identification and assay. For this reason, much of the characterization of HO• chemistry with organic substrates has made use of the Fenton process.

Fenton chemistry is the use of reduced transition metal ions (Fe^{II}, Mn^{II}, V^{III}, and Ti^{III}) in stoichiometric combination with HOOH to generate HO• in situ at a slow rate (equation 88).[50] The dynamics of (HO•) reactivity with organic substrates are assessed as relative rates vis-à-vis the fate of the Fenton-generated hydroxyl radical in these competitive reactions (equations 89–91).[51,60]

$$[Fe^{II}(OH)_2)_6]^{2+} + HOOH + H_2O \xrightarrow[pH\ 2]{k} [(H_2O)_5{}^{+}Fe^{II}OOH + H_3O^{+}] \longrightarrow (H_2O)_5{}^{2+}Fe^{III}OH + HO\cdot$$

$$k = 42\ M^{-1}s^{-1} \qquad (88)$$

Table 12 Radical strength of oxygen radicals (YO•) in terms of their YO–H bond formation free energies, and dissociative bond energies for H–R molecules

Oxy radical (YO•)	Bond (YO–H)	$(-\Delta G_{BF})(aq)^a$ (kcal mol^{-1})	Bond (H–R)	$(\Delta H_{DBE})(g)^b$ (kcal mol^{-1})
HO•	HO–H	111	$H–CH_3$	105
$O^-\cdot$	$^-O–H$	109	H–(n-C_3H_7)	100
•O•	•O–H	98	H–(c-C_6H_{11})	95

MeC(O)O•	MeC(O)O–H	98	H–OPh	86

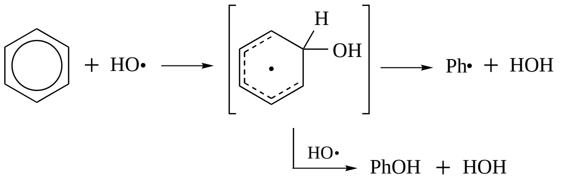
[a]Sawyer.[58] [b]Lide.[29]

$$\mathrm{Fe^{II}L_{\mathit{n}} + HO\bullet \longrightarrow L_{\mathit{n}}Fe^{III}OH} \qquad k = 2 \times 10^{8}\,\mathrm{M^{-1}s^{-1}} \tag{89}$$

$$\mathrm{RH + HO\bullet \longrightarrow R\bullet + HOH} \qquad k = 10^{8}\text{–}10^{10}\,\mathrm{M^{-1}s^{-1}} \tag{90}$$

$$\mathrm{HOOH + HO\bullet \longrightarrow HOO\bullet + HOH} \qquad k = 1 \times 10^{7}\,\mathrm{M^{-1}s^{-1}} \tag{91}$$

With a 1:1 $Fe^{II}L_n$/HOOH ratio at modest concentrations in the presence of excess substrate, the attack of substrate is favored. Although H-atom abstraction is the common path for most substrates, the large bond energy of aromatic C–H bonds (ΔH_{DBE}, 111 kcal mol^{-1}; Table 12) precludes this as a facile process. However, addition to the conjugated π-electron system is energetically favored (equation 92).



(92)

5.2 Reactivity of HOO•

The hydroperoxyl radical (HOO•) is the conjugate acid of superoxide ion ($O_2^{-}\bullet$) (equation 93) and constitutes about 1% of the $O_2^{-}\bullet$ that is formed in aqueous systems at pH 7.[77] Although the O–O bond of HOO• traditionally is viewed to be the same as the single σ bond of HO–OH (ΔH_{DBE}, 51 kcal mol^{-1}), its bond energy (ΔH_{DBE}) is about 85 kcal mol^{-1}, which is more consistent with the 1.5 bond order of $O_2^{-}\bullet$. However, HOO• is unstable in protic media (such as water and alcohols) and rapidly decomposes via heterolytic and homolytic disproportionation (equations 94 and 95).[78]

$$\mathrm{HOO\bullet + H_2O \rightleftharpoons H_3O^{+} + O_2^{-}\bullet} \qquad \mathrm{p}K_a = 4.9 \tag{93}$$

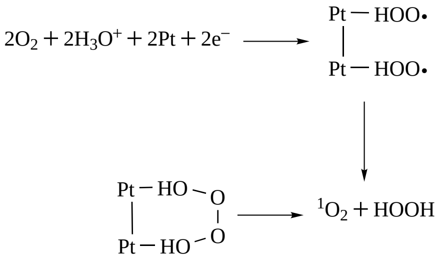
$$\mathrm{HOO\bullet + O_2^{-}\bullet \xrightarrow{H_2O} HOOH + HO^{-} + O_2} \qquad k = 1 \times 10^{8}\,\mathrm{M^{-1}s^{-1}} \tag{94}$$

$$\mathrm{HOO\bullet + HOO\bullet \longrightarrow HOOH + O_2} \qquad k = 8.3 \times 10^{5}\,\mathrm{M^{-1}s^{-1}} \tag{95}$$

Another route to the formation of HOO•/$O_2^{-}\bullet$ is UV irradiation of HOOH in aqueous solutions.[79] Aerobic organisms produce minor fluxes of superoxide ion ($O_2^{-}\bullet$, and thereby HOO•) during respiration and oxidative metabolism; for example, possibly up to 10–15% of the O_2 reduced by cytochrome *c* oxidase and by xanthine oxidase passes through the HOO•/$O_2^{-}\bullet$ state.[80] Thus, the chemistry of HOO• (and of $O_2^{-}\bullet$) may be important to an understanding of oxygen toxicity in biological systems. In aprotic media, the rate of protonation of $O_2^{-}\bullet$ is proportional to the acidity of the associated Brønsted acids (equation 96).[81] Electrolytic oxidation of HOOH in acetonitrile yields stoichiometric fluxes of HOO• (equation 97).[29] Reduction of O_2 in MeCN at a platinum electrode in the presence of excess protons yields adsorbed Pt(HOO•) (equation 98) which forms [HOOOOH] via radical coupling at the surface and homolytically dissociates to $^{1}O_2$ and HOOH.[67]

$$\mathrm{O_2^{-}\bullet + HA \xrightarrow[k\,\propto\,K_{HA}]{k} HOO\bullet + A^{-}} \tag{96}$$

$$\mathrm{HOOH \xrightarrow[MeCN]{H_2O} HOO\bullet + H_3O^{+} + e^{-}}$$
$$\mathrm{HOO\bullet \xrightarrow[MeCN]{HOO\bullet} HOOH + O_2} \qquad k = 1 \times 10^{7}\,\mathrm{M^{-1}\,s^{-1}} \tag{97}$$



(98)

The homogeneous disproportionation of HOO• in aprotic solvents does not yield $^{1}O_2$ and appears to involve a 'head-to-tail' dimer intermediate that undergoes H-atom transfer (equation 99).[37,82]

$$\mathrm{2HOO\bullet \longrightarrow [HOO\bullet\,HOO\bullet] \longrightarrow HOOH + \bullet O_2\bullet}\; k_d \tag{99}$$

The rate constants (k_d) for the homogeneous disproportionation of HOO• in various solvent systems range from $1.7 \times 10^{4}\,\mathrm{M^{-1}\,s^{-1}}$ (DMSO) to $6.3 \times 10^{8}\,\mathrm{M^{-1}\,s^{-1}}$ (PhCl) and $8.3 \times 10^{5}\,\mathrm{M^{-1}}$ (H_2O).[29,37,77,81,83] This second-order parameter limits the steady-state concentration (flux) of HOO• in a given solvent and thereby its reactivity with substrates. Hence, DMSO provides a matrix that stabilizes HOO• better than the other solvents.

An early study[83] used radical-initiated autoxidation experiments in acetonitrile (MeCN) and in chlorobenzene (PhCl) to demonstrate that HOO• abstracts hydrogen atoms from allylic hydrocarbons, for example, 1,4-cyclohexadiene (1,4-CHD). Subsequent investigations[37] have used $O_2^{-}\bullet$ in DMSO with limiting fluxes of protons to generate HOO• at a controlled rate (equation 96). Because the disproportionation of HOO• is a second-order process, such limiting conditions favor H-atom abstraction by HOO• from excess 1,4-CHD (especially true for DMSO solvent in which HOO• disproportionation is slower than in other solvents). Hence, the presence of 1,4-CHD (1,4-c-C_6H_8) enhances the rate of disappearance of HOO• because of its parallel oxidation of an allylic hydrogen to give a radical that disproportionates to 1,3-CHD and benzene:

$$\mathrm{HOO\bullet + 1,4\text{-}c\text{-}C_6H_8 \longrightarrow 1,3\text{–}\dot{C}_6H_7 + HOOH}$$

$$k_{ox} = 1.6 \times 10^2 M^{-1}s^{-1} \tag{100}$$

Analysis of the kinetic data for the decay of the HOO• concentration in such systems provides evaluations of k_{ox}.

Table 13 summarizes values of k_{ox} in three solvents (DMSO, MeCN, and PhCl) for the oxidation of 1,4-CHD by HOO•,[37,83] as well as for several other substrates in water/alcohol solvents.[37,83–87] A reasonable reaction sequence for the formation and reaction of HOO• is outlined in Scheme 6. Initial formation of HOO• (at diffusion-controlled rates for strong acids) is followed by its disproportionation (k_d) or attack of 1,4-CHD (k_{ox}). As with the rates of dehydrogenation for HOO•, its relative rate of oxidation of 1,4-CHD in the three solvents is in the same order, PhCl > MeCN > DMSO. For DMSO, the value of k_{ox} is slightly greater than $k_d^{1/2}$, but with MeCN and PhCl the values of k_{ox} are an order of magnitude smaller than their $k_d^{1/2}$ values. Hence, the propensity of HOO• to initiate the autoxidation of allylic groups is greater in DMSO and occurs at much lower concentrations of substrate. The rate constants (k_{ox}) for the allylic hydrogen oxidation of linoleic acid and arachidonic acid in protic media also are slightly greater than $(k_d^{1/2})_{H_2O}$ (Table 13). The large rate constants (k_{ox}) for the reaction of HOO• with antioxidants (α-tocopherol, cysteine, and ascorbic acid) are consistent with their protective role in biology.

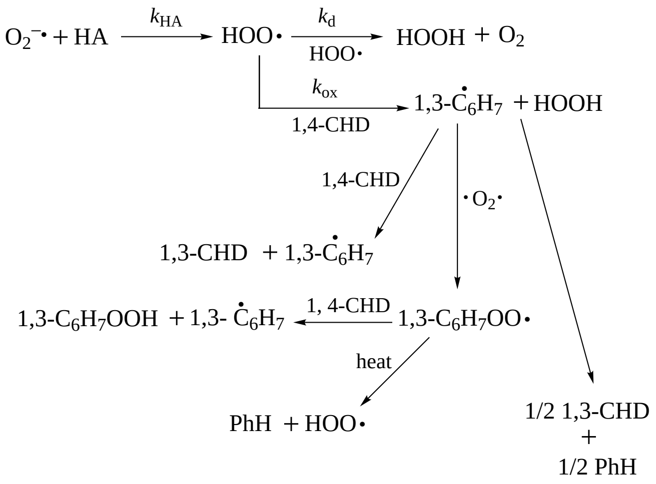
The reactivity of ROO• radicals parallels that of HOO•, and is essentially equivalent because its bond energy (ROO–H; $-\Delta G_{BF}$, 83 kcal mol^{-1}) is the same as that for the HOO–H bond ($-\Delta G_{BF}$, 82 kcal mol^{-1}). However, the 'head-to-tail' mechanism for the disproportionation of HOO• (via H-atom transfer, equation 99) is not possible. Instead, ROO• radicals dimerize via radical–radical coupling to form a dialkyl tetraoxide (equation 101).[88]

$$2ROO\bullet \xrightarrow{k_d} [ROOOOR] \longrightarrow ROOR + {}^1O_2 \tag{101}$$

The [ROOOOR] intermediate decomposes to dialkyl peroxide and singlet dioxygen, but also reacts more vigorously than $^1O_2$ with '$^1O_2$ substrates' (1,4-CHD, 1,3-diphenylisobenzofuran, rubrene).

Table 13 Rate constants for the second-order oxidation by HOO• of allylic and other X–H functions of organic substrates

Substrate	Solvent	k_{ox} ($M^{-1} s^{-1}$)
1,4-CHD	Me_2SO	1.6×10^2
	MeCN	3.5×10^2
	PhCl	1.4×10^3
Linoleic acid	85:15 EtOH/H_2O	1.2×10^3
Arachidonic acid	85:15 EtOH/H_2O	3.0×10^3
α-Tocopherol	85:15 EtOH/H_2O	2.0×10^5
Cysteine	H_2O	1.8×10^4
Ascorbic acid	H_2O	1.6×10^4

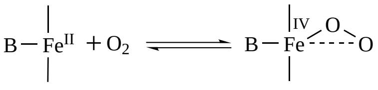


Scheme 6 Formation and reactivity of HOO•

6 REACTIVITY AND ACTIVATION OF DIOXYGEN (•O₂•)

Ground-state dioxygen has two unpaired electrons (•O_2•), which makes it a biradical with a triplet electronic state (see Table 4). Its radical character is limited because the H–OO• bond is weak ($-\Delta G_{BF}$, 51 kcal mol^{-1}), and the triplet state precludes direct reaction with singlet-state substrate molecules with saturated σ bonding.

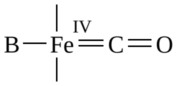
Perhaps the most important (but nonproductive) reaction chemistry for $^3O_2$ is its reversible binding by metalloproteins: hemoglobin, myoglobin, hemerythrin, and hemocyanin. Nature developed such systems to obviate the limited solubility of O_2 in water (≈1 mM at 1 atm O_2), which restricts the energy flux from oxidative metabolism in aerobic organisms. In the case of myoglobin (a reduced heme protein with an axial histidine base; B), the reversible binding of •O_2• causes the paramagnetic iron(II) center ($S = 4/2$) of the heme to become diamagnetic via the formation of two covalent Fe–(O_2) bonds (the estimated charge transfer for the iron to the bound O_2 is about 0.1 electron) (equation 102).[89]



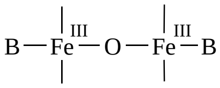
(d^{6}sp, $S = 4/2$) (d^{6}sp, $S = 0$) (102)

$$K_{O_2} = \frac{1}{(P_{1/2})_{O_2}} \approx 10^3\ atm^{-1}$$

where $(P_{1/2})_{O_2}$ represents the partial pressure of O_2 when one-half of the heme centers have an O_2 adduct. Carbon monoxide is more strongly bound, with a K_{CO} value of about 10^6 atm^{-1} via an analogous nucleophilic interaction by the reduced imidiazole-liganded iron–porphyrin center (**24**, d^{6}sp, $S = 0$).

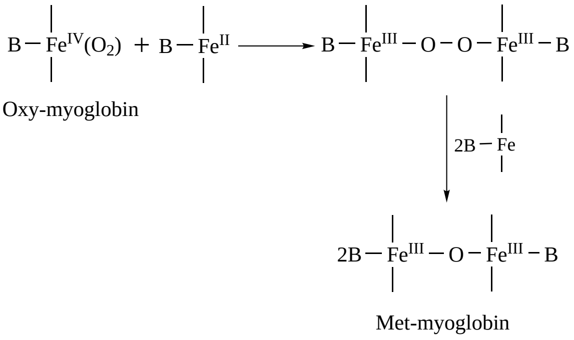


(**24**)



(**25**)

Although the function of the O_2-binding proteins is the enhancement of the O_2 concentration for transport and storage, there is an inevitable degradation of the oxy–heme system, primarily via interaction with nonoxygenated reduced hemes to give (**25**). The kinetics and mechanism for this irreversible process have been characterized through the use of hindered ('picket-fence') iron–porphyrin models for myoglobin (equation 103).[90]



(103)

The 'picket fence' hinders the face-to-face approach of the two hemes, but less effectively than the polypeptide chains of the heme protein. The autoxidation pathway for the heme in myoglobin (equations 102 and 103) is sufficiently slow to give the protein a useful life of several weeks, but is analogous to that for all reduced-iron systems.

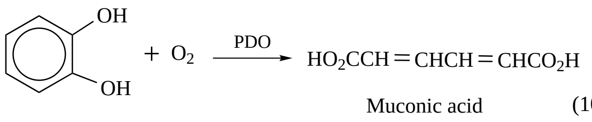
Biological systems overcome the inherent unreactive character of $^3O_2$ by means of metalloproteins (enzymes) that activate dioxygen for selective reaction with organic substrates. For example, the cytochrome P-450 proteins (thiolated protoporphyrin IX catalytic centers) facilitate the epoxidation of alkenes, the demethylation of N-methylamines (via formation of formaldehyde), the oxidative cleavage of α-diols to aldehydes and ketones, and the monooxygenation of aliphatic and aromatic hydrocarbons (RH) (equation 104).[91] The methane monooxygenase proteins (MMO, dinuclear nonheme iron centers) catalyze similar oxygenation of saturated hydrocarbons (equation 105).[92,93]

$$O_2 + (2H^+ + 2e^-) + RH \xrightarrow{\text{cyt P-450}} ROH + H_2O \quad (104)$$

cytochrome P-450 reductase

$$O_2 + (2H^+ + 2e^-) + CH_4 \xrightarrow{\text{MMO}} MeOH + H_2O \quad (105)$$

reductase



(106)

$$^3O_2 \xrightarrow[\text{Rose Bengal}]{h\nu} {}^1O_2$$

$$^3O_2 \xrightarrow[\text{Rose Bengal}]{h\nu} {}^1O_2 \quad (107)$$

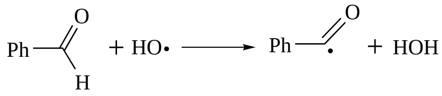
Both of these systems activate O_2 via a two-equivalent reduction (without the protein catalysts this would give HOOH). In contrast, pyrocatechol dioxygenase (PDO) (a nonheme iron protein)[94] activates $^3O_2$ without a reductive cofactor (equation 106).

The most direct means to activate $^3O_2$ is by reduction with electrons or hydrogen atoms to give O_2^-•, HOO•, HOOH, and HOO^-. Ground-state dioxygen ($^3O_2$) also can be activated by photochemical energy transfer to yield singlet dioxygen ($^1O_2$) (equation 107).[95]

6.1 Radical–Radical Coupling and Autoxidation

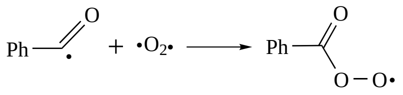
Although $^3O_2$ is unreactive with singlet substrates and is unable to abstract hydrogen atoms from hydrocarbon substrates, it is a biradical and as such can undergo coupling with other radicals (carbon and nonmetals as well as transition metals). Such radical–radical coupling reactions usually have zero activation energy. Thus, an HO• radical can initiate the reaction of organic substrates with $^3O_2$:

Initiation

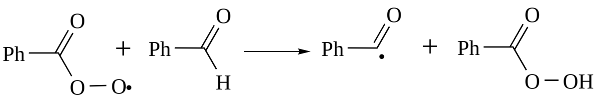


(108)

Propagation

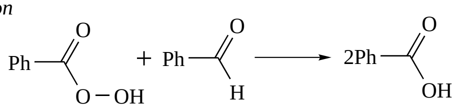


(109)



(110)

Termination



(111)

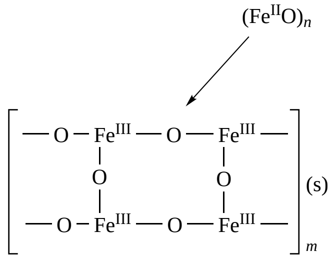
Propagation in such autoxidation cycles by $^3O_2$ requires that the ROO• intermediate be a sufficiently strong radical to break a C–H bond of the substrate. Allylic, aldehydic, and benzylic C–H bonds are examples that meet this limitation.

Reduced transition metals with unpaired electrons also undergo autoxidation via radical–radical coupling. For example, reduced-iron porphyrins are rapidly converted to dinuclear

μ-oxo dimers (equation 112).[96] Similar heterogeneous radical–radical coupling occurs at the solution–surface interface of metallic iron (equation 113).

$$\underset{(d^6sp,\ S = 4/2)}{Fe^{II}(TPP) + O_2} \rightleftharpoons (TPP)Fe^{IV}(O_2) \xrightarrow{Fe^{II}(TPP)} (TPP)Fe^{III}OOFe^{III}(TPP) \xrightarrow{2Fe^{II}(TPP)} \underset{(d^5sp^2,\ S = 5/2)}{2(TPP)Fe^{III}OFe^{III}(TPP)} \quad (112)$$

$$Fe\,(s) + O_2 \longrightarrow Fe(O_2)\ (s) \xrightarrow{Fe} FeOOFe\ (s) \xrightarrow{2Fe} \underset{(Fe^{II}O)_n}{[OFe^{II}OFe^{II}O]_n\,(s)}$$



$(Fe^{III}{}_2O_3)_m$ (113)

6.2 Metal-induced Activation of $^3O_2$ for the Initiation of Autoxidation

Reduced transition metal complexes are traditionally implicated as the initiators for the autoxidation of fats, lipids, and foodstuffs.[97] However, whether this involves direct activation of O_2 or of reduced dioxygen ($O_2^{-}\bullet$, $HOO\bullet$, and HOOH) is unclear. Reduced metal plus HOOH yields $HO\bullet$ via Fenton chemistry and probably is the pathway for initiation of autoxidation in many systems. Although there has been an expectation that one or more of the intermediates from the autoxidation of reduced transition metals (equation 112) can act as the initiator for the autoxidation of organic substrates, direct experimental evidence has not been presented.

The addition of trace levels ($>10^{-6}$ M) of bis(bipyridine)cobalt(II) to O_2-saturated solutions of aldehydes in acetonitrile initiates their rapid autoxidation to carboxylic acids.[83] The initial reaction rates appear to be first order in catalyst concentration, first order in substrate concentration, and first order in O_2 concentration. However, within one hour the autoxidation process is almost independent of catalyst concentration.

6.3 Metal-induced Activation of $^3O_2$ for Dehydrogenation and Oxygenase Chemistry

The addition of $Co^{II}(bipy)_2{}^{2+}$ to dioxygen-saturated acetonitrile solutions of *N*-methylanilines catalyzes their demethylation via a monooxygenase pathway to give formaldehyde and demethylated aniline.[98] This is analogous to the chemistry facilitated by cytochrome P-450 proteins with *N*-methylanilines.[91] The $Co^{II}(bipy)_2{}^{2+}$ /O_2/MeCN system also dehydrogenates benzylamines and basic benzyl alcohol:

$$2PhCH_2NH_2 + O_2 \xrightarrow{Co^{II}(bipy)_2{}^{2+}} 2PhCH{=}NH + 2H_2O \xrightarrow{H_2O} 2PhCHO + 2NH_3 \quad (114)$$

$$2PhCH_2OH + O_2 \xrightarrow{(HO)Co^{II}(bipy)_2{}^{+}} 2PhCHO + 2H_2O \quad (115)$$

The rates of transformation are first order in $Co^{II}(bipy)_2{}^{2+}$ concentration, first order in O_2 concentration, and first order in substrate concentration. In the case of the dehydrogenation of benzyl alcohols, the $Co^{II}(bipy)_2{}^{2+}$ catalyst is inactive and must be neutralized with one equivalent of HO^- (equation 116).

$$\bullet Co^{II}(bipy)_2{}^{2+} + HO^- \longrightarrow HO\dot{C}o^{II}(bipy)_2{}^{+} \quad (116)$$

Either $HOC(O)O^-$ or Et_3N can be used in place of HO^-, but the reaction rates are slower. In the absence of substrate, the neutralized catalyst is autoxidized via residual water in the solvent to generate HOOH (equation 117).

$$2HO\dot{C}o^{II}(bipy)_2{}^{+} + O_2 + 2H_2O \longrightarrow 2(HO)_2Co^{III}(bipy)_2{}^{+} + HOOH \xrightarrow{2H_2O} 2Co^{III}(OH)_3\,(s) + 2H(bipy)_2{}^{+} \quad (117)$$

6.4 Metal-induced Reductive Activation of $^3O_2$ for Monooxygenation

Diphenylhydrazine (PhNHNHPh) is an effective reaction mimic for the flavin cofactors in xanthine oxidases and

Table 14 Monooxygenation and dehydrogenation of organic substrates via a model system for the cytochrome P-450 monooxygenase/reductase enzymes[a]

Substrate (RH)	Product	% Reaction efficiency
Ph_3P	Ph_3PO	100 ± 5
$PhCH_2OH$	PhCH(O)	30 ± 4
Ph_2SO	$Ph_2S(O)_2$	25 ± 3
1,4-Cyclohexadiene	PhH	10 ± 2

[a]Solution conditions: 1 mM $Fe^{II}(MeCN)2+$:4, 1.6 mM O_2, 1 mM PhNHNHPh, 0.1 mM HO^-, and 3 mM substrate in MeCN. Reaction time, 0.5 h.

cytochrome P-450 reductases, and in combination with O_2 yields HOOH (equation 118).[48]

$$PhNHNHPh + O_2 \xrightarrow{base} PhN{=}NPh + HOOH \qquad (118)$$

Table 14 summarizes the product yields from the combination of substrate (Ph_3P, Ph_2SO, $PhCH_2OH$, or 1,4-cyclohexadiene) with O_2, PhNHNHPh, and $Fe^{II}(MeCN)_4{}^{2+}$ in DMF.[99] The system acts as an effective monooxygenase/dehydrogenase, and as such mimics the reaction cycle of the cytochrome P-450 monooxygenase/reductase system:

$$Ph_2SO + O_2 + PhNHNHPh \xrightarrow{[Fe^{II}(MeCN)_4]^{2+}} Ph_2SO_2 + H_2O + PhN{=}NPh \qquad (119)$$

The activation of dioxygen for the monooxygenation of saturated hydrocarbons by the methane monooxygenase enzyme systems (MMO; hydroxylase/reductase) represents an almost unique biochemical oxygenase, especially for the transformation of methane to methanol.[92,93,100] The basic process involves the insertion of an oxygen atom into the C–H bond of the hydrocarbon via the concerted reduction of O_2 by the reductase cofactor (equation 120).

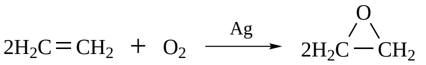
$$CH_4 + O_2 \xrightarrow{MMO/H_2} MeOH + H_2O \qquad (120)$$

The combination of bis[(2,6-carboxyl-carboxylato)pyridine]iron(II) [$Fe^{II}(DPAH)_2$] and O_2 results in the rapid autoxidation of the iron complex and is essentially unreactive with hydrocarbon substrates (e.g. c-C_6H_{12}). However, the presence of excess PhNHNHPh gives a system that is a hydrocarbon monooxygenase (c-C_6H_{12} $\rightarrow$ c-$C_6H_{11}OH$).[101] The distribution of R–OH isomers from 2-Me-butane indicates a selectivity in the order $\equiv CH > {=}CH_2 > {-}CH_3$; the relative reactivities per C–H bond are 1.00, 0.29, and 0.05, respectively. With $Fe^{II}(PA)_2$/HOOH Fenton chemistry in 1.8:1 py/HOAc, the relative reactivities are 1.00, 0.43, and 0.07,[53] and the values for aqueous HO• are 1.00, 0.48, and 0.10.[102] Thus, the reactive intermediate from the $Fe^{II}(DPAH)_2/O_2$/PhNHNHPh system is more selective than Fenton-derived and free HO•.

The ability of the $Fe^{II}(DPAH)_2/O_2$/PhNHNHPh system (where PhNHNHPh is a mimic for flavin reductases)[48,100] to monooxygenate saturated hydrocarbons closely parallels the chemistry of the methane monooxygenase proteins.[92,93,101] However, the enzyme oxygenates 2-Me-butane with an isomer distribution of 82% primary alcohol, 10% secondary, and 8% tertiary.[103] The present model gives a distribution of 21% primary, 29% secondary, and 50% tertiary. Clearly the protein affords a cavity that is selective for $-CH_3$ groups.

6.5 Metal Surface Induced Activation of Dioxygen for Oxygenase Chemistry

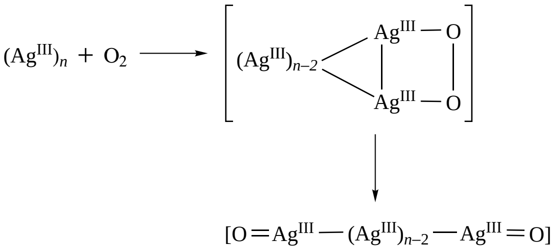
Supported silver is used for the activation of the O_2 in ambient air for the gas-phase selective epoxidation of ethylene (equation 121).[104]



(121)

Although the mechanism for O_2 activation is not known, the model for Compound I of horseradish peroxidase, $[(Cl_8TPP)^{+}\bullet]Fe^{IV}{=}O$, is an especially effective epoxidation reagent. The bond energy ($-\Delta G_{BF}$) for the Fe=O bond in this model is 46 kcal mol^{-1}, which is in accord with its facile epoxidation of alkenes ($-\Delta G_{BF}$, 77 kcal mol^{-1}). Because the gas-phase bond energy (ΔH_{DBE}) for the Ag=O bond is about 53 kcal mol^{-1} ($-\Delta G_{BF} \sim 45$ kcal mol^{-1}),[41] this entity should be an effective O-atom transfer agent for alkene epoxidation.

If the silver surface is an infinite oligomer of trivalent Ag atoms $(Ag^{III})_n$, then a reasonable O_2-activation reaction should lead to $(Ag^{III})_{n-1}{-}Ag^{III}{=}O$ groups on the surface (equation 122).



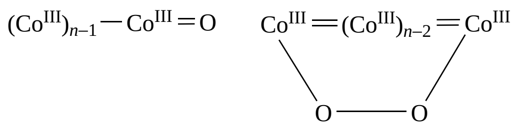
(122)

Such groups will have Ag=O bond energies ($-\Delta G_{BF}$) that are less than 45 kcal mol^{-1}, and should be effective epoxidation agents.

Another heterogeneous O_2-activation system uses supported cobalt metal to catalyze the gas-phase oxygenation of cyclohexane to cyclohexanol and cyclohexanone, which are intermediates for the production of adipic acid ($HO_2C(CH_2)_4CO_2H$) (equation 123).

$$c\text{-}C_6H_{12}(g) + O_2 \xrightarrow{(Co)_n} c\text{-}C_6H_{11}OH + c\text{-}C_6H_{10}O + H_2O \qquad (123)$$

As in the case of silver, the cobalt surface probably is an infinite oligomer of trivalent cobalt atoms $(Co^{III})_n$ that may activate O_2 to give reactive intermediates such as (**26**) and (**27**).



(**26**) (**27**)

Dioxygen appears to form similar M–O–O–M groups on all transition metal surfaces, but most systems rapidly degrade to M–O–M (equation 124).

This is especially true for manganese, iron, and coinage metal (Cu, Ag, Au) surfaces,[105] but apparently is not favored with cobalt.

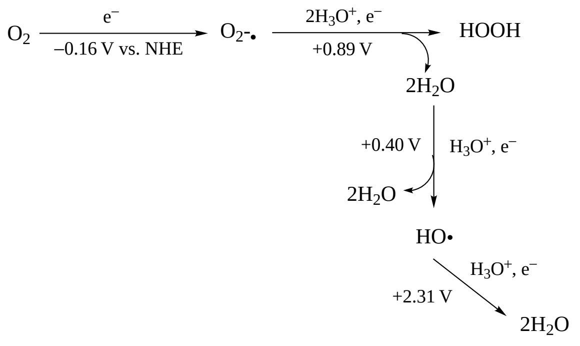
$$(\mathrm{M})_{n-1}\text{–M–O–O–M–}(\mathrm{M})_{n-1} \longrightarrow (\mathrm{M})_{n-2}\text{–M–O–M–O–M–}(\mathrm{M})_{n-1} \quad (124)$$

6.6 Biological Systems

Nature uses a variety of metalloproteins and flavoproteins to activate (or catalyze) dioxygen for useful chemistry.[106–109] These can be subdivided into (a) oxidases (electron-transfer oxidation by O_2, e.g. cytochrome *c* oxidase); (b) dehydrogenases (removal of two hydrogen atoms from the substrate by O_2; many so-called oxidases actually dehydrogenate substrates, for example, glucose oxidase and xanthine oxidase); (c) monooxygenases (oxygen-atom transfer to substrate from O_2; usually have a reductase (hydrogenase) cofactor to reduce the second oxygen atom of O_2 to H_2O (hence the archaic name of 'mixed function' oxidases), e.g. cytochrome P-450 and methane monooxygenase); and (d) dioxygenases (transfer of the two oxygen atoms of O_2 to a substrate molecule, e.g. pyrocatechol dioxygenase). Each class of O_2-activating systems includes a variety of proteins and functions.

Within aerobic biology, the 'harvesting' of the oxidative energy of O_2 is fundamental to oxidative metabolism. Because this is accomplished via the electron-transfer oxidation of four cytochrome $c(\mathrm{Fe^{II}})$ molecules ($E^{\circ\prime}_{\mathrm{pH7}}$, +0.3 V vs. NHE) per O_2, the challenge is to facilitate the reduction of O_2 via four one-electron steps, each with a potential greater than +0.4 V versus NHE at pH 7 (equation 125). The thermodynamics for the uncatalyzed electron-transfer reduction of O_2 does not meet this criterion (equation 126) especially for the initial pH-independent electron transfer to O_2.

$$O_2 + 4(H_3O^+)_{\mathrm{pH7}} + 4\mathrm{cyt}\ c(\mathrm{Fe^{II}}) \xrightarrow{\mathrm{cyt}\ c\ \mathrm{oxid}} 4\mathrm{cyt}\ c(\mathrm{Fe^{III}})^+ + 6H_2O \quad (125)$$



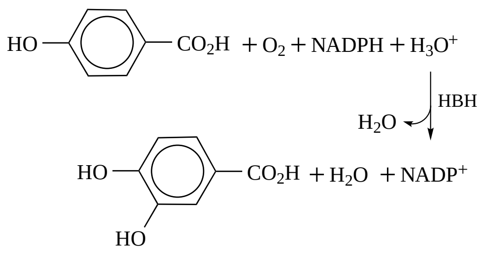
(126)

The cytochrome *c* oxidase protein is thought to consist of two heme–iron centers (heme *a* with two axial histidines and heme a_3 with one axial histidine (analogous to myoglobin)) and two copper centers (Cu_A with two histidine, two cysteine, and one water/tyrosine ligand in its oxidized state; and Cu_B with three histidine, one methionine, and one H_2O/HO^- ligands).[110,111] The Cu_A/heme *a* pair constitute two coupled, one-electron redox couples (low potential, ≈0.4 V) that facilitate (a) electron transfer from cytochrome $c(\mathrm{Fe^{II}})$ at the matrix side of the inner mitochondrial membrane as well as (b) proton transfer from the mitochondrial matrix across the inner membrane to the cytosol. At the cytosol side of the inner mitochondrial membrane, the Cu_B/heme a_3 pair constitute the binding site for O_2 as well as the conduit for its high-potential four-electron, four-proton reduction to two H_2O molecules.

Cytochrome P-450, which is the most extensively studied of the monooxygenase proteins, has a heme–iron active center with an axial thiol ligand (a cysteine residue). However, most chemical model investigations[91,106] use simple iron(III) porphyrins without thiolate ligands. As a result, model mechanisms for cytochrome P-450 invoke a reactive intermediate that is formulated to be equivalent to Compound I of horseradish peroxidase, $(\mathrm{por}^{+\bullet})\mathrm{Fe^{IV}{=}O}$, with a high-potential porphyrin cation radical. Such a species would be reduced by thiolate, and therefore is an unreasonable formulation for the reactive center of cytochrome P-450.

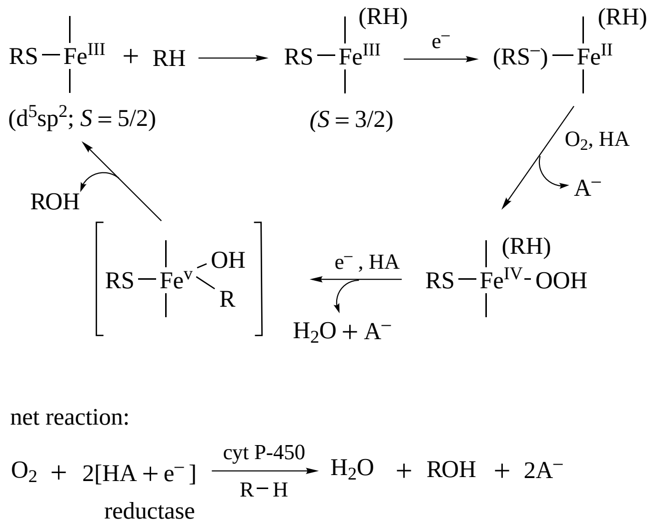
Again, on the basis of (a) the chemistry for O_2 in the presence of transition metals and reducing agents and (b) reasonable bonding energetics for the components of the cytochrome P-450 monooxygenase/reductase system ($(\mathrm{por})\mathrm{Fe^{III}}$–SR/$O_2$/(NADH, H_3O^+/flavin)/substrate), a self-consistent mechanism is proposed and outlined in Scheme 7. The presence of an axial Fe–SR bond enhances the covalence of the iron, reduces the Fe–O bond energy, and thereby increases the radical character and reactivity of the (RS–$\mathrm{Fe^{IV}}$–OOH) group, and precludes formation of a high-potential porphyrin cation-radical one-electron oxidant.

Another example of a monooxygenase, *p*-hydroxybenzoate hydroxylase (HBH), makes use of a flavin cofactor in combination with a reductase (equation 127).[112]



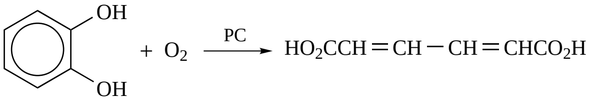
(127)

Spectral studies of rapid-quench experiments indicate that the substrate/oxidized flavin/O_2/reductase combination forms an initial reactive intermediate that subsequently oxygenates



Scheme 7 Proposed mechanism for the activation of O_2 for the monooxygenation of substrates (RH) by cytochrome P-450

the substrate.[113,114]



(128)

Pyrocatechase (PC) is representative of a class of proteins that facilitates the transfer of both atoms of O_2 to a substrate molecule. With this particular dioxygenase, pyrocatechol is transformed to muconic acid (equation 29).

There is agreement that the enzyme contains nonheme iron at the active site with N or O ligands (probably histidine, tyrosine, and/or aspartate residues),[115,116] but there is less certainty as to the oxidation state, coordination sphere, and mode of O_2 binding and activation for the iron center. Because the $Fe^{II}(DPAH)_2/O_2$/pyrocatechol system[117] parallels the chemistry of the enzyme (equation 128), some of the essential elements of O_2 binding and activation may be the same. On the basis of what is known for the enzymatic process and the $Fe^{II}(DPAH)_2/O_2$/pyrocatechol system, a nonionic oxygen-atom transfer mechanism for O_2 activation by pyrocatechol dioxygenase is proposed and outlined in Scheme 8. Key elements of the mechanism include recognition that (1) only reduced-iron binds dioxygen, (2) the net process is two O-atom transfers per substrate and not electron transfer, and (3) only a single dioxygenated product is formed. The latter requires a reactive intermediate (**28**) with two equivalent oxygen atoms that can be transferred in a concerted manner.

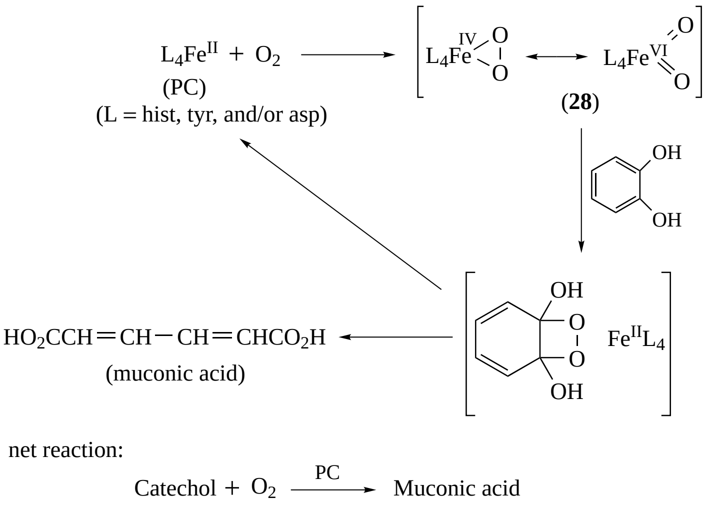
6.7 Singlet Dioxygen ($^1O_2$)

Ground-state dioxygen ($^3O_2$) can be activated by photolytic energy transfer to the singlet state ($^1O_2$) (equation 129) and this may be duplicated at the surface of biomembranes by solar radiation. In the laboratory, singlet dioxygen is conveniently produced by the stoichiometric oxidation of hydrogen peroxide by hypochlorous acid (equation 130).

$$^3O_2 \xrightarrow[\text{Rose Bengal}]{h\nu} {}^1O_2 \tag{129}$$

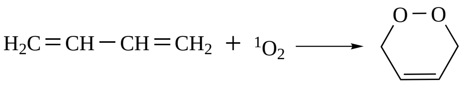
$$HOOH + HOCl \longrightarrow {}^1O_2 + H_2O + HCl \tag{130}$$

Singlet dioxygen in biological systems is highly selective; $^1O_2$ is unreactive with most organic functional groups (e.g. saturated σ bonds, simple alkenes, and carbonyl groups). In part, this is due to its limited lifetime (2 μs in H_2O, 58 μs in ^2H_2O, 16 μs in DMF, 65 μs in MeCN, and 610 μs in d_3-MeCN),[118,119] to its paired valence-electron shell, and to its

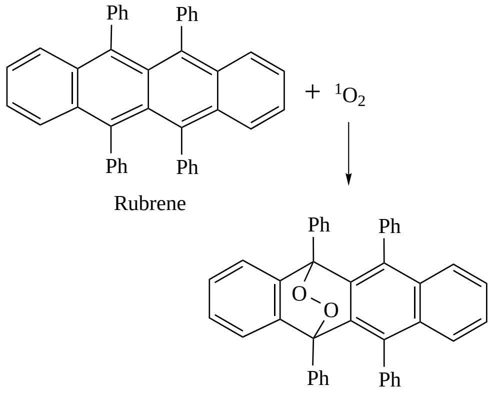


Scheme 8 Proposed mechanism for the activation of O_2 by pyrocatechase (PC) for the dioxygenation of catechols

strong O–O bond (ΔH_{DBE}, 119 kcal mol^{-1}). The suspected biological hazard of $^1O_2$ has prompted extensive research with a substantial literature in several disciplines. A recent review[120] provides a comprehensive overview of the reactivity for $^1O_2$ in various phases and matrices. The most facile chemistry for $^1O_2$ is addition to conjugated polymers and polynuclear aromatic molecules (equations 131–133).[121,122]

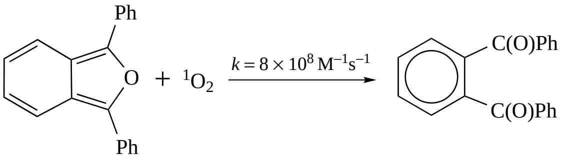


(131)



Rubrene

(132)



1, 3-Diphenylisobenzofuran (DPBF)

o-Dibenzoylbenzene (DBB)

(133)

Unfortunately, much of the chemistry attributed to $^1O_2$ actually is due to a precursor in its generation cycle. Thus, many have used *cis*-stilbene (c-PhCH=CHPh) to indicate the presence of $^1O_2$ via the production of PhCHO. Careful experiments with authentic photochemically generated $^1O_2$ (equation 129) have established that c-PhCH=CHPh has a small reaction rate.[123] Hence, the large yields of PhCHO that are attributed to $^1O_2$ may result from oxygenation by an $^1O_2$ precursor molecule.

7 REACTIVITY OF SUPEROXIDE ION ($O_2^{-}\bullet$)

Reduction by electron transfer yields superoxide ion ($O_2^{-}\bullet$),[31] which has its negative charge and electronic spin density delocalized between the two oxygens. As such, it has limited radical character (H–OO$^-$ bond energy ΔG_{BF}, 72 kcal mol^{-1})[73] and is a weak Brønsted base in water (equation 134).[124]

$$\mathrm{HOO\bullet} \xrightarrow{\mathrm{H_2O}} \mathrm{H_3O^+} + \mathrm{O_2}^{-}\bullet \qquad k_{diss} = 2.0 \times 10^{-5} \tag{134}$$

The dynamics for the hydrolysis and disproportionation of $O_2^{-}\bullet$ in aqueous solutions have been characterized by pulse radiolysis.[124–128] For all conditions, the rate-limiting step is second order in $O_2^{-}\bullet$ concentration, and the maximum rate occurs at a pH that is equivalent to the pK_a for HOO• (it decreases monotonically with further decreases in the hydrogen-ion concentration) (equations 135–137).

$$\mathrm{HOO\bullet} + \mathrm{O_2}^{-}\bullet \xrightarrow{\mathrm{H_3O^+}} \mathrm{HOOH} + \mathrm{O_2} \qquad k_2 = 1.0 \times 10^{8}\,\mathrm{M^{-1}s^{-1}} \tag{135}$$

$$\mathrm{HOO\bullet} + \mathrm{HOO\bullet} \longrightarrow \mathrm{HOOH} + \mathrm{O_2} \qquad k_2 = 8.6 \times 10^{5}\,\mathrm{M^{-1}s^{-1}} \tag{136}$$

$$\mathrm{O_2}^{-}\bullet + \mathrm{O_2}^{-}\bullet + 2\mathrm{H_2O} \longrightarrow \mathrm{HOOH} + \mathrm{O_2} + 2\mathrm{HO^-} \qquad k_4 < 0.3\,\mathrm{M^{-1}s^{-1}} \tag{137}$$

7.1 Brønsted Base

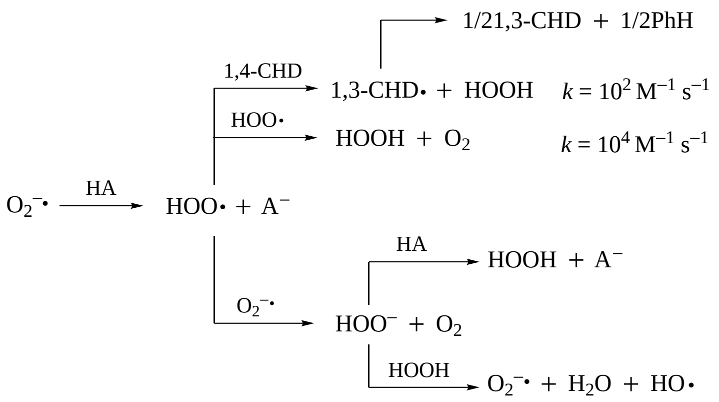
In water, at pH 7 the disproportionation equilibrium is far to the right[129] and even at pH 14 it is complete (equation 139).

$$2\mathrm{O_2}^{-}\bullet + 2\mathrm{H_3O^+} \rightleftharpoons \mathrm{HOOH} + \mathrm{O_2} \qquad K = 4 \times 10^{20} \tag{138}$$

$$2\mathrm{O_2}^{-}\bullet + \mathrm{H_2O} \rightleftharpoons \mathrm{HOO^-} + {}^{-}\mathrm{OH} + \mathrm{O_2} \qquad K = 9.1 \times 10^{8} \tag{139}$$

Thus, the dominant characteristic of $O_2^{-}\bullet$ in any medium is its ability to act as a strong Brønsted base via formation of HOO•, which reacts with allylic hydrogens, itself, or a second $O_2^{-}\bullet$ (Scheme 9). Such a proton-drive disproportionation process means that $O_2^{-}\bullet$ can deprotonate acids much weaker than water (up to p$K_a \sim 23$).[34]

The propensity of $O_2^{-}\bullet$ to remove protons from substrates accounts for its reactivity with acidic reductants and their overall oxidation. Thus, combination of $O_2^{-}\bullet$ with protic substrates (α-tocopherol, hydroquinone, 3,5-di-*t*-butylcatechol, L(+)-ascorbic acid) yields products that are consistent with an apparent one-electron oxidation of the substrate and the production of HOOH. However, the results of electrochemical studies[130] provide clear evidence that these substrates are not oxidized in aprotic media by direct one-electron transfer to $O_2^{-}\bullet$. The primary step involves abstraction of a proton from the substrate by $O_2^{-}\bullet$ to give substrate anion and the disproportionation products of HOO• (HOOH and O_2). In turn, the substrate anion is oxidized by O_2 in a multistep process to yield oxidation products and HOOH. Thus, by continuously purging the O_2 that results from the



Scheme 9 Proton-induced activation of $O_2^{-}\cdot$ in Me_2SO

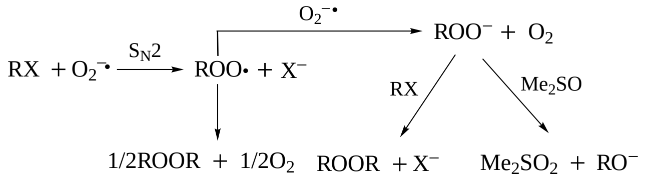
disproportionation of $O_2^{-}\cdot$ when it is combined with α-tocopherol (by vigorous Ar bubbling through the solution), quantitative yields of substrate anion are obtained without significant oxidation.

7.2 Nucleophilicity

Although superoxide ion is a powerful nucleophile in aprotic solvents, it does not exhibit such reactivity in water, presumably because of its strong solvation by that medium ($\Delta H_{\text{hydration}}$, 100 kcal mol^{-1}) and its rapid hydrolysis and disproportionation. The reactivity of $O_2^{-}\cdot$ with alkyl halides via nucleophilic substitution was first reported in 1970.[131,132] These and subsequent kinetic studies[133–135] confirm that the reaction is first order in substrate, that the rates follow the order primary > secondary ≫ tertiary for alkyl halides and tosylates, and that the attack by $O_2^{-}\cdot$ results in inversion of configuration (S_N2).

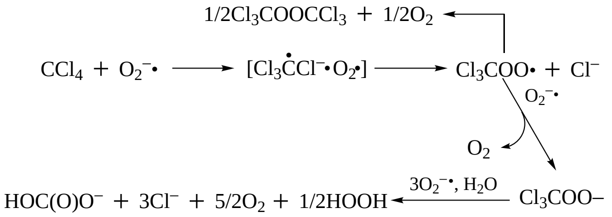
The nucleophilicity of $O_2^{-}\cdot$ toward primary alkyl halides (Scheme 10) results in an S_N2 displacement of halide ion from the carbon center. The normal reactivity order, benzyl > primary > secondary > tertiary, and leaving group order, I > Br > OTs > Cl, are observed, as are the expected stereoselectivity and inversion at the carbon center.[136–141] In DMF, the final product is the dialkyl peroxide. The peroxy radical (ROO•), which is produced in the primary step and has been detected by spin trapping,[142] is an oxidant that is readily reduced by $O_2^{-}\cdot$ to form the peroxy anion (ROO^-). Because the latter can oxygenate Me_2SO to its sulfone, the main product in this solvent is the alcohol (ROH) rather than the dialkyl peroxide.

Although formation of the dialkyl peroxide is shown in the prototype reaction (Scheme 9), hydroperoxides, alcohols, aldehydes, and acids also have been isolated. The extent of these secondary paths depends on the choice of solvent and reaction conditions. Secondary and tertiary halides also give substantial quantities of alkenes from dehydrohalogenation by $O_2^{-}\cdot/HOO^-/HO^-$.



Scheme 10 Nucleophilic displacement of alkyl halides by $O_2^{-}\cdot$

The reaction of $O_2^{-}\cdot$ with CCl_4 and $RCCl_3$ compounds almost certainly cannot occur via an S_N2 mechanism because the carbon-atom center is inaccessible. Rather, superoxide ion appears to attack a chlorine atom with a net result that is equivalent to an electron transfer from $O_2^{-}\cdot$ to chlorine (equation 140).



(140)

This step is analogous to the 'single-electron-transfer' (SET) mechanism that has been proposed for many nucleophilic reactions, that is, an initial transfer of an electron followed by the collapse of a radical pair (equation 141).[143]

$$E^+ + Nu^- \longrightarrow [E\cdot\cdot Nu] \longrightarrow E\text{–}Nu \qquad (141)$$

The initiation step for the $(O_2^{-}\cdot)/CCl_4$ reactions must be followed by rapid combination in the solvent cage of $\cdot O_2\cdot$ and $Cl_3C\cdot$ to form the $Cl_3COO\cdot$ radical. This radical is thought to initiate lipid peroxidation,[144] which could account

for the hepatoxicity of CCl_4.[145] The rates of reaction for $O_2^{-}\bullet$ with $RCCl_3$ compounds are proportional to their reduction potentials, which is consistent with the SET mechanism.[136] A plot of log k_1/[S] against the reduction potentials of $RCCl_3$ compounds is approximately linear with a slope of −4.9 decade per volt.

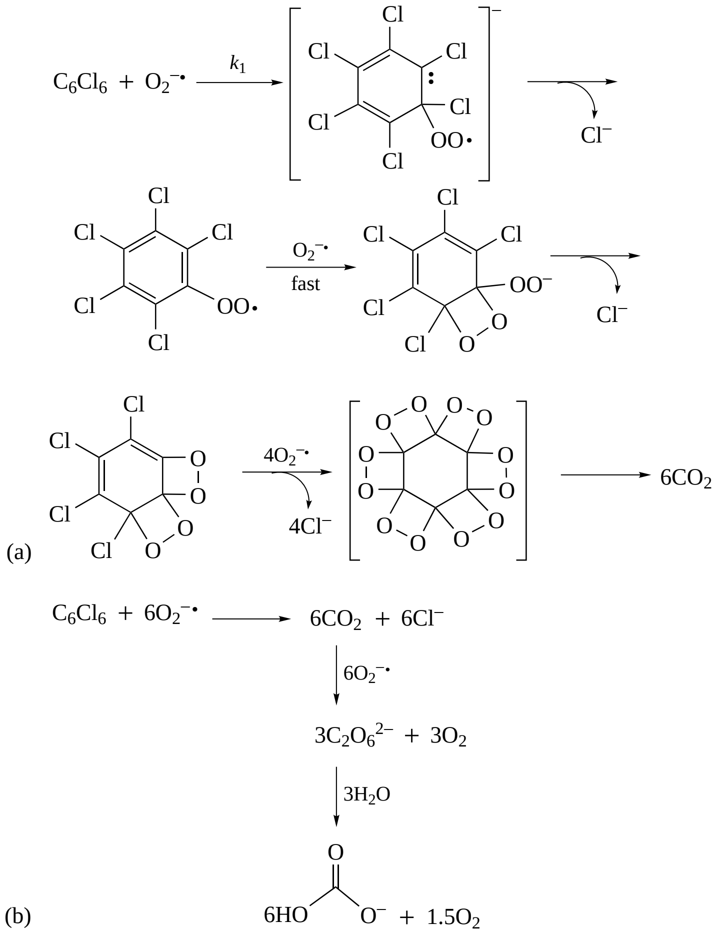
Polyhalogenated aromatic hydrocarbons (e.g. hexachlorobenzene (HCB, C_6Cl_6) and polychorobiphenyls (PCBs)) are rapidly degraded by superoxide ion in DMF to bicarbonate and halide ions.[140] Because halogen-bearing intermediates are not detected, the initial nucleophilic attack is the rate-determining step. The rates of reaction exhibit a direct correlation with the electrophilicity of the substrate (reduction potential) (e.g. C_6Cl_6, $E^{\circ\prime} = -1.48$ V vs. SCE; $k_1/[S] = 1 \times 10^3\,M^{-1}\,s^{-1}$; and 1,2,4-$C_6H_3Cl_3$, $E^{\circ\prime} = -2.16$ V; $k_1/[S] = 2 \times 10^{-2}\,M^{-1}\,s^{-1}$).

Although polyhaloaromatics are degraded by $O_2^{-}\bullet$ in MeCN and DMSO, the rates of reaction are about one-tenth as great in MeCN and 20 times slower in DMSO. A reasonable initial step for these oxygenations is nucleophilic addition of $O_2^{-}\bullet$ to the polyhalobenzene (e.g. C_6Cl_6; Scheme 11).

Subsequent loss of chloride ion will give a benzoperoxy radical, which will close on an adjacent aromatic carbon center and add a second $O_2^{-}\bullet$ to become a peroxo nucleophile that can attack the adjacent carbochlorine center with displacement of chloride ion and a highly electrophilic tetrachloro center. The latter undergoes facile reactions with $O_2^{-}\bullet$ to displace the remaining chloro atoms.

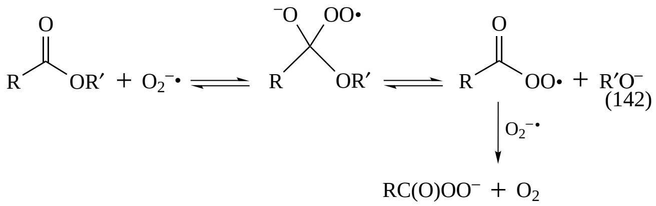
When Aroclor 1268 (a commercial PCB fraction that contains a mixture of Cl_7, Cl_8, Cl_9, and Cl_{10} polychlorobiphenyls) is combined with excess $O_2^{-}\bullet$, the entire mixture is degraded. Samples taken during the course of the reaction confirm that (a) the most heavily chlorinated members react first (the initial nucleophilic addition is the rate-determining step) and (b) all components are completely dehalogenated. Tests with other PCB mixtures establish that those components with three or more chlorine atoms per phenyl ring are completely degraded by $O_2^{-}\bullet$, within several hours.

Superoxide ion reacts with esters, diketones, and carbon dioxide.[34,146–148] Initial reaction occurs via a reversible

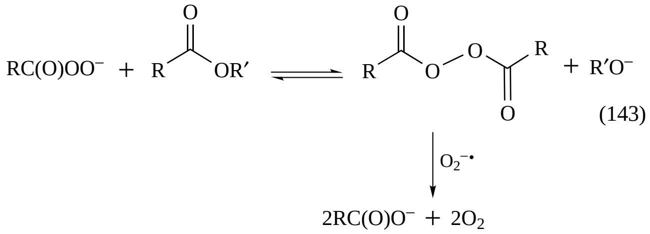


Scheme 11 Nucleophilic degradation of hexachlorobenzene (HCB) by $O_2^{-}\bullet$

addition–elimination reaction at the carbonyl carbon (equation 142).



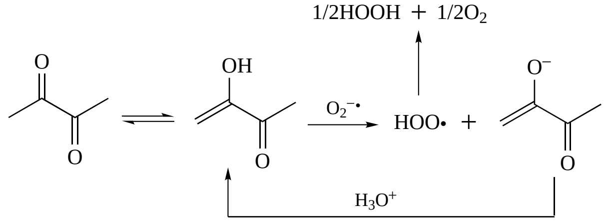
(142)



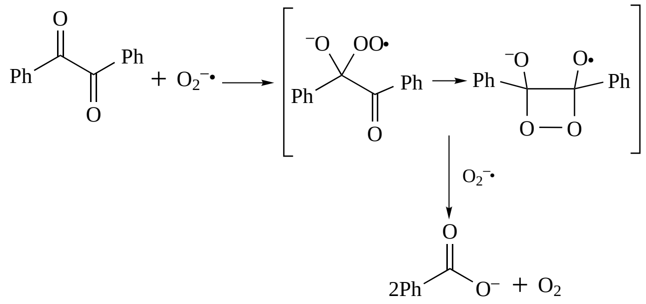
(143)

This conclusion is supported by the products that are observed in the gas-phase reaction of $O_2^{-}\cdot$ with phenyl acetate and phenyl benzoate, which has been studied by Fourier transform mass spectrometry.[149] In effect, there is a competition between loss of $O_2^{-}\cdot$ and loss of the leaving group. Carbanions are poor leaving groups, so that simple ketones without acidic α-hydrogen atoms are unreactive.

Simple diketones such as 2,3-butanedione are rapidly deprotonated by $O_2^{-}\cdot$, but the original diketone is recovered upon acidification (equation 144). However, benzil (PhCO-COPh) cannot enolize and is dioxygenated by $O_2^{-}\cdot$ to give two benzoate ions (equation 145). Carbon dioxide reacts rapidly with $O_2^{-}\cdot$ in aprotic solvents with a net stoichiometry in acetonitrile (equation 146) and the proposed reaction path involves an initial nucleophilic addition (equation 147).

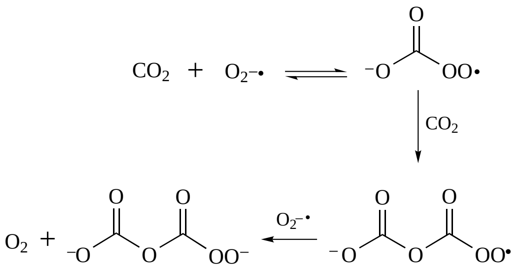


(144)



(145)

$$2CO_2 + 2O_2^{-}\cdot \longrightarrow C_2O_6^{2-} + O_2 \qquad (146)$$



(147)

The primary product from the nucleophilic addition of $O_2^{-}\cdot$ to electrophilic substrates with leaving groups (RX) is a peroxy radical (ROO•). The presence of a large excess of substrate often precludes the diffusion-controlled reduction of ROO• by $O_2^{-}\cdot$, and results in the reaction manifold that is outlined in Scheme 12. The limits on the rate constants are consistent with the observed reactivities and product profiles for the indicated substrates.[150] Thus, the dimerization of ROO• to give ROOOOR is a radical–radical coupling and should be close to a diffusion-controlled process. The lifetime of [ROOOOR] is related to its O–O bond energies, which are smaller when R is an electron-withdrawing group (Cl_3C). A recent study of singlet dioxygen ($^1O_2$) production by these systems confirms that the ROOOOR intermediates decompose to ROOR and $^1O_2$,[151] while a separate investigation[150] indicates that ROOOOR is more reactive than $^1O_2$ and is a dioxygenase of rubrene and *cis*-stilbene.

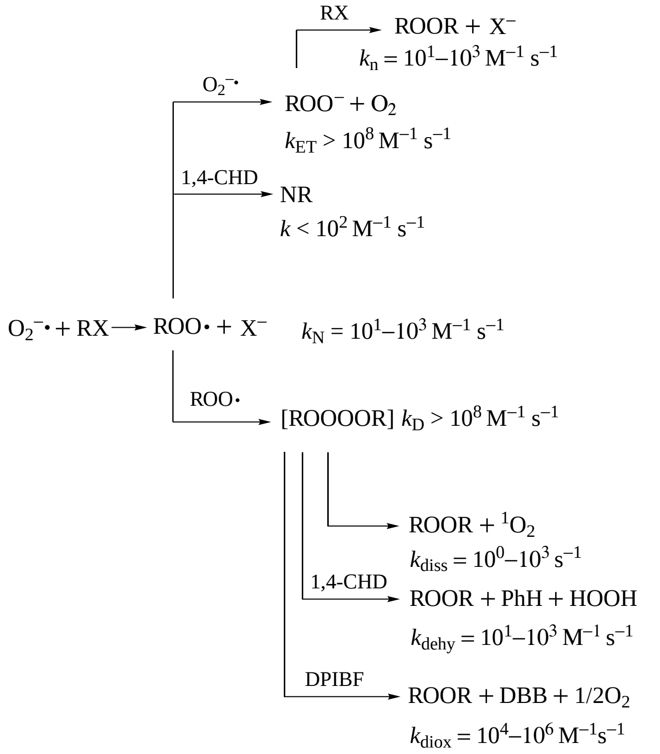
7.3 One-electron Reductant

Another characteristic of $O_2^{-}\cdot$ is its ability to act as a moderate one-electron reducing agent. For example, combination of $O_2^{-}\cdot$ with 3,5-di-*t*-butylquinone (DTBQ) in DMF yields the semiquinone anion radical $DTBSQ^{-}\cdot$ as the major product.[152] The relevant redox potentials in DMF are $O_2/O_2^{-}\cdot$, $E^{\circ\prime} = -0.60$ V versus NHE, and $DTBQ/DTBSQ^{-}\cdot$, $E^{\circ\prime} = -0.25$ V versus NHE, which indicate that the equilibrium constant K for the reaction of $O_2^{-}\cdot$ with DTBQ has a value of 0.8×10^6 (equation 148). Electrochemical studies of sulfur dioxide[153] ($SO_2/SO_2^{-}\cdot$, $E^{\circ\prime} = -0.58$ V vs. NHE) and of molecular oxygen[130] in DMF indicate that the equilibrium constant (K) for the reaction of SO_2 with $O_2^{-}\cdot$ has a value of 1.1 (equation 149).

$$O_2^{-}\cdot + DTBQ \rightleftharpoons DTBSQ^{-}\cdot + O_2 \qquad (148)$$

$$SO_2 + O_2^{-}\cdot \rightleftharpoons O_2 + SO_2^{-}\cdot \qquad (149)$$

However, the reaction goes to completion because $SO_2^{-}\cdot$ is complexed by SO_2 and also dimerizes to dithionite ion.[154] Thus, $O_2^{-}\cdot$ is a stronger and more effective reducing agent than dithionite ion in aprotic solvents. In aqueous media, the equilibrium constant for the reduction of [iron(III)]–cytochrome *c* by $O_2^{-}\cdot$ has a value of 3.7×10^4.[155] Within DMF, the reduction of [iron(III)]–porphyrin is even



(RX = CCl_4, F_3CCCl_3, $PhCCl_3$, PhCOCl, BuBr, BuCl;1,4-CHD = 1, 4-cyclohexadiene; DPIBF = diphenylisobenzofuran; DBB = dibenzoylbenzene)

Scheme 12 ($O_2^{-}•$)-induced formation of ROO• and its reaction paths

more complete (equation 150).

$$(TPP)Fe^{III}(DMF)^+ + O_2^{-}• \longrightarrow O_2 + (TPP)Fe^{II} \qquad K = 7 \times 10^{11} \qquad (150)$$

7.4 Sequential Deprotonation–Dehydrogenation of Dihydro Groups

The direct transfer of an electron to $O_2^{-}•$ is an unlikely process because of the extreme instability of the O_2^{2-} species. As a result, most of the reported electron-transfer oxidations by $O_2^{-}•$ actually represent an initial proton abstraction to give substrate anion and HOO•, which disproportionates (or reacts with $O_2^{-}•$) to give O_2 and HOOH (or HOO^-). One or more of these species oxidizes the substrate anion.

Superoxide ion is an effective hydrogen-atom oxidant for substrates with coupled heteroatom (O or N) dihydro groups such as 3,5-di-*t*-butylcatechol ($DTBCH_2$), ascorbic acid (H_2Asc), 1,2-disubstituted hydrazines, dihydrophenazine (H_2Phen), and dihydrolumiflavin (H_2Fl).[48,156,157]

The general mechanism involves the rapid sequential transfer to $O_2^{-}•$ of a proton and a hydrogen atom to form HOOH and the anion radical of the dehydrogenated substrate (equations 151–153).

$$O_2^{-}• + DTBCH_2 \longrightarrow DTBC^{-}• + HOOH \qquad (151)$$

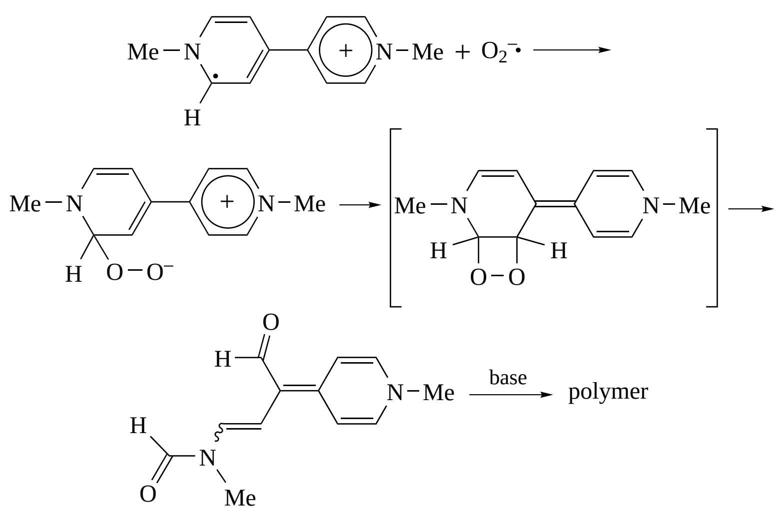
$$O_2^{-}• + H_2Asc \longrightarrow Asc^{-}• + HOOH \qquad (152)$$

$$O_2^{-}• + PhNHNHPh \longrightarrow Ph\bar{N}-\dot{N}Ph + HOOH;\quad Ph\bar{N}-\dot{N}Ph \xrightarrow{O_2} O_2^{-}• + PhN{=}NPh \qquad (153)$$

With 1,2-diphenylhydrazine (PhNHNHPh), the azobenzene anion radical is rapidly oxidized by dioxygen to azobenzene, which also is true for the phenazine and lumiflavin anion radicals. Hence, $O_2^{-}•$ acts as an initiator for the autoxidation of these compounds (equation 153). For 1,2-diphenylhydrazine, turnover numbers in excess of 200 substrate molecules per $O_2^{-}•$ have been observed. The 1,2-diphenylhydrazine autoxidation cycle can be initiated by HO^-, which indicates that $O_2^{-}•$ is formed in the HO^- initiated process. Superoxide ion also initiates the autoxidation of dihydrophenazine, which is a model for dihydroflavin. For example, the addition of 1 mM $(Me_4N)O_2$ in DMF to 10 mM H_2Phen in an O_2-saturated DMF solution results in the complete oxidation of the substrate (about 80% recovered as phenazine) and the production of 9–10 mM HOOH.

Support for the general mechanism outlined in equation (153) is provided by gas-phase Fourier transform mass spectrometric studies of the anionic reaction products of several substrates with $O_2^{-}•$ (produced by electron impact with O_2; HO^- can be produced by electron impact with H_2O).[149] In these experiments, neutral products are not detected. Both $O_2^{-}•$ and HO^- react rapidly with 1,2-diphenylhydrazine in the gas phase ($P \sim 10^{-7}$ Torr) to give the anion radical of azobenzene ($PhN^-•NPh$; $m/e = 182$) and the anion from deprotonation (PhN^-NHPh; $m/e = 183$), respectively. When $O_2^{-}•$ is ejected from the experiment, the peak at $m/e = 182$ disappears. In contrast to the exponential decay that is observed for the HO^- peak with time, the ion current for $O_2^{-}•$ decays to a steady-state concentration.

Analogous FTMS studies with 1,2-dihydroxybenzenes also provide support for the general mechanism. Superoxide ion reacts rapidly with 3,5-di-*t*-butylcatechol ($DTBCH_2$) in the gas phase to give the anion ($DTBCH^-$; $m/e = 221$) and the anion radical of 3,5-di-*t*-butyl-*o*-benzoquinone ($DTBSQ^{-}•$ $m/e = 220$) in an approximate ratio of 3:1. With hydroquinone (p-$C_6H_4(OH)_2$), the dominant product (ca. 70%) is the anion radical ($SQ^{-}•$ $m/e = 108$). When HO^- is the gas-phase reagent, the only product for $DTBCH_2$ (and for o-$C_6H_4(OH)_2$) is the anion from deprotonation. The fact that the anion radicals of the dehydrogenated substrates are produced in the gas phase as well as in aprotic solvents confirms that the reaction sequence of deprotonation/hydrogen-atom abstraction to form HOOH must either be a rapid sequence or a nearly concerted process. Because $O_2^{-}•$ is expected to abstract hydrogen atoms much less easily than HOO•, the initial step is deprotonation



Scheme 13 Oxygenation of methyl viologen cation radical via radical–radical coupling with $O_2^{-}\cdot$

of the substrate by $O_2^{-}\cdot$ to form HOO•; the latter (contained within the solvent cage or weakly bonded to the substrate in a 'sticky collision' in the gas phase) then abstracts a hydrogen atom from the substrate anion to form HOOH and the anion radical of the dehydrogenated substrate.

Thus, the $O_2^{-}\cdot$ induced autoxidations of 1,2-disubstituted hydrazines, dihydrophenazines, and dihydroflavins in aprotic media provide a simple pathway for rapid conversion of dioxygen to HOOH, and one that does not involve catalysis by metal ions or metalloproteins. This is exemplified by the net reaction for dihydrolumiflavin:

$$H_2Fl + O_2 \xrightarrow{O_2^{-}\cdot,\ HO^{-}} Fl + HOOH \qquad (154)$$

7.5 Radical–radical Coupling

Combination of superoxide ion with the cation radical ($MV^{+}\cdot$) of methyl viologen (1,1′-dimethyl-4,4′-bipyridinium ion, Paraquat) is one of the best-documented examples of a stoichiometric $O_2^{-}\cdot$ radical coupling reaction.[158,159] The initial addition to give an unstable diamagnetic product is assumed to be at α-carbon atoms (which possess the maximum unpaired spin density in the cation radical), followed by formation of a dioxetane-like intermediate that decomposes to a complex mixture of products (Scheme 13). This process may provide a means to explain the mechanism of Paraquat toxicity. Several other reports have proposed direct coupling of $O_2^{-}\cdot$ to cation radicals.[160]

Although superoxide ion reacts with reduced transition metal complexes (Fe^{II}, Mn^{II}, Co^{II}, Fe^{II}(EDTA), Fe^{II}(TPP))[161,162] to give oxidized products, for simple solvated cations the reaction sequence is a Lewis acid catalyzed disproportionation (equation 155)[161] with subsequent Fenton chemistry (equation 156).

$$[Fe^{II}(OH_2)_6]^{2+} + 2O_2^{-}\cdot \longrightarrow O_2 + HOOH + Fe^{II}(OH)_2 + 4H_2O \qquad (155)$$

$$2Fe^{II}(OH)_2 + HOOH \longrightarrow 2Fe^{III}(OH)_3(s) \qquad (156)$$

In the cases of Fe^{II}(EDTA) and Fe^{II}(TPP), the peroxide products (Fe^{III}(EDTA)(O_2^{-})[162] and Fe^{III}(TPP)(O_2^{-})[163]) were believed to result from an outer-sphere electron transfer from the metal to $O_2^{-}\cdot$ with subsequent coordination of the oxidized metal by O_2^{2-}. However, the reduction of $O_2^{-}\cdot$ to 'naked' O_2^{2-} requires an exceptionally strong reducing agent (e.g. sodium metal), and is precluded for Fe^{II}(EDTA) and Fe^{II}(TPP).

Investigations[164] of the interaction of $O_2^{-}\cdot$ with sterically protected metalloporphyrins ((Cl_8TPP)Fe^{II}, (Cl_8TPP)Mn^{II}, and (Cl_8TPP)Co^{II}; Cl_8TPP=tetrakis(2,6-dichlorophenyl)-*meso*-porphyrin) establish that adducts are formed via radical–radical coupling to form a metal–oxygen covalent bond (analogous to $H\cdot + O_2^{-}\cdot \rightarrow H{-}OO^{-}$) (equation 157).

$$(Cl_8TPP)Fe^{II} + O_2^{-}\cdot \longrightarrow (Cl_8TPP)Fe^{III}{-}OO^{-} \quad (-\Delta G_{BF} = 12\ \text{kcal mol}^{-1})$$
$$(Cl_8TPP)Fe^{III}{-}OO^{-} \xrightarrow{H_2O} (Cl_8TPP)Fe^{III}{-}OOH + HO^{-}$$
$$(Cl_8TPP)Fe^{III}{-}OOH \xrightarrow{H_2O} (Cl_8TPP)Fe^{III}{-}OH + HOOH \qquad (157)$$

Similar reactivities occur with the manganese and cobalt porphyrins to give (Cl_8TPP)Mn^{III}–OO^{-} ($-\Delta G_{BF}$, $17\ \text{kcal mol}^{-1}$) and (Cl_8TPP)Co^{III}–OO^{-} ($-\Delta G_{BF}$, $8\ \text{kcal mol}^{-1}$). Such radical–radical coupling is favored for all reduced transition metal complexes with unpaired electrons

and probably is the reaction path for $O_2^{-}\cdot$ with $Fe^{II}(EDTA)$[162] and $Fe^{II}(TPP)$.[163]

Thus, the radical–radical coupling reaction path is favored under neutral conditions with reduced transition metal complexes, and provides insight to the mechanisms for superoxide ion disproportionation that are catalyzed by the iron and manganese superoxide dismutase proteins. The combination of $(Cl_8TPP)Fe^{II}$ or $(Cl_8TPP)Mn^{II}$ with $O_2^{-}\cdot$ does not result in electron transfer from the metal; instead they couple to form $(Cl_8TPP)Fe^{III}–OO^{-}$ and $(Cl_8TPP)Mn^{III}–OO^{-}$. The latter abstract protons from the medium, and the $(Cl_8TPP)Fe^{III}OOH$ and $(Cl_8TPP)Mn^{III}OOH$ products react with a second $O_2^{-}\cdot$ and a proton to give HOOH and O_2 (equation 158).

$$(Cl_8TPP)Fe^{II} + O_2^{-\cdot} + HA \longrightarrow (Cl_8TPP)Fe^{III}—OOH + A^{-} \xrightarrow{O_2^{-\cdot},\ HA} (Cl_8TPP)Fe^{II} + O_2 + HOOH + A^{-} \quad (158)$$

Hence, $(Cl_8TPP)Fe^{II}$ and $(Cl_8TPP)Mn^{II}$ facilitate the disproportionation of $O_2^{-}\cdot$, which is equivalent to the function of the iron and manganese superoxide dismutase proteins.

8 REACTIVITY OF OXYANIONS (HO^{-}, RO^{-}, HOO^{-} AND ROO^{-})

The preceding section describes the primary reaction chemistry of superoxide ion ($O_2^{-}\cdot$) to be that of (a) a Brønsted base (proton transfer from substrate), (b) a nucleophile (via displacement or addition), (c) a one-electron reductant, and (d) a dehydrogenase of secondary amine groups. The chemistry is characteristic of all oxyanions (HO^{-} (RO^{-}), HOO^{-} (ROO^{-}), and $O_2^{-}\cdot$), but the relative reactivity for each is determined by its pK_a and one-electron oxidation potential, which are strongly affected by the anionic solvation energy of the solvent matrix. The present focus is on the reactivity of hydroxide ion (HO^{-}), but the principles apply to all oxyanions and permit assessments of their relative reactivity.

The reactivity of hydroxide ion (and that of other oxyanions) is interpreted in terms of two unifying principles: (a) the redox potential of the $YO^{-}/YO\cdot$ (Y = H, R, HO, RO, and O) couple (in a specific reaction) is controlled by the solvation energy of the YO^{-} anion and the bond energy of the R–OY product ($RX + YO^{-} \rightarrow R–OY + X^{-}$), and (b) the nucleophilic displacement and addition reactions of YO^{-} occur via an inner-sphere *single-electron* shift.[165] The electron is the ultimate base and one-electron reductant which, upon introduction into a solvent, is transiently solvated before it is 'leveled' (reacts) to give the conjugate base (anion reductant) of the solvent. Thus, in water the hydrated electron $(e^{-})_{H_2O}$ yields HO^{-} via addition to the H–OH bond of water (equation 159).

$$(e^{-})_{H_2O} + H–OH \longrightarrow H\cdot + (HO^{-})_{H_2O} \qquad E^\circ = -2.93 \text{ V vs. NHE} \quad (159)$$

The product combination ($H\cdot + HO^{-}$) represents the ultimate thermodynamic reductant for aqueous systems. In the absence of an H• atom (and the stabilization afforded to HO• by formation of the 119 kcal mol^{-1} H–OH bond), the hydroxide ion becomes a much less effective reductant (equation 160).

$$(e^{-})_{H_2O} + HO\cdot \longrightarrow (HO^{-})_{H_2O} \qquad E^\circ = +1.89 \text{ V vs. NHE} \quad (160)$$

8.1 Solvent Effects on the Redox Chemistry of HO^{-}

Table 15 summarizes the redox potentials in water and in acetonitrile for the single-electron oxidation of HO^{-} and other bases.[23,26,38] In MeCN, the $HO\cdot/HO^{-}$ redox potential is more negative by about 1.0 V and the $O_2/O_2^{-}\cdot$ redox potential by about 0.5 V relative to their values in H_2O. Most of this is due to the decrease in the energy of solvation for HO^{-} and $O_2^{-}\cdot$ in MeCN (compared to water, where each has an estimated energy of hydration of about 100 kcal mol^{-1}).[166] The increase in the ionization energy for HO^{-} from 1.8 eV in the gas phase to 6.2 eV in water[166] attests to its large solvation energy and to its dramatic deactivation as a base and nucleophile in water.

Hydroxide ion is a stronger base and a better one-electron donor in MeCN and DMSO than in water, because these organic solvents have solvation energies for HO^{-} that are 20–25 kcal mol^{-1} ($\approx$1 eV) less than water.[22] Thus, reduced solvation of HO^{-} decreases its ionization energy and causes it to have a more negative redox potential and to be a stronger electron donor. This dramatically enhances the reactivity of HO^{-} toward the electrophiles shown in Table 15 and reveals a facet of HO^{-} chemistry that is effectively quenched by water, namely, its ability to function as a one-electron reducing agent.

The redox potentials for the electron acceptors that react with HO^{-} (Table 15) are such that a pure outer-sphere single-electron transfer (SET) step would be endergonic (the $HO\cdot/HO^{-}$ redox potential is more positive than the redox potential of the electron acceptor). Hence, the observed net reactions must be driven by coupled chemical reactions, particularly bond formation by the HO• to the electrophilic atom of the acceptor molecule that accompanies a single-electron shift. (The formation of the bond provides a driving force sufficient to make the overall reaction thermoneutral or exergonic: 1.0 V per 23.1 kcal mol^{-1} of bond energy.) The effect of various transition metal complexes on the oxidation potential for HO^{-} in MeCN illustrates some of these effects; the results are summarized in Table 16.[38]

8.2 Reaction Classifications (Single-electron Shift Mechanism)

The reaction continuum for HO^- can be subdivided into three discrete categories that are outlined in Scheme 14: (a) displacement reactions in which the leaving group departs with an electron supplied by HO^- (polar-group transfer), (b) addition reactions in which a covalent bond is formed (polar-group addition), and (c) simple electron-transfer reactions in which HO^- acts as an electron donor (single-electron transfer). This view of the chemistry of HO^- also applies to the reactions of superoxide ion ($O_2^-\bullet$) and other nucleophilic oxyanions (Table 16).

The polar pathways are formally equivalent to a discrete electron-transfer step, that is, a pure SET step that is followed by a chemical step. If a hypothetical SET step is followed by coupling of a radical pair that is produced in the SET step, the overall reaction is the equivalent of a polar-group coupling reaction (Scheme 14(b)). If the coupling is accompanied by the elimination of a leaving group, a polar-group transfer reaction results (Scheme 14(a)).

The 'single-electron shift' mechanism appears to be general and applicable for electron, proton, atom, and group transfer reactions. The assumptions for this proposition include: (a) polar and SET pathways share a common feature, a single-electron shift from an electron donor to an electron acceptor; (b) the barrier heights for the exchange of an electron, proton, atom, or group of atoms can be described by the same general equation;[167] (c) for an unsymmetrical polar-group transfer reaction the net energy change, $-\Delta G$ (the thermodynamic component of the energy barrier), is proportional to the sum of (i) the difference of the redox potentials for the electron

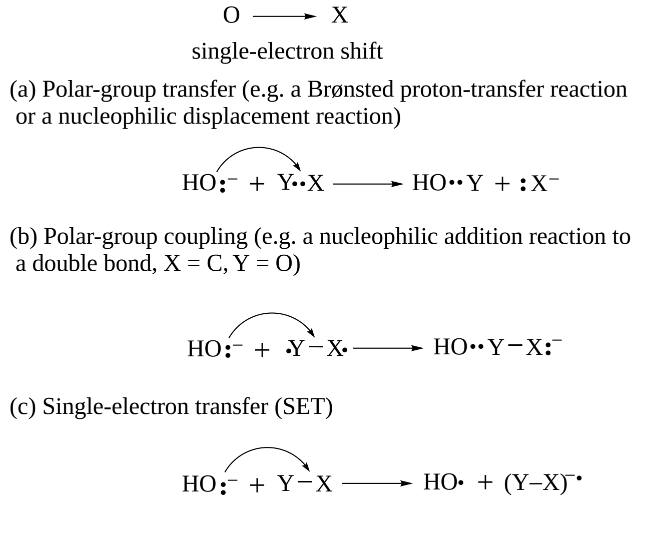

Scheme 14 Single-electron shift (equivalent to the transfer of an electron from O to X)

acceptor (Y–X) and the electron donor (HO^-) and (ii) the bond energy (BE) for the group transfer product (HO–Y; see Scheme 15).

Table 17 lists a number of reactions of hydroxide ion and, for comparison, superoxide ion with electron donors. These reactions are classified conventionally and according to the categories shown in Scheme 14. When water is replaced by a dipolar aprotic solvent (e.g. MeCN or DMSO), many of these electron donor–electron acceptor reactions proceed at dramatically faster rates and produce much larger yields of free-radical products. (DMF is generally avoided because of the possible hydrolysis of the amide bond by hydroxide ion).[168]

Although Brønsted proton transfer reactions appear to belong to a unique category not described by Scheme 14, they are examples of polar-group transfer reactions and are not different in principle from nucleophilic displacement reactions. Deprotonation by hydroxide ion can be regarded as the shift of an electron from HO^- to the Brønsted acid synchronously with the transfer of a hydrogen atom from the Brønsted acid to the incipient HO• radical, with the reaction driven by covalent bond formation between the HO• radical and the H• atom to form water (equation 161).

$$\mathrm{HO{:}^-} + \mathrm{H{\cdot\cdot}B} \rightleftharpoons [\mathrm{HO{\cdot\cdot}H{:}B^-}] \rightleftharpoons \mathrm{HO{:}H} + \mathrm{B{:}^-} \qquad (161)$$
$$(-\Delta G_{BF})_{HO-H} = 111\ \text{kcal mol}^{-1}$$

Consistent with the idea that the single-electron shift is a fundamental process is the notion that the electron distribution (or partial charge) on atoms near the reaction site changes during the course of the reaction. This is so obvious as to seem trivial, but bears repeating because our thinking often is misdirected by the assignment of oxidation numbers (or

Energy change (J mol^{-1})

$$-\Delta G_{reac} = nF\Delta E^{\circ\prime}_{reac}$$

Scheme 15 Redoc energetics for single-electron shift reactions

oxidation states) to atoms via arbitrary rules. For example, by convention the oxidation state +1 is assigned to the hydrogen and −2 is assigned to the oxygen in hydronium ion, water, and hydroxide ion. However, the partial charges on the hydrogen and oxygen atoms change substantially in this series: H_3O^+ (+0.35, −0.05); H_2O (+0.12, −0.25); and HO^- (−0.35, −0.65).[169]

From Scheme 14 and the notion of the charge number (or partial charge on an atom), the reaction of hydroxide ion (oxygen charge −1) with a proton (charge +1) to form H_2O (H and O zero charge) involves a single-electron shift from HO^- to H^+ (H_2O) to form HO• and •H(H_2O) that form a covalent bond (HO–H) with a bond energy ($-\Delta G_{BF}$) of 111 kcal mol^{-1}. This reaction does not result in the formation of a detectable radical, but is an example of a polar-group transfer reaction (Scheme 14(b)) in which an atom transfer occurs synchronously with the electron shift.

Thus, the reaction of H_3O^+ with HO^- is a prototype example of a charge transfer or redox reaction that is also a polar-group transfer reaction. It can be resolved into three component reactions (see Scheme 16) (equations 162–164) and combined (equations 165 and 166).

$$\mathrm{H^+(aq)} + e^- \longrightarrow \mathrm{H\bullet\,(aq)} \qquad (162)$$
$$E^{\circ\prime}_{162} = -2.10\ \text{V vs. NHE}$$

   $4HO^- + CCl_4 \rightarrow 3Cl^- + ClCO_2^- + 2H_2O$
   $5O_2^{-\bullet} + CCl_4 + H_2O \rightarrow 4Cl^- + HOCO_2^- + 7/2O_2 + 1/2HOOH$
   $HO^- + C_6Cl_6 \rightarrow C_6Cl_5OH + Cl^-$

2. Polar-group coupling reactions
   (a) Nucleophilic addition reactions

   $HO^- + CO_2 \rightarrow HOCO_2^-$
   $O_2^{-\bullet} + CO_2 \rightarrow \bullet OOC(O)O^-$

   (b) Reductive addition reactions

   $HO^- + Au^+ \rightarrow AuOH$
   $HO^- + Fe^{III}(TPP)^+ \rightarrow (TPP)Fe^{III}OH$
   $HO^- + Fe^{III}(TPP)(py)_2^+ \rightarrow Fe^{II}(TPP) + (1/n)[py(\bullet OH)]_n$
   Other $M^{III}/{}^-OH$ reactions

3. Single-electron transfer reactions

   $HO^- + O_2 \rightarrow pyO_2^-\bullet + (1/n)[py(\bullet OH)]_n$
   $HO^- + (CN)_2C{=}C(CN)_2 \rightarrow [(CN)_2C{=}C(CN)_2]^{-\bullet} + 1/2HOOH$

   $HO^- + S_8 \longrightarrow HOS_5\bullet + S_3^-\bullet$
   $\downarrow HO^-$
   $HOSSOH + S_3^-\bullet$
   $\downarrow$
   $HOOH + 1/4S_8$

$$HO\bullet(aq) + e^- \longrightarrow HO^-(aq) \qquad (163)$$

$$E^{\circ\prime}_{163} = +1.89\ V$$

$$H\bullet(g) + HO\bullet(g) \longrightarrow HOH(g) \qquad (164)$$

$$-\Delta G^{\circ\prime}_{164} = 111.4\ kcal\,mol^{-1}(+4.83\ V)$$

$$H^+(aq) + HO^-(aq) \xrightarrow{K_f} HOH(aq) \qquad (165)$$

$$-\Delta G^{\circ\prime}_{165} = nE^{\circ\prime}_{165}F$$

$$-\Delta G^{\circ\prime}_{165} = -(\Delta G^{\circ\prime}_{162} - \Delta G^{\circ\prime}_{163} + \Delta G^{\circ\prime}_{164}) = 19.2\ kcal\,mol^{-1}\ (+0.83\ V) \qquad (166)$$

The evaluation of $-\Delta G^{\circ\prime}_{165}$ neglects the small differences in the hydration energies of H•, HO•, and H_2O, but provides a reasonable measure of the formation constant (K_f) (equation 167).

$$\log K_f = \frac{+0.83}{0.059} = 14 \qquad (167)$$

In the net reaction (equation 165), the energy from bond formation (equation 164) provides a driving force of nearly 5 V, which is more than sufficient to overcome the unfavorable electron-transfer energy (−3.89 V).

The reaction of superoxide ion ($O_2^{-\bullet}$), a radical anion, with water also can be viewed as a polar-group transfer reaction (equation 168). The product HOO• is a radical that reacts bimolecularly to form hydrogen peroxide and dioxygen (equation 169).

$$\bullet OO{:}^- + H{:}OH \rightleftharpoons [\bullet OO{:}H{:}^-OH] \rightleftharpoons \bullet OO{:}H + {}^-{:}OH \qquad (168)$$

$$2HOO\bullet \longrightarrow HOOH + O_2 \qquad (169)$$

The formation of the stable covalent bonds in the product molecules provides the driving force that allows superoxide ion to deprotonate Brønsted acids that are much weaker acids than HOO•.

Most accept the view that many nucleophilic displacement reactions occur by a SET mechanism.[170] In a number of cases, radical intermediates have been identified, which is consistent with a discrete SET step. Only a slight extension of this concept is required to encompass all nucleophilic reactions within the categories described in Scheme 14.

The reactions of HO^- and $O_2^-\bullet$ with alkyl halides exhibit the same general pattern (Scheme 16), with second-order kinetics and inversion of configuration.[134,135] Radicals are not detected in the reactions with hydroxide ion, which indicates that there probably is not a discrete SET step, but rather that the transfer of the entering and leaving groups is synchronous with a single-electron shift.

The reaction of superoxide ion with alkyl halides produces a radical in the primary step, because the spin angular momentum of the unpaired electron of the superoxide anion radical is conserved. Again, the transfer of the entering and leaving group is presumed to be synchronous with the single-electron shift. The alternative mechanism, a discrete SET step followed by expulsion of the leaving group and coupling of the radical with dioxygen, is implausible because the reduction potentials of most alkyl halides are at least 0.8 V more negative than the $O_2/O_2^-\bullet$ redox potential and the formation of alkyl radicals has not been observed.

Thus, the reaction of HO^- with BuBr is another example of a redox reaction that involves a polar-group transfer. This can be resolved into three component reactions (in MeCN) (equations 170–174).

$$BuBr + e^- \longrightarrow Bu\bullet + Br^- \qquad (170)$$

$$E^{\circ\prime}_{170} = -1.45\ V\ vs.\ NHE$$

$$HO\bullet + e^- \longrightarrow HO^- \qquad (171)$$

$$E^{\circ\prime}_{171} = +1.89\ V$$

$$Bu\bullet(g) + HO\bullet(g) \longrightarrow BuOH(g) \qquad (172)$$

$$-\Delta G^{\circ\prime}_{172} = 86\ kcal\,mol^{-1}(+3.72V)$$

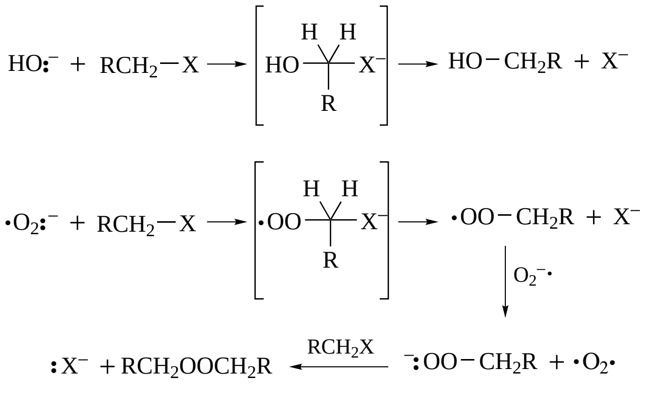
$$BuBr + HO^- \longrightarrow BuOH + Br^- \qquad (173)$$

$$-\Delta G^{\circ\prime}_{172} = nE^{\circ\prime}_{173}F$$

$$-\Delta G^{\circ\prime}_{173} = -(\Delta G^{\circ\prime}_{170} - \Delta G^{\circ\prime}_{169} + \Delta G^{\circ\prime}_{172}) = 8.8\ kcal\,mol^{-1}\ (+0.38\ V) \qquad (174)$$

Similar analyses are possible for the initial polar-group transfer step for CCl_4 ($E^{\circ\prime}_{red}$, −0.91 V vs. NHE), C_6Cl_6 ($E^{\circ\prime}_{red}$, −1.26 V), and $C_{12}Cl_{10}$ (PCB; $E^{\circ\prime}_{red}$, −1.30 V). Each of these substrates undergoes a net exergonic redox reaction with HO^-; the initial step is analogous to that of equation (173).

The reactions of HO^- and $O_2^-\bullet$ with the carbonyl group of esters[34,171] and quinones[172,173] share a common feature, the addition of the nucleophile to the carbonyl carbon. When a suitable leaving group is present, there is an essentially concerted elimination to give products, as shown



Scheme 16 Nucleophilic substitution

in Scheme 17. The addition of HO^- to a carbonyl group in quinones, which have no leaving group, yields an adduct that is sufficiently stable to characterize.[172]

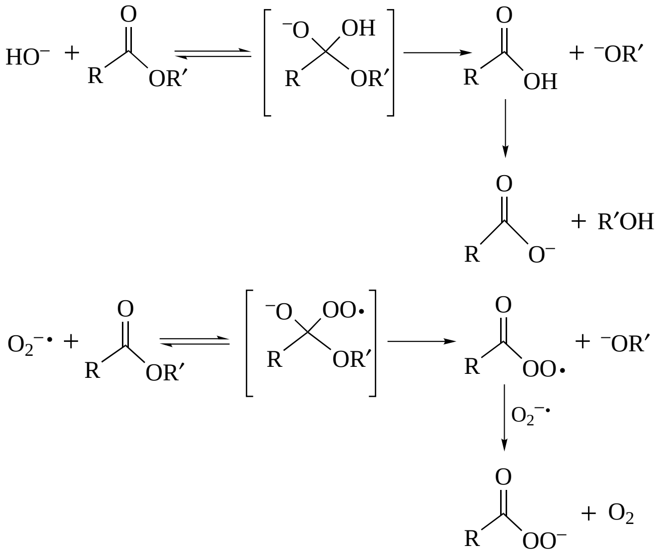
The most common addition reaction is to a carbonyl group without an adequate leaving group. Examples include the reaction of HO^- and $O_2^{-}\bullet$ with CO_2 and quinones.[172] A common feature of these reactions is the formation of an adduct that is sufficiently stable to be isolated or characterized (see Scheme 18). The same orange-colored species results from the reaction of solid tetramethylammonium superoxide with gaseous CO_2 and with neat CCl_4,[174] and is believed to be an anion radical, •OOC(O)O$^-$.[150]

The reaction of HO^- with 9,10-anthraquinone in MeCN produces an adduct (stable at −20 °C),[156] which reacts further at room temperature to yield the semiquinone anion radical ($AQ^-\bullet$). The equilibrium constants for the formation of the adducts and the rate constants for the reaction of the adduct with a second quinone molecule are given in Table 18 (see Scheme 18).

Several examples of reduction by HO^- of transition metal complexes are known (see Table 17).[38,164,175–178] The reaction of Au^+ with HO^- in MeCN is believed to be a prototype of reactions that involve a single-electron shift and the formation of a metal atom/hydroxyl radical bond (equation 175).

$$HO\!:^- + Au^+ \longrightarrow [HO\bullet\bullet Au] \longrightarrow HO\!:\!Au^I(s) \qquad (175)$$

The $E^{\circ\prime}$ for the Au^+/Au redox couple in MeCN is +1.58 V versus NHE compared to +0.9 V for the $HO\bullet/HO^-$ couple;[38,175] hence electron transfer is an exergonic process. Electrochemical oxidation of HO^- at a gold electrode in MeCN occurs at −0.19 V versus NHE, which indicates an Au–OH bond energy of 26 kcal mol^{-1} ($-\Delta G_{BF}$). (However, a Au–Au bond must be broken (54 kcal mol^{-1}); this gives a value of 53 kcal mol^{-1} (26 + 54/2) for the Au–OH bond[41]).

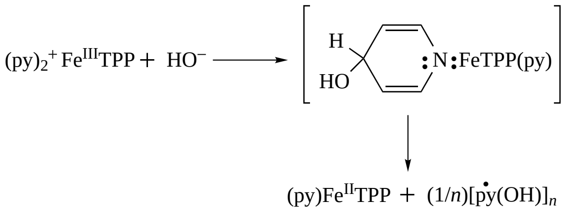


Scheme 17 Polar group transfer; HO^- and $O_2^{-}\bullet$ reactions with esters

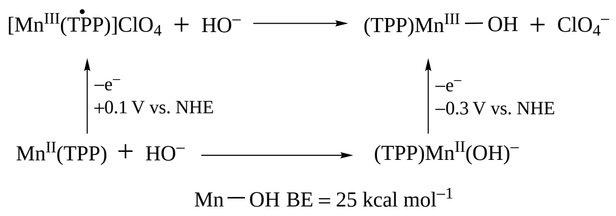
The addition of HO^- to manganese(III) complexes ($Mn^{III}(O_2\text{–bipy})_3^{3+}$, $Mn^{III}(TPP)^+$, $Mn^{III}(PA)_3$, and $Mn^{III}(OAc)_3$) in aprotic media results in the rapid precipitation of the same inorganic manganese oxide (equation 176).[38]

$$Mn^{III}L_3 + 3HO^- \longrightarrow 3L^- + Mn^{III}(OH)_3(s) + H_2O \qquad (176)$$

The ligands of $Mn^{III}L_3$ are reduced by electron transfer from three HO^- ions. The resulting $HO\bullet$ radicals are stabilized via three $d^5sp\text{–}p$ covalent metal–oxygen bonds (equation 178). Similar electron-transfer reductions by HO^- have been reported for Ru^{III} complexes[160] and for $(py)_2Fe^{III}TPP(ClO_4)$ (equation 179).[177] The direct reduction of X within $[(TPP)Fe^{III}X]$ via addition of HO^- has been demonstrated by electrochemical measurements[164] and an NMR titration.[178]

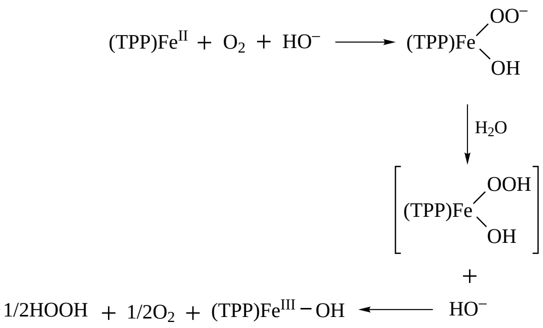


(177)



(178)

$$(TPP)Fe^{III}X + HO^- \longrightarrow (TPP)Fe^{III}\text{–}OH + X^- \qquad (179)$$



(180)

Another example of reductive addition by HO^- is its termolecular reaction with reduced $Fe^{II}(TPP)$ in the presence of dioxygen (equation 180).[171] The net effect is the reduction of O_2 to bound superoxide ion, which hydrolyzes to bound

HOO•; the latter dissociates from the iron center and disproportionates to HOOH and O_2.

The most striking and unexpected reactions of HO^- are those that produce anion radicals when hydroxide is added to solutions of aromatic ketones, quinones, paraquats, and strong electron acceptors such as tetracyanoethylene.[170] If the primary reaction is a SET reaction, a radical pair will be produced (equation 181).

$$HO{:}^- + Y{:}X \longrightarrow HO\bullet + Y{:}X^{-\bullet} \qquad (181)$$

Because HO• is a strong oxidant (although about 1 V weaker in MeCN than in water), a single-electron transfer would be greater than 1 V endergonic for quinones, paraquats, and ketones. All of these compounds, unless substituted with electron-withdrawing groups, are reduced at potentials less negative than −0.3 V versus NHE in MeCN, compared to +0.9 V for the HO•/HO^- redox couple. Hence, the reactions of quinones, paraquats, and ketones with HO^- are unlikely examples of the SET process. Only synchronous coupling of the electron transfer to a chemical reaction that results in covalent bond formation of the HO• can account for the spontaneous reactivity. Although the coupling of two HO• to form HOOH is one possibility, a more likely primary step for reactants is attack by HO^- of an unsaturated center (aromatic or carbonyl carbon compound) or, in the case of the paraquats, a dequaternization reaction initiated by addition. The observed radicals are then produced in subsequent reactions that involve the intermediates from the primary step. Thus, the production of a radical is not adequate evidence that the primary step is a SET reaction.

In aprotic solvents, HO^- reacts with elemental sulfur (S_8) via a net SET process to give the trisulfide anion radical ($S_3^-\bullet$) and HOOH (equation 182).[179]

Perhaps this is the most compelling example that HO^- represents a stabilized electron and can affect the electron-transfer reduction of a nonmetal to give an anion radical.

$$3S_8 + 8HO^- \longrightarrow 8S_3^-\bullet + 4HOOH \qquad (182)$$

8.3 Relative Reactivity of $HOO^-/O_2^-\bullet/HO^-$ with Electrophilic Substrates

The nucleophilicity of oxyanions (YO^-) is directly related to their oxidation potentials ($E^{\circ\prime}{}_{B^-/B\bullet}$, Table 15) and the bond energies of their products (YO–R) with electrophilic substrates (RX) (equation 183).

$$YO^- + RX \longrightarrow YO{-}R + X^- \qquad (183)$$

Hence, the more negative the oxidation potential and the larger the YO–R bond energy, the proportionally greater nucleophilic reactivity that will result. The shift in the oxidation potential of HO^- from +1.89 V versus NHE in H_2O to +0.92 V in MeCN reflects the 'leveling effect' of protic solvents on the nucleophilicity of oxyanions. Likewise, the shift in potential for HOO^- [+0.20 V (H_2O) to −0.34 V (MeCN)] is in accord with the exceptional reactivity of HOO^- in aprotic solvents. In aqueous media, the reactivity of HOO^- is leveled by extensive anionic solvation,[180] but remains significant with many substrates owing to its unique orbital energies[181] and the presence of an unshared pair of electrons on the atom adjacent to the nucleophilic center (α effect).[182]

The reactivity of $O_2^-\bullet$ with alkyl halides in aprotic solvents occurs via nucleophilic substitution. Kinetic studies confirm that the reaction order is primary > secondary >>> tertiary and I > Br > Cl >>> F for alkyl halides, and that the attack by $O_2^-\bullet$ results in inversion of configuration (S_N2). Superoxide ion also reacts with CCl_4, $Br(CH_2)_2Br$, C_6Cl_6, and esters in aprotic media. The reactions are via nucleophilic attack by $O_2^-\bullet$ on carbon, or on chlorine with a concerted reductive displacement of chloride ion or alkoxide ion. As with all oxyanions, water suppresses the nucleophilicity of $O_2^-\bullet$ (hydration energy, 100 kcal mol^{-1}) and promotes its rapid hydrolysis and disproportionation. The reaction pathways for these compounds produce peroxy radical and peroxide ion intermediates (ROO• and ROO^-).

Hydroperoxide ion (HOO^-) is unstable in most aprotic solvents, but persists for several minutes in pyridine (k_{decomp}, $4.6 \times 10^{-3}\ s^{-1}$), which allows studies of its nucleophilic reactivity. In pyridine, HOO^- is oxidized in a one-electron transfer to give HOO•, which

Table 18 Equilibrium and rate constants for the reactions of quinones with hydroxide ion

[h]Kinetics in pyridine.

is in accord with previous studies in MeCN (equation 184).

$$HOO^- \longrightarrow HOO\bullet + e^- \quad (184)$$
$$E_{p,a} = -0.34 \text{ V vs. NHE(MeCN)}$$

In the case of HOO^- (and t-BuOO$^-$), the general 'leveling' of nucleophilic reactivity by protic solvents (water and alcohols) enhances its lifetime such that the net reactions for HOO^- with electrophilic substrates usually are most efficient and complete in H_2O or t-BuOOH. Almost all other solvents react with HOO^- or facilitate its decomposition. The relative lifetime of HOO^- in various solvents is in the order: $H_2O \gg$ MeOH $>$ EtOH $\gg$ diglyme $>$ pyridine $\sim$ PEGM 350 $\gg$ MeCN $>$ DMF $\gg$ DMSO.[183]

Table 19 summarizes the relative reactivities of $HO^-(H_2O)/HO^-(MeOH)/HOO^-/O_2^{-}\bullet$ with halocarbons and esters in pyridine and the kinetics for the reaction of $O_2^{-}\bullet$ with the substrates in aprotic solvents.[183] The relative reactivity with primary halides (n-BuBr and $PhCH_2Br$) in pyridine is HOO^- (3.0) $>$ t-BuOO$^-$ (2.1) $>$ $O_2^{-}\bullet$ (1.0) $>$ HO^-(MeOH) (0.3) $>$ $HO^-(H_2O)$ (0.2). For CCl_4 the relative reactivities are HOO^- (1.8) $>$ t-BuOO$^-$ (1.2) $>$ $O_2^{-}\bullet$ (1.0) $>$ HO^-(MeOH) (0.6) $>$ $HO^-(H_2O)$ (0.4), and for $PhCl_6$ are HOO^- (5.0) $>$ t-BuOO$^-$ (2.9) $>$ $O_2^{-}\bullet$ (1.0) $>$ HO^-(MeOH) (0.2) $>$ $HO^-(H_2O)$ (0.0).

Although Br(Me)CHCN has two active sites for reaction with HOO^- (Br and CN), its relative rate is similar to that for n-BuBr and it reacts with HOO^- at the bromo carbon to yield Br^-, NCO^-, and MeCHO. In contrast, Br(Me)CHCN reacts with HO^- to give HO(Me)CHCN. The apparent reaction rate (k/[S]) between HOO^- and Br(Me)CHCN is 9.8×10^2 M^{-1} s^{-1} in MeCN, which is almost 10^4 times faster than the apparent rate for the reaction of HOO^- with MeCN (k/[S] $= 2.1 \times 10^{-1}$ M^{-1} s^{-1}).[183]

The relative reactivity of HOO^-/HO^-(MeOH) with primary halocarbons (n-BuBr, $PhCH_2Br$, $BrCH_2CH_2Br$) is about 10 in pyridine (Table 19), which compares with a ratio of 13 for their reaction with $BrCH_2CO_2H$ in H_2O[184] and 35 for reaction with $PhCH_2Br$ in 50% acetone/water.[185] Although $O_2^{-}\bullet$ is a powerful nucleophile in aprotic media, it does not exhibit such reactivity in water, presumably because of its strong solvation by that medium and its rapid hydrolysis and disproportionation. Kinetic and electrochemical studies for the reaction of $O_2^{-}\bullet$ with primary halocarbons confirm that the initial step is rate limiting and first order with respect to substrate and $O_2^{-}\bullet$, and occurs via a nucleophilic reductive displacement of halide ion with inversion of configuration (S_N2). The other oxyanions of Table 19 are believed to react via an analogous nucleophilic displacement.

The reactions of hexachlorobenzene (C_6Cl_6) with the oxyanions are unique. Thus, HOO^- is five times as reactive as $O_2^{-}\bullet$ and 33 times as reactive as HO^-(MeOH) (Table 19). Superoxide ion reacts with C_6Cl_6 via an initial nucleophilic addition followed by displacement of Cl^-. The other oxyanions probably follow the same pathway. In the case of HOO^- the displacement of Cl^- gives C_6Cl_5OOH, which is deprotonated by a second HOO^- (or HO^-) to give $C_6Cl_5OO^-$. The latter displaces an adjacent chlorine to give the o-quinone.

The relative rates of reaction between esters and oxyanions (HOO^- (4.5) $>$ $O_2^{-}\bullet$ (1.0) $>$ HO^-(MeOH) (0.2)) are similar to those for C_6Cl_6, which indicates that both substrates undergo an initial nucleophilic addition to an unsaturated carbon (carbonyl and aryl chlorine, respectively).[183] When a suitable leaving group is present, there is a net nucleophilic substitution.

The reactivity of oxyanions with nitriles relative to that for $O_2^{-}\bullet$ cannot be measured because the latter does not give a net reaction. However, the reaction between MeCN and HOO^- is rapid (k_{HOO^-}/[S], 0.21 M^{-1} s^{-1}) via nucleophilic addition to the unsaturated carbon (equation 185).[183]

$$\text{MeC}\equiv\text{N} + \text{HOO}^- \longrightarrow [\text{(Me)(HOO)C=N}^-]$$
$$\longrightarrow [\text{(Me)}(^-\text{OO})\text{C=NH}]$$
$$\xrightarrow{H_2O} [\text{(Me)(HOO)}(^-\text{O})\text{CNH}_2] \xrightarrow{H_2O} \text{MeC(OH)(O}^-)\text{NH}_2 + \text{HOOH} \quad (185)$$

Intramolecular rearrangement and hydrolysis yield the (HO^-) adduct of acetamide. The (k_{HOO^-}/k_{HO^-}) ratio for p-$NCPhCO_2H$ in water[184] is about 10^3 and for PhCN in 50:50 H_2O/Me_2CO[185] is $10^{4.6}$.

Glossary

Donor: an atom or assemblage of atoms that is a net donor of electrons to another atom or assemblage of atoms
Ligand: a moiety that is bound to a central atom, usually a metal
Phosphorus: a nonmetal, the second member of group 15, collectively called the pnictogens

PART I
Ligands with Three-coordinate Phosphorus Atoms

1 INTRODUCTION

Why use P-donor ligands instead of, for example, N-donor ligands? Prominent among the reasons is their ability to form a molecular complex that often stabilizes unusual valency states. Furthermore, though demanding, their syntheses are mainly straightforward using conventional laboratory techniques and apparatus. Also of interest is the fact that metal–phosphorus bonding has been factored into three components: σ-bonding, π-bonding, and steric effects (*see* σ*-Bond*; π*-Bond*; and *Steric Effect*). The ability to vary each component independently, or almost so, has found important uses in the development of homogeneous transition metal catalysts and their 'fine tuning' for optimum product yields. To this list may be added their ability to meet the recent demands for *chiral* synthesis by the pharmaceutical industry. Finally, but by no means least, there are the enormous advantages in analysis of ^{31}P NMR and P-specific GC detectors in following complex reactions. While none of these reasons is unique to phosphorus, the combination makes P-donor phosphorus ligands highly attractive.

For the purpose of Part I of the article, we consider P-donor ligands of the type R_3P that are neutral molecules with a *Lone Pair* of electrons available for complex formation. Therefore this is essentially tervalent phosphorus chemistry. Anionic species such as PPh_2^- are excluded, but the simple inorganic compounds such as the phosphorus trihalides are included.

Part I of this article has been divided into four sections. The introduction is followed by a description of the variety of P-donor ligands available. The third section is devoted to the bonding of P-donor ligands with metals. Finally, an attempt is made to show the enormous structural diversity of P-donor ligands, ranging from simple phosphines to those with sophisticated and elaborate architecture.

It was about a decade after the first preparation of a tertiary phosphine, PMe_3, in 1847,[1] that the coordinating power of phosphorus was appreciated. Hoffman[2] and later Cahours[3] prepared the first P-donor complexes in the 1850s. The exponential growth of P-donor chemistry started with the pioneering work of Mann[4] and Jensen[5] in the 1930s and was continued in the immediate postwar era by Dwyer,[6] Chatt,[7] and Nyholm,[8] to name but three.

2 THE EFFECT OF SUBSTITUENTS R ON R_3P DONOR LIGANDS

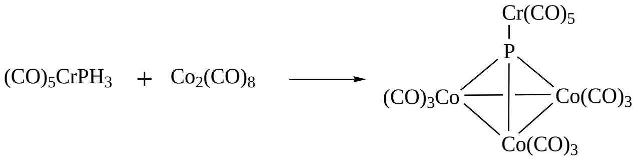
The P-donor ligands we consider in this Part I are phosphorus(III) compounds. We avoid the classification difficulties of phosphine, PH_3, as based on P-oxidation state −III by referring throughout to tervalent phosphorus. Low-coordination number phosphorus species, such as RP, RCP, $R_2C{=}PR'$, and P_n, are presented in Part II. The P-donor ligands considered in Part I are covered by the generalized formula PR_3 for a P-donor ligand. The PR_3 ligands have a pyramidal shape due to their sterically active lone pair of electrons. In terms of a *Valence Shell Electron Pair Repulsion Model* model, the lone pair occupies the 'vacant' tetrahedral site of the phosphorus center.

The elements bonded to the P-Atom commonly found in R_3P ligands are E = H, C, Si, N, O, S, F, and Cl; other elements are known but are rare. Driven by the quest for ever more sophisticated semiconductor devices, material scientists are constantly extending the range of precursors for MOCVD processes (*see Metal–Organic Chemical Vapor Deposition*), and inter alia compounds with P–Al/Ga/In linkages are rapidly gaining importance. All the common elements bound to P-donor ligands, except hydrogen, are members of the p-block.

It will be seen later (Part I, Section 3) that the π acidity of P-donor ligands is primarily a function of the σ^* antibonding orbital of the ligand molecules. In general, the greater the e*lectronegativity* difference between E and P (Table 1), the lower is the energy of the σ^* orbital and the stronger the π acidity of the ligand (*see π-Acid Ligand*). The elements, E, will be discussed briefly group by group.

2.1 Phosphorus Hydrides as P-donor Ligands

Phosphine and its derivatives containing P–H bonds, the primary (RPH_2) and secondary (R_2PH) phosphines, do not have a well-developed coordination chemistry. The greater the number of hydrogen substituents, the more modest is the steric requirement of the ligand (see Section 3.1.3). PH_3, with a *Cone Angle* of 87°, is the least sterically demanding phosphine. The majority of transition metal complexes formed with hydrogen-containing phosphines is used to prepare phosphide bridged species (see, for example, equation 1).



(1)

Homoleptic phosphine complexes with transition metals, such as $[Ni(PH_3)_4]$ or $[Ni(PPh_2H)_4]$, have been prepared.[10,11] The main group Me_3GaPH_3 coordination compound can be pyrolyzed to afford GaP in Na^+/H^+ exchanged zeolite Y.[12]

Table 1 Selected electronegativities of the elements[9]

Element	Pauling	Allred–Rochow	Mulliken	Spectroscopic data
P	2.19	2.06	2.39	2.25
H	2.20	2.20	3.06	2.30
C	2.55	2.50	2.67	2.54
Si	1.90	1.74	2.03	1.92
N	3.04	3.07	3.08	3.07
O	3.44	3.50	3.21	3.61
F	3.98	4.10	4.42	4.19
Cl	3.16	2.83	3.54	2.87

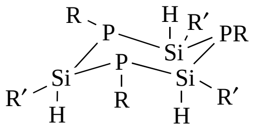
2.2 Phosphorus–Group 14 Compounds as P-donor Ligands

2.2.1 *Carbon*

Tertiary phosphines (PR_3) are, by a large margin, the commonest of the P-donor ligands and, as such, are constantly referred to throughout this article. Their bonding is discussed in detail in Section 3 and their structural aspects in Section 4. Since this section is primarily describing electronegativity effects, it is appropriate to include here the effect of electron-withdrawing substituents on organo groups, which effectively increases electronegativity. The effect of using perfluoroalkyl substituents is to increase the π acidity of the phosphine; $P(CF_3)_3$ is comparable to CO in π acceptor properties. Although these compounds were prepared in the 1960s,[13] the preparative difficulties restricted their use. Improved preparative procedures have resulted in a renaissance in perfluoroalkylphosphine coordination chemistry; examples include $(CF_3)_2PCF_2CF_2P(CF_3)_2$ and $(CF_3)_2P(CH_2)_nP(CF_3)_2$ ($n = 2$, 3), prepared by Cavell and coworkers,[14] and $(C_2F_5)_2PCH_2CH_2P(C_2F_5)_2$, prepared by Roddick and Ernst.[15] The analysis of the CO stretching frequencies of the nickel $[(CF_3)_2PCX_2CX_2P(CF_3)_2Ni(CO)_2]$[13] and molybdenum $[(CF_3)_2PCX_2CX_2P(CF_3)_2Mo(CO)_2]$[14] complexes (X = H, F) clearly indicates that these bidentate fluorine-containing ligands are strong π acceptors. Brookhart and coworkers[16] noted that the CO stretching frequencies of $[\{(C_2F_5)_2PCH_2CH_2P(C_2F_5)_2\}Fe(CO)_3]$ are substantially higher than those of the dppe analog $[(Ph_2PCH_2CH_2PPh_2)Fe(CO)_3]$ and comparable to those of $[(PF_3)_2Fe(CO)_3]$.

2.2.2 *Silicon*

Silylphosphines, $(R_3Si)_3P$, are well known. On the basis of electronegativity (Table 1) they are weaker π acids than organophosphines. With the isolation of $R_2Si{=}PR'$ compounds,[17,18] an increased variety of structures is available. Six-membered silicon–phosphorus heterocycles (**1**) have been proposed as ligands for catalyst candidates, owing to the steric accessibility of the transition metal.



(**1**) R′ = Mes*; R = Cy

It has been shown by Schumann and Benda[19] that, while molybdenum coordinated to all three phosphorus sites, chromium used only two. Driess and coworkers[20]

characterized the ligand (**1**; R = Cy, R′ = Mes), and its $M(CO)_3$ complexes (M = Cr, Mo).

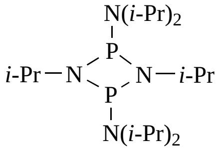
2.3 Phosphorus–Group 15 Compounds as P-donor Ligands

2.3.1 Nitrogen

Aminophosphines, $P(NR_2)_3$, are well known and form a part of a wide variety of structural types including heterocycles and P–N cage compounds. In terms of π acidity, aminophosphines (other substituent effects being equal) lie between organophosphines (PR_3) and the phosphites ($P(OR)_3$).

Of the aminophosphines, tris(dimethylamino)phosphine is the most widely used. It has the feature of combining three hard nitrogen and the soft phosphorus sites, thus being potentially an eight-electron donor ligand. In complexes such as $[M(CO)_5P(NMe_2)_3]$, it is a two-electron P-donor ligand.[21]

The cage ligand $P(N(Me)CH_2)_3CMe$ is often studied in relation to the phosphite and carbocyclic analogs.[22] Cyclic amines such as (**2**), potentially a six-electron pair donor,[23] are available but are not often used as ligands.



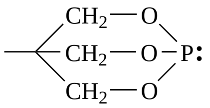
(**2**)

2.4 Phosphorus–Group 16 Compounds as P-donor Ligands

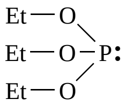
2.4.1 Oxygen

Of the P-donor ligands the triorganophosphites $P(OR)_3$, together with the phosphonites $R'P(OR)_2$ and phosphinites R'_2POR, are second only to the organophosphines in number. They are often contrasted with the organophosphines in ligating properties because of their increased π acidity, together with their ready availability. Their steric requirements are less than those of the analogous phosphines; for example, $P(OMe)_3$ and PMe_3 have cone angles of 107° and 115° respectively (see Section 3.1.3). The diphenylphosphinic methyl, ethyl, and phenyl esters have cone angles of 132°, 133°, and 139°, respectively, showing the lowering of cone angle by oxygen insertion; compare the cone angles of the corresponding phosphines: Ph_2PMe 132°, Ph_2PEt 140°, and Ph_3P 145°.

A stereoelectronic effect shown particularly by phosphites is the so-called α-effect. This is the enhanced nucleophilicity of phosphorus (or other nucleophilic center) when the adjacent atom has free lone pairs of electrons. Steric constraints such as ring systems can reduce the α-effect;[24,25] (**3**) is a weaker nucleophile than (**4**).

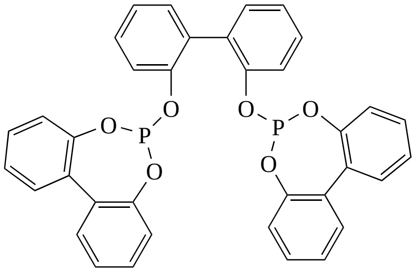


(**3**)

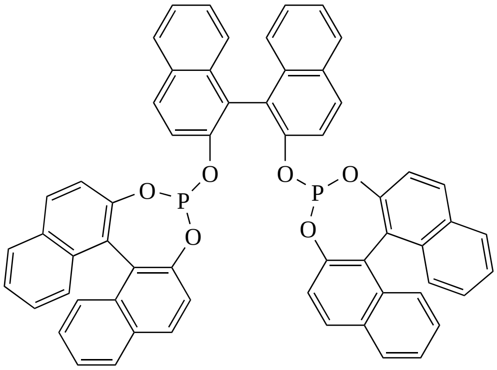


(**4**)

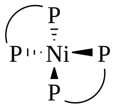
The biphosphite ligands, (**5**) and (**6**), react with $[(cod)_2Ni]$ to form nickel complexes of type (**7**). Nickel phosphite complexes are catalysts in the hydrocyanation of butadiene; complex (**7**) is more robust than the monodentate phosphite analogs.[26,27]



(**5**)



(**6**)



(**7**)

The reactions of phosphite esters with transition metal centers are usually unexceptional, but in some cases an oxidative cleavage of one of the O–C bonds is observed (see, for example, equation 2).

$$L_nMX + P(OMe)_3 \longrightarrow [L_{n-1}M(X)P(OMe)_3] \longrightarrow [L_{n-1}MP(O)(OMe)_2] + MeX \quad (2)$$

These Arbuzov-like reactions (*see Arbuzov Rearrangement*) of phosphite ester transition metal complexes have been reviewed by Brill and Landon.[28]

2.5 Phosphorus–Group 17 Compounds as P-donor Ligands

2.5.1 Fluorine

PF_3 is the strongest of the P-donor π acids and its ability to replace carbon monoxide in a zerovalent transition metal complex was realized in the 1940s by Chatt.[29] However, Wilkinson[30] was the first to isolate a homoleptic PF_3 complex, viz. $[Ni(PF_3)_4]$ (*see Homoleptic Compound*), which turned out to be more thermally stable than $[Ni(CO)_4]$; subsequent research into the PF_3 complexes of transition metals was carried out by Nixon.[31] Bidentate ligands with two PF_2 moieties have been prepared; an example is F_2P(1,2-cyclo-C_6H_{10})PF_2.[32] The volatility of the homoleptic PF_3 transition metal species together with their relative stability has led to their use in MOCVD processes; $[Pt(PF_3)_4]$, for instance, has been used to deposit platinum films.[33]

2.5.2 The Remaining Halogens

Chlorine, bromine, and iodine are considered here together because of their relative rarity in P-donor ligands. A selection of homoleptic PX_3 complexes is given in Table 2. Edwards and Fawcett,[34] in their analysis of the vibrational spectra of $[Ni(PX_3)_4]$ (X = F, Cl, Br, and Me), show that the force constant k_R(P–X) decreases as the stability of the complex decreases (Table 3). This reflects the fall in electronegativity down the group.

Table 2 Mononuclear homoleptic transition metal PX_3 complexes (X = F, Cl, Br, or I)

Ligand	Complex
PF_3	$Cr(PF_3)_6$[35]
	$Fe(PF_3)_5$[35]
	$Ni(PF_3)_4$[30,35]
	$Mo(PF_3)_6$[36]
	$Ru(PF_3)_5$[37]

PBr_3	$[Ni(PBr_3)_4]$[30,42]
PI_3	$[Ni(PI_3)_4]$[43]

Table 3 Nickel–phosphorus stretching force constants for $[Ni(PX_3)_4]$ complexes[34]

Compound	k_R (10^{-8} N Å $^{-1}$)
$[Ni(PF_3)_4]$	3.45
$[Ni(PCl_3)_4]$	1.67
$[Ni(PMe_3)_4]$	1.62
$[Ni(PBr_3)_4]$	1.27

3 P-DONOR–METAL BONDING

P-donor ligands usually form phosphorus–metal bonds with a main group or transition metal that are essentially covalent and in which the phosphorus is the lone pair donor. Despite the vast number of complexes prepared, often with elaborate architecture, the nature of the phosphorus–metal bond remains elusive and controversial, in particular, for transition metals. The simple statement of the bond as a neutral donor–acceptor complex has been elaborated by identifying the many contributing factors. We will discuss the steric factor and the electronic component of the P–M bond separately. The separation of the electronic component into σ and π factors is a formal exercise, the reality being *Synergic Bonding*, wherein these electronic factors are mutually dependent.

3.1 The Influence of Basicity on σ-Bonding

The measure of basicity of phosphine ligands most widely quoted in the literature is pK_a (aqueous), which is a measure of Brønsted basicity or proton affinity. A selection of pK_a values for various phosphines is given in Table 4. Angelici and coworkers[44] have established a method for determining proton affinities from enthalpies of protonation using the extremely powerful acid CF_3SO_3H. The enthalpy values (ΔH_{HP}) and pK_a values are related by the empirical equation (3):

$$\Delta H_{HP} = 1.82\ pK_a + 16.3\ (\text{kcal mol}^{-1}) \quad (3)$$

They extended the method[52] to obtain values for bisphosphines for the first and second equilibrium constants (Table 5).

Reliable pK_a values are not often available, although reasonable estimates (±1 unit) can be calculated. Kabachnik and Mastryukova[53] showed that the Hammett equation is applicable to organophosphorus acids, deriving σ^{ϕ} substituent constants for substituents on phosphorus. These σ^{ϕ} are claimed[54] to be superior to Hammett/Taft parameters.[55]

The basicity of phosphines is affected by the bulk of the substituents. Increasing bulk increases the R–P–R angle, which in turn increases the p character of the lone pair. The highest reported pK_a is that of tris(t-butyl)phosphine, 11.4. In general, alkylphosphines are stronger bases than arylphosphines. However, in the case

Table 4 pK_a and ΔH_{HP} values for tertiary phosphines[a]

Tertiary phosphine	pK_a	$-\Delta H_{HP}$ (kcal mol^{-1})[45]

[a]The methodology of the various workers varied so the interested reader should refer to the original paper for experimental details.

of tris(2,4,6-trimethyoxyphenyl)phosphine, where electron-donating OMe groups reinforce the effect of the bulk of the substituted aryl rings, a pK_a of 11.2 has been recorded.[56]

It is often stated that the stability of the metal–phosphorus σ bond decreases in the series P(t-Bu)$_3$ >P(OR)$_3$ >PR$_3$ ∼ PPh$_3$ >PH$_3$ >PF$_3$ >P(OPh)$_3$,[57] on the basis of, for example, ligand-substitution experiments (equation 4):[58]

$$[(RNH_2)W(CO)_5] + PR_3 \longrightarrow [(R_3P)W(CO)_5] + RNH_2 \qquad (4)$$

The rate of substitution of a given amine has been found to reflect the phosphine basicity: PBu$_3$ ∼ PCy$_3$ > P(OCH$_2$)$_3$CEt > P(SCH$_2$)$_3$CMe > P(OBu)$_3$ > PPh$_3$ > P(OPh)$_3$.

Questions have been raised concerning the relevance of pK_a values, based on the hard acid H^+ interactions, to bonding of the soft acids, that is, low-valent transition metals. The large electric field created by a proton is not generated in the case of, for example, a zerovalent transition metal carbonyl. These deficiencies have subsequently generated interest in gas-phase basicities as a measure of electron availability (Section 3.1.1).

3.1.1 *Basicities of Phosphines in the Gas Phase*

The availability of the electron pair in the isolated ligand can be directly measured by photoelectron spectroscopy. The comparative ionization potentials show a reverse of the proton affinities in aqueous systems. For example, the gas-phase basicity of PPh$_3$ (lower ionization energy) is greater than that of PMe$_3$;[45] a selection of values is given in Table 6. These differences between solution based gas-phase basicities are ascribed to solvation effects.

Some recent quantum mechanical calculations[63] show that all P-donor ligands, PX$_3$, are good σ donors, including PF$_3$. These calculations estimate that the σ donor contribution to the proton affinity is only 10% larger in PMe$_3$ than in PF$_3$. Thus, the controversy about the significance of phosphine basicities is far from settled.

3.1.2 *π-Bonding in Phosphorus–Transition Metal Complexes*

An empirical π acid series may be compiled[64] from experimental data, mainly spectroscopic, and P-donor ligands are notable members covering a wide range. The π acid series that emerges is: NO > CO ∼ RNC ∼ PF$_3$ > PCl$_3$ > PCl$_2$(OR) > PCl$_2$R > PBr$_2$R > PCl(OR)$_2$ > PClR$_2$ > P(OR)$_3$ > PR$_3$ ∼ SR$_2$ > RCN > o-phenanthroline > RNH$_2$ ∼ R$_2$O.

The explanation of the transition metal carbonyl bonding in terms of π *Back Bonding* led to its application to phosphorus–transition metal bonding, notably by Chatt.[65] Pidcock has outlined the early development of Chatt's theories.[66] The symmetry requirements for π back bonding between transition metals and phosphorus d orbitals appear to be met. The d orbitals of a transition metal in an octahedral field are split into bonding e_g orbitals and nonbonding t_{2g} orbitals. The e_g orbitals form σ-bonds with the six ligands, leaving the nonbonding t_{2g} orbitals directed between the six metal–ligand bonds. The σ-bond is formally between a transition metal

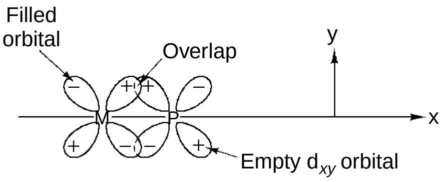

Figure 1 Back bonding to an empty $3d_{xy}$ phosphorus orbital from a filled metal orbital of complementary symmetry. This is repeated in the *yz* plane

d^2sp^3 hybrid orbital and an sp^3 hybrid phosphorus orbital (*see* ***Coordination & Organometallic Chemistry: Principles***). Thus the π back bonding between the empty d orbitals of phosphorus and the filled t_{2g} orbitals of the transition metal (Figure 1) is intuitively appealing and has been widely used in descriptive inorganic chemistry. However, it was pointed out[67,68] that the phosphorus 3d orbitals are too diffuse and also energetically unfavorable to participate in metal–phosphorus bonding. Quantum mechanical calculations[69] have shown that, for the frontier orbitals of PH_3, PF_3, and PMe_3, the *LUMO* has most 3p character:

PX_3	%3p	%3d
PH_3	36	23
PF_3	44	23
PMe_3	14	10

Marynick and coworkers[70,71] made the more extreme assumption, finding no need to include 3d orbitals in the phosphorus basis set. Their results for zerovalent Cr–PH_3 bonding in $[Cr(NH_3)_5PH_3]$ are shown in Figure 2. They suggest that the empty P–X σ^* antibonding orbital is the π acceptor for metal back bonding electronic charge.

The previously held view was that the greater π acidity of PF_3 and PH_3 (see the π acidity series described above) was due to an electronegativity effect, thus lowering the energy

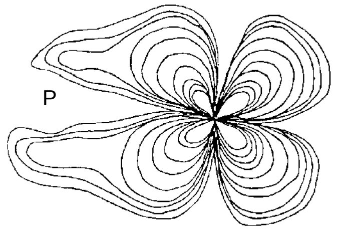

Figure 2 The electron density plot of one of the two π donating orbitals in $Cr(NH_3)_5PH_3$, omitting the phosphorus d orbitals from the calculations. (Reprinted with permission from Ref. 70. © 1984 American Chemical Society)

of the 3d phosphorus orbitals and making them accessible to the metal back bonding charge. Marynick's radical alternative paradigm is that the highly polar P–F bonds have low lying antibonding σ^* orbitals of suitable symmetry for overlap with the metal d orbitals and, further, that they would be superior acceptors than the higher energy P–H σ^* orbitals. In other words, the greater is the polarity P → E of the σ-bond because of electronegativity differences, the greater the σ^* 'reverse polarity' to phosphorus (increased π acidity), resulting in increased σ^*–metal d–π overlap. Giordan and coworkers[72] measured the attachment energy for the formation of negative ions by electron transmission spectroscopy, that is, a direct estimation of the phosphine LUMO. They found that the orbital energies of PR_3 are sensitive to substitution. If the LUMO were 3d in character, or predominately 3d, then it would be insensitive, or relatively so, to substitution effects.

Indeed, Orpen and Connelly,[73] in their analysis of bond length data derived from X-ray crystallography (Table 7), support the σ^* theory but in modified form, reintroducing a 3d orbital contribution from phosphorus. This revisionist view, maintaining a role for the phosphorus 3d orbitals, albeit diminished, has received support from quantum mechanics calculations of Pacchioni and Bagus.[63] They find that the phosphorus d orbital basis functions are essential for an accurate description of the length and strength of the phosphorus–metal bond. The phosphorus d orbital role is that of polarization functions. The vacant antibonding P–X orbitals of PX_3 are π acids even without d orbital mixing, although the π acidity is enhanced by the inclusion of the d orbital equations. In the case of alkylphosphines, the π acidity is appreciable in the presence of the phosphorus 3d orbitals, but modest if these are omitted.

Various authors have proposed schemes that claim to distinguish between phosphorus σ donor and π acceptor contributions to the transition metal–phosphorus bond. Alyea and Song[74] have suggested ^{95}Mo NMR analysis of $Mo(CO)_{6-n}(PR_3)_n$ complexes, together with Kabachnik $\Sigma\sigma^{\phi}$ parameters (see Section 3.1) as a probe of the nature of phosphorus(III) ligands. A plot of $\Sigma\sigma^{\phi}$ against $\delta(^{95}Mo)$ affords a quantitative differentiation of the σ and π bonding effects (Figure 3).

Giering and coworkers[50,75] have combined electrochemical and spectroscopic analyses to develop a method, the quantitative analysis of ligand effects (QALE), for the separation of P-donor ligands into pure σ donors and those with a significant degree of phosphorus π acceptor character (Figure 4).

3.1.3 The Influence of Steric Factors

Tolman[76,77] introduced the concept of the cone angle in 1970 to separate and quantify steric and electronic factors in the reactions of phosphines with transition metals. The original measurements were made from simple physical models, and this approach has been extended to mathematical and computer modeling. Other workers have used X-ray diffraction data to observe and measure cone angles directly. These various approaches are outlined below.

Table 7 Metal–phosphorus and phosphorus–substituent bond lengths[73]

Complex	Charge	Counterion	M–P^a (Å)	P–X^a (Å)
$[Fe(CO)\{P(OMe)_3\}_2(\eta^4\text{-}C_4Ph_4)]$	0	–	2.146(1)	1.598(3)

Tolman's Cone Angle. The model Tolman used[77] to define the cone angle is shown in Figure 5. In order to make the cone angles comparable, he chose an arbitrary value for d, the M–P bond length, of 2.28 Å. The phosphine depicted in Figure 5(a), PR_3, is a symmetrical model. In order to accommodate unsymmetrical ligands, the model was developed to include a measure of each substituent's contribution to the steric bulk, its half cone angle, $\theta_i/2$ (Figure 5b). The cone angle θ of a chiral ligand is given by two-thirds of the half cone angles, that is, $\theta = \frac{2}{3}\sum \phi_i/2$. Thus, if the cone angles for PR'_3, PR''_3 and PR'''_3 are known, then that of $PR'R''R'''$ may be calculated. In the cases of complex or long chain substituents, the conformer chosen is that which gives the minimum cone angle.

Tolman found a slight increase in cone angle with the increase in chain length with the other features unchanged. Thus, for the bidentate phosphine sequence $Ph_2P(CH_2)_nPPh_2$, cone angles for $n = 1$, 2, and 3 were 121°, 125°, and 127°, respectively; when the chain length was held constant, the variation with substituent for the bidentate sequence $R_2PCH_2PR_2$ was 107°, 115°, 125°, and 142° for R = Me, Et, Ph, and Cy, respectively,

Mathematical Modeling of Cone Angles. In what amounts to a pencil and paper conversion of Tolman's molecular models, Imyanitov[78] devised a technique of estimating cone angles from atomic radii, van der Waals radii, and molecular geometry. He combined the mathematical formula for θ, above, with graphical methods (Figure 6a) that are applicable to any ligand. In the case of complex substituents, a more sophisticated geometrical construction (Figure 6b) is necessary to convert the substituent into a sphere equivalent to R in Figure 8(a). In choosing a M–P distance of 2.23 Å, Imyanitov's cone angles are systematically 5° higher than Tolman's,[77] which are based on d(M–P) of 2.28 Å.

In their study of lanthanide and actinide complexes, Bagnall and Zing-Fu[79,80] investigated the steric demands of a wide variety of ligands. They defined first- and second-order steric crowding. First-order steric crowding is a measure of the steric demands of the coordinating atom. Second-order steric crowding is due to the substituents of the coordinating atom. In the case of a single coordinating atom, such as a chloride anion, there is no second-order crowding. They quantified these effects by two terms: the *cone angle factor* (CAF), which is the solid angle of the cone, comprising the apical center and the coordinating atom or ligand divided by 4 (Figure 7a), and the *fan angle*, which describes the crowding in the plane and is the angle subtended by the atom or group in the various symmetry planes (Figure 7b). This is equivalent

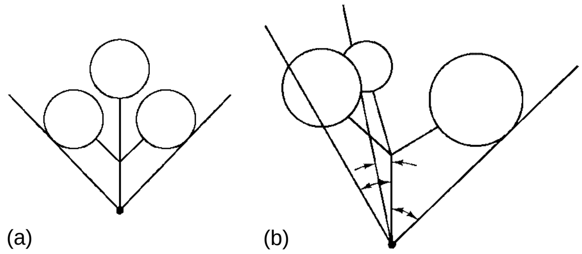

Figure 5 Tolman's cone angle: (a) simple symmetrical tertiary phosphine and (b) chiral phosphine

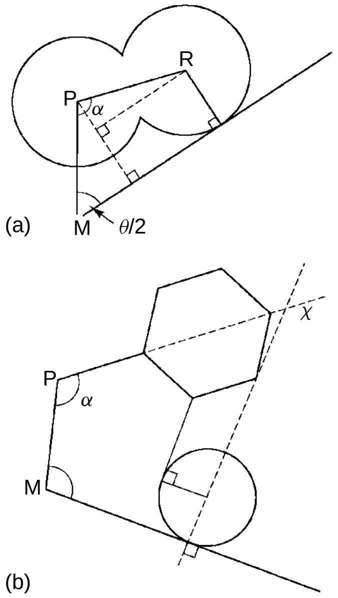

Figure 6 Imyanitov's methodology: (a) simple substituents and (b) complex substituents

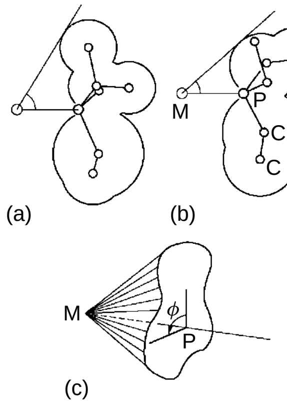

Figure 8 The geometry used by Immirzi and Musco[81b] to show the variations of the angular encumbrance of the orientation of, for example, PEt_3. In (a) and (b), the metal–ligand tangent angle is seen to vary with orientation and (c) shows the summation of all the tangents

to the *ligand profile* defined by Ferguson *et al.*,[81a] and to *ligand angular encumbrance* defined by Immirzi and Musco (Figure 8).[81b]

Mingos[82] applied the cone angle concept to metal clusters stabilized by P-donor ligands. This led him to define a *plane of coverage* for the ligand (Figure 9a). For the idealized ligand shown, this plane is a circle of diameter d. However, in actual systems, the projection would be coglike.[80,81] Further, since the significance of the ligand geometry is the cluster rather than the specific atom to which it is coordinated, Mingos defined a *cluster cone angle* δ (Figure 9b). This is similar to the cone angles of phosphine oxides described by Bagnall and Zing-Fu.[79] The M′–P bond length is by definition longer than the M–P distance. Since, for a given system, a cone angle is inversely proportional to the length of the metal–ligand bond, cluster cone angles are smaller than the corresponding ligand cone angles.

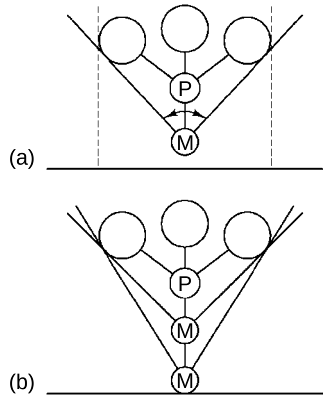

Figure 9 (a) Tolman's cone angle used in mononuclear complexes, indicating the 'plane of coverage' and (b) a diagram showing the parameters of the cluster cone angle

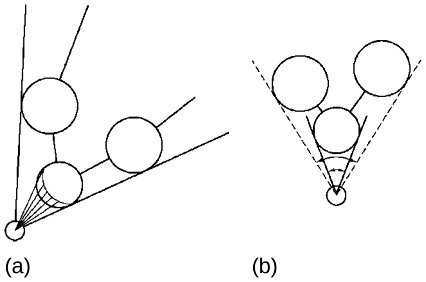

Figure 7 (a) First- and second-order cone angles and (b) fan angles. Irregularly shaped ligands have various fan angles in different planes

Cone Angles and Molecular Mechanics. The explosion in the availability of computer power in the last decades has made molecular mechanics calculations a common laboratory tool. P-donor ligands were investigated by Mosbo and coworkers,[83] who used semiempirical molecular orbital calculations (MINDO/3). They used the following bond lengths and angles: (P–H) 1.4 Å, (P–C) 1.8 Å, (C–C)alkyl 1.5 Å, (C–C)aryl 1.4 Å, (C–H) 1.1 Å, (R–P–R) 109.5°, (R–C–C)alkyl 109.5°, and (R–C–R)aryl 120°; all the low-energy conformations of the ligands were calculated. The energy minima of the conformers of H_2PR (R = Et, *i*-Pr, and 2-MeC_6H_4) were computed. The group used Tolman's M–P distance of 2.28 Å on the vector through P normal to the plane defined by the three points 1.00 Å from P to the substituent R. The rotation ϕ about the M–P axis through 360° in 1° increments generated the half cone angles $\theta/2$ of the outermost atoms. The $g_r g_l$ conformer of H_2P–*i*-Pr is shown in

Figure 10. The weighted average of all conformations was the optimum value for the cone angle; these are listed in Table 8.

Cone Angles and X-ray Studies. The large and growing database of X-ray crystal structures has attracted several workers into systematizing steric effects by the direct observation of real systems.

Ferguson, Alyea, and coworkers,[81,84,85] in their studies of bulky phosphine ligands and their transition metal complexes, noted a limitation in Tolman's cone angle concept in the solid state. Essentially Tolman describes ligands as if they were solid cones, but Ferguson and coworkers noted the uneven shape given by the phosphine substituents and the gaps between them, which they describe as the 'depth of tooth' of the 'conic cog'. In their graphical analyses of the data they refer to 'ligand profiles'. These profiles are obtained by rotating the ligand about the axis of the M–P bond (ϕ is the angle of rotation), thus obtaining the half cone angle $\theta/2$ from the tangent to the maximum van der Waals radius through M (Figure 11).[81]

The ligand profile is the graph of the angle of rotation ϕ versus the half cone angle $\theta/2$; some of their measured cone angles, together with selected crystallographic data, are shown in Table 9. Ferguson defined the cone angle as the maximum value shown in the profile. Using this approach, the cone angle for a given ligand varies with the complex; for example, for tri(cyclohexyl)phosphine (Tolman 170°), Ferguson's group calculates a cone angle of 181° in $[Hg(NO_3)_2(PCy_3)]_2$ and 163° in $[PtI_2(PCy_3)_2]$.

Other workers noted the intermeshing of ligands in crystal structures and proposed various graphical representations. Oliver[86] suggested using circular coordinates (Figure 12) to show the intermeshing of PCy_3 ligands in $[Pt(C_3H_5)(PCy_3)_2]PF_6$. Cone angles for other phosphorus compounds are listed in Tables 10–12.

3.2 The Effect of Soft and Hard Acids and Bases on the Transition Metal–Phosphorus Bond

The generalizations of the soft and hard acids and bases (SHAB) principle are extremely useful in rationalizing the facts of inorganic chemistry. However, they are guidelines rather than 'laws'. On the basis of SHAB theory, complex formation between hard Mn^{II} and soft R_3P would not be favored nor predicted. In fact, an extensive series of MnX_2L[92] and MnX_2L_2[93] (X = halogen, pseudohalogen; L = PR_3, R = organyl) complexes have been synthesized. Further, the

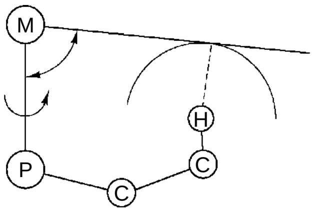

Figure 11 Details of the calculation of the maximum semicone angle, $\phi/2$. The point of contact of the cone generating vector M → X from the metal, with the van der Waals sphere of the hydrogen atom, is coplanar with the metal, phosphorus, and hydrogen atoms

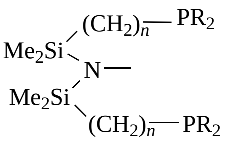
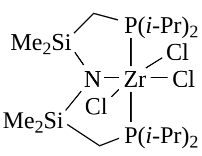
even harder Mn^{III} has also formed a phosphine complex, $MnI_3(PMe_3)_2$, with a trigonal bipyramidal structure.[94]

This is not to say that there are no SHAB problems of donor–acceptor incompatibility. Several groups have adopted the strategy of synthesizing ligands that have hard and soft moieties, such as (**8**). For example, Fryzuk and coworkers[95] use ligands with a hard center to anchor to the hard metal, in this case Zr^{IV} or Hf^{IV} enabling the phosphorus chelating moieties to form a stable complex (**9**).



(**8**)



(**9**)

The deliberate mixing of hard and soft centers has been extended to macrocyclic systems (Part I, Section 4.6).

4 THE STRUCTURAL DIVERSITY OF P-DONOR LIGANDS

Within the format of this contribution, only a brief outline of the vast range of P-donor ligand architecture can be given. Most of the examples given are based upon P–C bonding, which reflects the historical development of the subject. Attention has already been drawn to the effect on π acidity of p-block substituents on phosphorus. It should also be noted that p-block elements may be introduced into a structure remote from phosphorus to provide a variation in ligand texture (hard

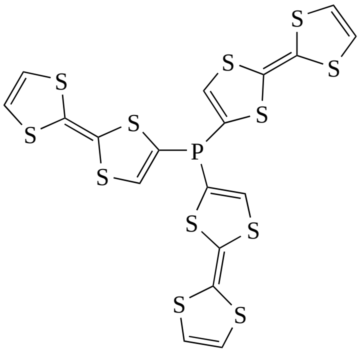
and/or soft sites) in order to generate cooperative effects in catalytic systems.

4.1 Simple P-donor Ligands

The 'simple' R_3P phosphine is the workhorse of P-donor chemistry. The preparative aspects are dealt with elsewhere (*see* ***Phosphorus: Organophosphorus Chemistry***) and they have been reviewed extensively.[96–100]

New resources are constantly being found in the superficially simple phosphine–transition metal chemistry. For example, West and coworkers[101] reacted the phosphorus(V) compound Et_3PTe with $[Mn(CH_2Ph)(CO)_5]$, which resulted in the redox (*see Redox Properties & Processes*) insertion of Te into the Mn–C bond. The phosphorus was reduced to the phosphine ligand, forming the complex $[Mn(TeCH_2Ph)(CO)_3(PEt_3)_2]$. McAuliffe and coworkers[102] have developed a new synthetic approach to the synthesis of phosphine–transition metal complexes that also involves a redox reaction. For example, the reaction between cobalt powder and trimethyldiiodophosphorane affords a trimethylphosphine complex, $[Co(PMe_3)_2I_3]$.[102] The reaction is quite general and a number of metal powders have been used, such as Fe,[103] Ni,[103] Zn,[104] and Mn.[105,106b] The same reaction can even be carried out with gold powder, which is dissolved by Me_3PI_2 to give $(Me_3P)_2AuI_3$.[106,106c] The products are not always those anticipated; indeed, several unique or rare complexes have been prepared by this route. Trivinylphosphine $(CH_2{=}CH)_3P$ has for some time been excluded from most studies with tertiary phosphines, but has recently become readily accessible and employed for coordination chemistry.[106d]

The electron-rich ligand[107a] tris(tetrathiafulvalenyl)phosphine (**10**) (*see Electron Rich Compound*) is one of the more recently available phosphines with great potential in materials science.



(**10**)

It is important to note that simple PR_3 ligands may also function as bridging units between two metal atoms with the P-atom becoming five coordinate as shown in Figure 13.[107b]

4.2 Bidentate P-donor Ligands

4.2.1 Methylene Bridged Bidentate P-donor Ligands

Bidentate (*see Bidentate Ligand*) methylene bridged bisphosphine ligands, $R_2P(CH_2)_nPR_2$ ($n = 1{-}16$), have ligating properties that characteristically depend on chain length. As with other P-donor ligands, of course, their behavior is also governed by the nature of R. Short chain ligands

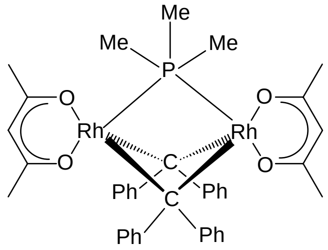


Figure 13 The PR_3 ligand functioning as bridging unit between two rhodium centers, with the P-atom becoming five coordinate[107b]

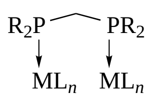
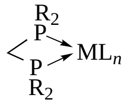
($n = 1$) have been excellently reviewed by Puddephatt[108] and Chaudret *et al.*[109] Because of ring strain, complexes such as (**11**) are formed rather than cyclic species (**12**).

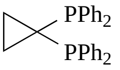


(**11**)



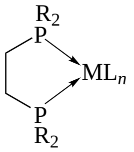
(**12**)

(**13**)

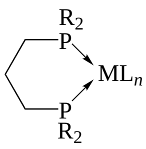


(**14**)

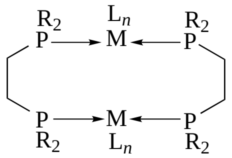
The bite angle and other properties can be varied by altering the substituents on the methylene bridge. Much interest has been shown in ligands such as (**13**) and (**14**). With chain lengths $n = 2$ or 3, the thermodynamically favored (the chelate effect) five- and six-membered rings are commonly formed [(**15**) and (**16**)]. Large *dinuclear* rings have also been isolated (**17**).



(**15**)

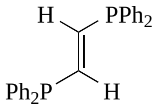


(**16**)

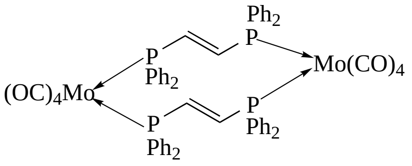


(**17**)

These dinuclear ring structures may be 'forced' by constraining the ligand; (**18**), for example, affords (**19**).[110]



(**18**)

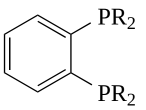


(**19**)

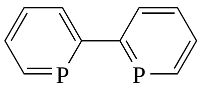
With long chain bis(phosphines) ($n = 4 - 16$), trans chelate rings become possible, although with the longest chains bridged dinuclear species would be expected.

4.2.2 Bidentate Phosphine Ligands with Ring Bridging

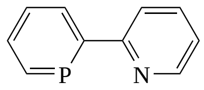
1,2-di(phosphino)benzenes (**20**) are the most widely used of this type of ligand, and many chiral ligands (see Section 4.3) are bidentate. Much interest has been shown in the phosphorus analog (**21**)[111] of 2,2′-bipyridyl and the mixed nitrogen/phosphorus ligand (**22**).[112]



(**20**)



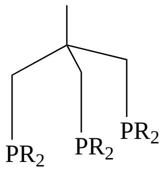
(**21**)



(**22**)

4.2.3 Polydentate P-donor Ligands

Increasing the number of ligating sites greatly increases the structural possibilities both of the ligand and of the complexes. Tridentate ligands may be either linear $R_2P(CH_2)_nP(R)(CH_2)_mPR_2$, or of the so-called tripod type (**23**) (*see Tripodal Ligand*).



(**23**)

Metal catalysts containing tripod phosphine ligands have been reviewed.[113] The limiting value for molecular polydentate ligands in practice is a hexakisphosphine such as $(Et_2PCH_2CH_2)_2PCH_2CH_2P(CH_2CH_2PEt_2)_2$; such compounds usually complex with two metal centers. There is no barrier to more complex structures, however.

4.3 Chiral Phosphines

These compounds are important in asymmetric catalysis, in which a prochiral substrate is converted into a chiral product. There are basically three types of chiral phosphines. Firstly, there are phosphines of the type PRR′R″, where the chiral center is the phosphorus atom. Secondly, the substituent(s) or the molecule as a whole may be chiral. Finally, a coordinated phosphine complex may be chiral at the metal center.

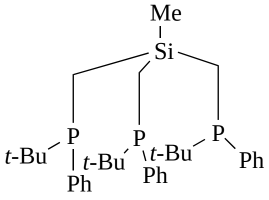
4.3.1 Phosphines with Chiral Phosphorus Centers

Simple chiral phosphines have already been mentioned (Section 3.1.3) and the macrocycle enantiomers are discussed below (Section 4.6). Current research in this area is concentrated on bidentate chiral phosphines, such as the ligands (**24**)–(**27**). Although their transition metal complexes are normally used for stereospecific synthesis, Whitmire and coworkers[114] used the molybdenum complexes to resolve their racemic bisphosphines via flash chromatography. The phosphines were 'decomplexed' by reductive cleavage at low temperatures (−78 °C) using sodium naphthalenide (Scheme 1).

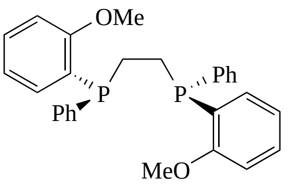
More complex chiral phosphines have also been prepared, for example, (**24**).[115a]

4.3.2 Phosphines with Chiral Substituents

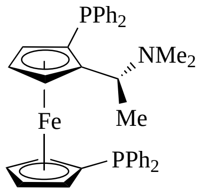
Phosphines that owe their chirality to their substituents or to general molecular asymmetry include (*S*)-BINAP (**28**),[116,117]



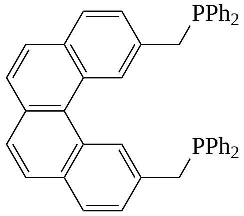
(**24**)



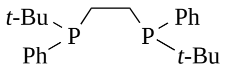
(**25**)



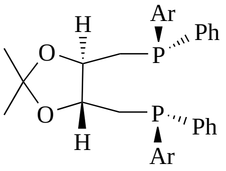
(**31**)



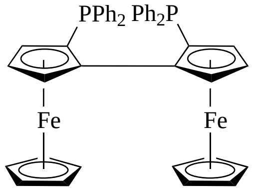
(**32**)



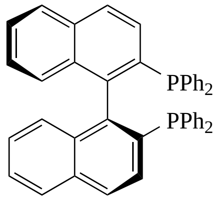
(**26**)



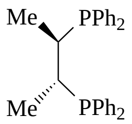
(**27**)



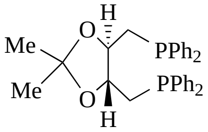
(**33**)



(**28**) (*S*)-BINAP



(**29**) (*R*,*R*)-CHIRAPHOS



(**30**) (*R*,*R*)-DIOP

(*R*, *R*)-CHIRAPHOS (**29**),[118] (*R*, *R*)-DIOP (**30**),[119] (*S*, *R*)-BPPFA (**31**),[120] (**32**),[121] and (**33**).[122] Such compounds are much more numerous than those with a chiral phosphorus atom. This is because the synthetic methods are much simpler, the readily obtainable R_2P^- (usually Ph_2P^-) being grafted into an optically active substrate. The pioneering work was summarized by Peterson *et al.*[123] Some more recent examples of enantiospecific reactions catalyzed by chiral phosphines are given in equations (5–7),[124–126] with the enantiomeric excess (ee) for the reaction. In equation (7), (**36**) = NEt_4 $[Ru_2\{(R)\text{-BINAP}\}_2Cl_4]$.

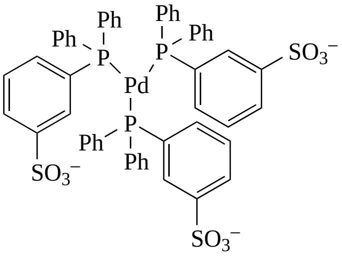
4.3.3 *Transition Metal Complexes with a Chiral Metal Center*

In principle, steric control may be exercised by a chiral transition metal catalyst in which the metal center is the asymmetry origin rather than the phosphine or its substituents. Gladysz and coworkers[127] have separated the enantiomers of rhenium complexes using HPLC.

4.4 Solubility Effects

Here, we are not alluding to changes in a reaction induced by the use of aprotic as opposed to aqueous solvents, but to the means of achieving solubility in the desired solvent. Organophosphines and -phosphites are usually soluble in organic solvents and so enhance the hydrophobic solubility of the transition metal moiety in their complexes. If necessary, the organic groups used may be large; for example, R = n-$C_{10}H_{21}$ to n-$C_{19}H_{39}$ in PR_3 and R = Et to n-C_9H_{19} in $P(4\text{-}RC_6H_4)_3$ have been used by Chipperfield.[128] Hartley and Franks[129] synthesized phosphines with the chains in the para position, that is, $(4\text{-}RC_6H_4)_3P$ (R = Et to C_9H_{19}), and used them to prepare complexes[130] soluble in hydrocarbon solvents.

The importance of water as a solvent has led to the development of water-soluble phosphines. This has been achieved by the incorporation of hydrophilic substituents into the phosphine structure. The choice of substituents, whether anionic, cationic, or neutral, depends on the exigencies of the end use. The anionic species $[Ph_2P(3\text{-}C_6H_4SO_3)]^-Na^+$ has been used to afford a water-soluble palladium catalyst (**37**) by Du Pont workers.[131a]

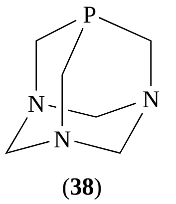


(**37**)

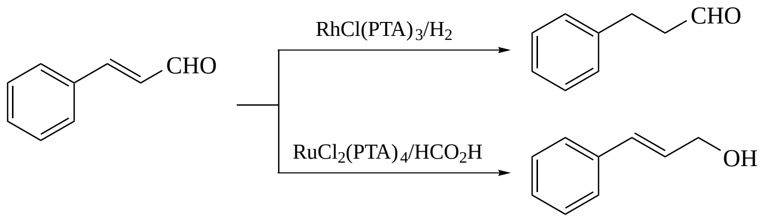
Variations on this theme, produced by varying the steric and electronic properties of sulfonated phosphines, have been carried out by Hanson and coworkers.[131b] They inserted alkyl chains between phosphorus and the sulfonated aryl group to give the series $P[(CH_2)_n(4\text{-}C_6H_4SO_3Na)]_3$ ($n = 1$, 2, 3, and 6). An investigation of the nickel complexes $[(CO)_3NiP\{(CH_2)_n(4\text{-}C_6H_4SO_3Na)\}_3]$ using Tolman's electronic parameter χ showed that the effect of the sulfonation is greater when $n = 0$, 1, or 2 and the electronic parameter approaches that of $P(n\text{-}Bu)_3$ when $n > 3$.

An example of the alternative cationic species is provided by $[Ph_2PCH_2NMe_3]^+I^-$. Baird and coworkers[132,133] developed this theme in preparing the all-phosphorus cationic phosphonium phosphines $[Ph_2P(CH_2)_nPMe_3]X^-$ ($n = 2, 3, 6, 10$; X = NO_3, Cl, PF_6), to which they gave the trivial names II-, III-, VI-, and X-phosphos. These ligands form water-soluble transition metal complexes such as $[(nbd)RhCl(\text{II-phosphos})][PF_6]$.[134]

The neutral triazaadamantane phosphine PTA (**38**) has been used by Darensbourg's group[135] to solubilize rhodium and ruthenium catalysts without impairing their selectivity (Scheme 2).

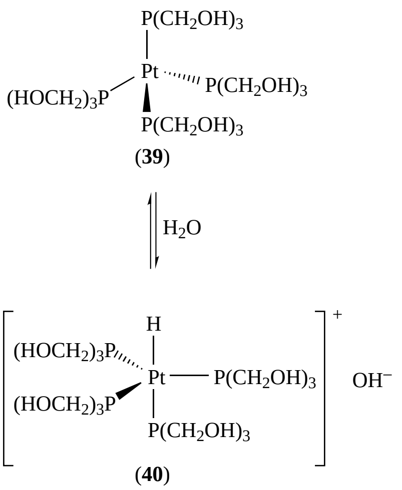


(**38**)



Scheme 2

Pringle and coworkers[136] have developed a neutral (in the sense of uncharged) hydrophilic phosphine, $P(CH_2OH)_3$, for use in catalysis. The palladium(0) and nickel(0) complexes $[M\{P(CH_2OH)_3\}_4]$ are soluble in water and polar organics such as MeOH and DMSO, but insoluble in halocarbon or hydrocarbon solvents. The analogous nominally platinum(0) complex $[Pt\{P(CH_2OH)_3\}_4]$ illustrates the fascinating unpredictability of chemistry. This complex gives a strongly alkaline aqueous solution, which Pringle ascribes to the equilibrium in equation (8), the species (**40**) being stabilized by the intramolecular hydrogen bonding of the phosphine hydroxyl groups to form a structure analogous to the tripod tetradentate ligand $P(CH_2CH_2PPh_2)_3$ (see Section 4.2.3), which is known to stabilize platinum trigonal bipyramidal geometry.

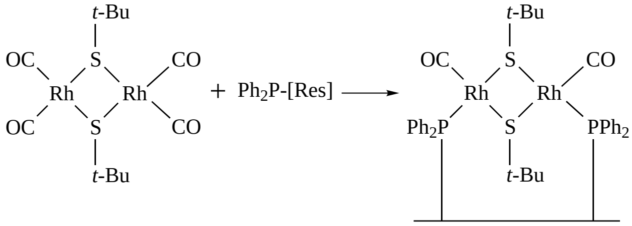


(8)

4.5 Polymer Supported Phosphines

The anchoring of homogeneous transition metal catalysts to polymers via anchored phosphine ligands combines the advantages of homogeneous and heterogeneous catalysis. Ideally there is ease of separation of the product and no loss of expensive metal, which is recycled. Several books outline the synthetic methods available[137–139] and illustrate two basic routes to functionalized polymers. Firstly, the phosphine may be polymerized or copolymerized to give the polyphosphine. Alternatively, the phosphine may be grafted on to an existing polymer. In each case the phosphine may be complexed to a transition metal. The useful polymers are insoluble, cross-linked resins, usually styrene–divinylbenzene copolymers. We use the representation [Res] for these resins rather than P, which is also commonly used, because of the ready confusion with the symbol for phosphorus.

The highly toxic osmium complex $Os_3(CO)_8(\mu\text{-Cl})_2PPh_3$ was immobilized via an anchored phosphine ligand as $Os_3(CO)_8(\mu\text{-Cl})_2Ph_2P$-[Res].[140] The bonding may be more complex, for example, Kalck and coworkers[141] have proposed that each rhodium atom of the dinuclear carbonyl is anchored to the resin (equation 9):



(9)

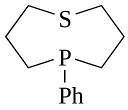
Unfortunately, in practice these anchored polymer systems often underperform owing to leaching of the metal and even the phosphine, especially under the conditions in continuous flow reactors. Critical accounts of these problems have been given by Garrou and Gates[142] and Garrou.[143] However, there are compelling environmental arguments[144] for the continued development of these polymeric ligands, inter alia minimizing toxic emissions to the biosphere.

An alternative approach to anchoring complexes is to embed them in a polymer. The complex is incorporated in the cross-linked polymer using a solvent that produces the maximum swelling. The solvent is evaporated and the surface washed free of excess complex. A second solvent that causes minimum swelling is used for reactions, so that the catalyst is effectively 'caged' in the polymer.[145]

4.6 P-donor Macrocyclic Ligands

Phosphorus-containing macrocycles have not proved to be popular ligands owing, in part, to their difficult multistage synthesis. We arbitrarily define phosphorus macrocycles as those with 10 or more ring members, at least one of which is phosphorus. It should be noted that the usual purpose of

using macrocyclic ligands is to encapsulate a metal and that rings with less than 12 members are thought to be too small for this purpose. Meso rings (seven to ten members) may act as multidentate ligands depending on their geometry; for example, Musker and coworkers[146] employed the ligand (**41**) to prepare complexes with platinum(II) in which it acted as a bidentate ligand (Figure 14). Melson's short form of macrocycle nomenclature is used in this article, and two examples, (**42**) and (**43**), are shown to indicate his method.



(**41**)

It is not within the scope of this article to detail the preparative aspects of organophosphorus chemistry (*see* ***Phosphorus: Organophosphorus Chemistry***). We limit ourselves to indicating the two basic routes to phosphorus macrocycles. The first route utilizes the conventional synthetic methods of organometallic chemistry and is illustrated by Ciampolini and coworkers[147–149] here, but others could

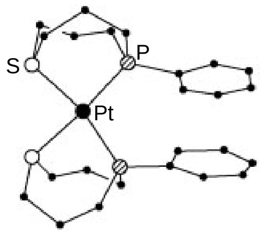


Figure 14 Structure of the *cis*-bis(5-phenyl-1-thia-5-phosphacyclo-octane)platinum(II) dication[146]

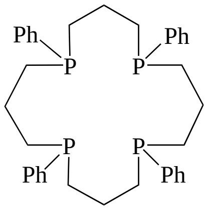
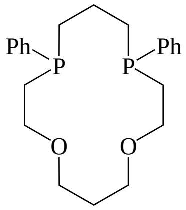


(**42**) [16]aneP_4



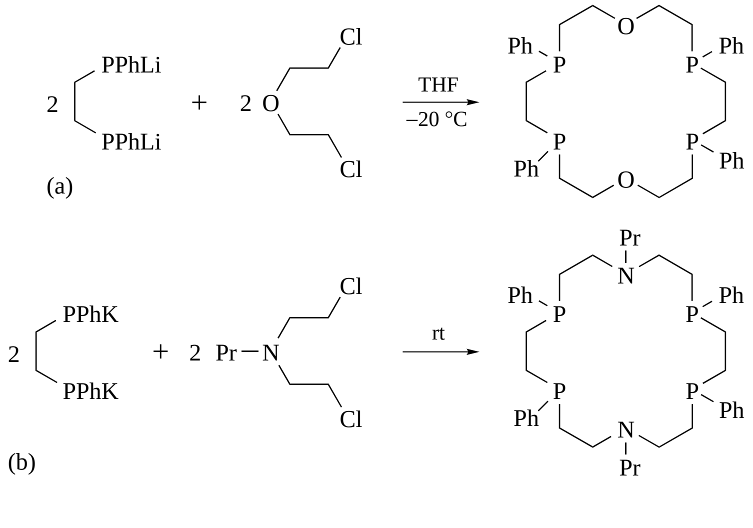
(**43**) [14]aneP_2O_2

have been chosen.[150–153] They reacted two moles of a dilithiophosphide in THF with two moles of bis(chloroethyl) ether in THF at low temperature, which gave a 12% yield of [18]aneP_4O_2 (Scheme 3a). The five diastereoisomers are separable by chromatographic methods. [18]aneP_4S_2 is produced in a similar way using a thioether. The nitrogen analog [18]aneP_4N_2 required the more vigorous potassium reagent (Scheme 3b).

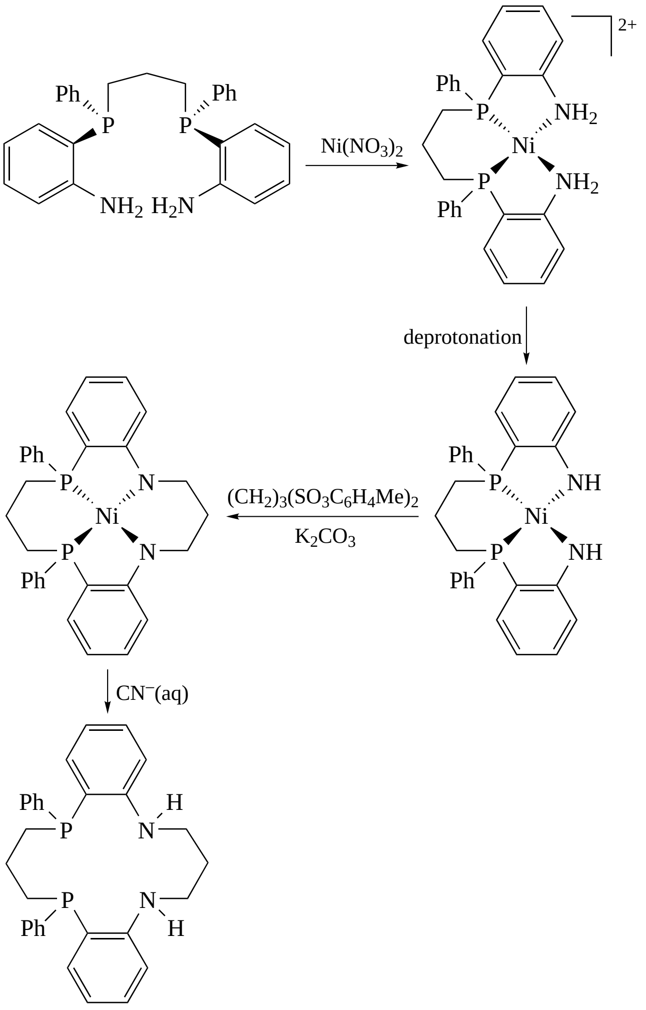
The alternative route to phosphorus macrocycles uses the coordinating properties of phosphine ligands to assemble the macrocycle precursors in favorable conformations using a transition metal as a template. The general principles are illustrated in Scheme 4, developed by Cooper and coworkers.[154] This template synthesis of macrocycles may occur fortuitously; for example, Musker and coworkers[146] fortuitously dimerized their ligand (**41**) to afford the macrocycle [16]aneP_2S_2 (**44**).

4.6.1 *The Macrocyclic Effect*

Quantitative data are sparse for phosphorus macrocycle complex stabilities. However, the broad thermodynamic principles that apply to nitrogen systems should apply to those of phosphorus. The macrocylic effect is the net effect of a number of factors, inter alia changes in entropy, enthalpy, pH, solvent effects, ring size, and conformation, that results

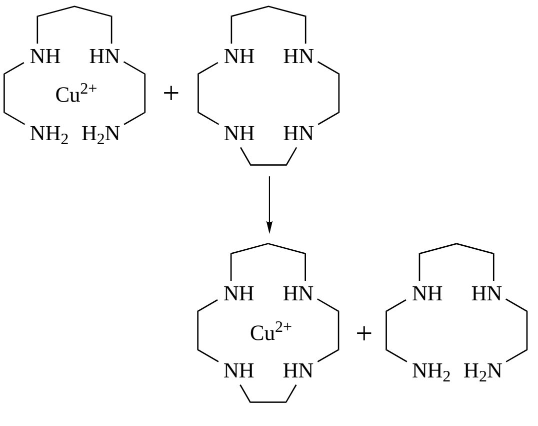


Scheme 3



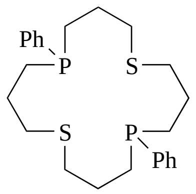
Scheme 4

in enhanced stability vis à vis their noncyclic analogs. The effect was neatly demonstrated in the case of the copper(II) complex in equation (10), where the macrocycle displaced the open-chain analog.[155]



(10)

log $K = 5.2$ at 27 °C

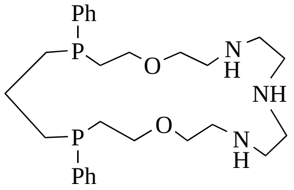


(**44**)

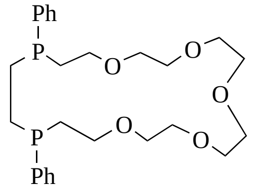
4.6.2 Ring Size Consideration for P-donor Macrocycles

The size of the ligating macrocycle chosen is governed by end use. If a stable mononuclear complex is required, then size is critical if the full macrocycle effect is to be harnessed. Kyba and coworkers[156] found that the [11]aneP_3 ring is too small to encapsulate a transition metal ion, which in this case ‘sits’ on top of the ring. They showed that [14]aneP_4 contained the optimum sized ring for metal binding.

There is interest in macrocycles capable of binding two metals independently with sufficient space between the sites to bind and activate substrate molecules, for example, 22[ane]$P_2O_2N_3$ (**45**) and 21[ane]P_2O_5 (**46**).[157] These ligands were designed to form heteronuclear bimetallic complexes sufficiently flexible to enable the adjacent metal centers to bind small molecule substrates. In terms of texture (hard or soft) these ligands are asymmetric, containing the hard oxygen and the soft phosphorus pockets, thus in principle selecting the sites of the metal. Both nickel and palladium form mono complexes with the soft P-center.[158]



(**45**)



(**46**)

4.6.3 Stereochemistry of Phosphorus Macrocycles and Their Complexes

Phosphorus macrocyclic isomerization is complex but the isomers are relatively stable, the barrier to phosphorus(III) pyramidal inversion being $\approx 30\,\text{kcal mol}^{-1}$, enabling room temperature isolation of the isomers. In the case of 18[ane]P_4O_2 there are five diastereoisomers (Figure 15). These isomers occur in nearly statistical amounts in the reaction mixture or upon thermal equilibration of a pure isomer. These macrocycles are flexible, but the preferred conformation with the metal will vary between the diastereoisomers; for example, the cobalt complexes of ε-18[ane]P_4S_2 (Figure 16)[159] and γ-18[ane]P_4S_2 are quite distinctive, the former being green and the latter orange, one of the sulfur atoms being uncoordinated. Increasing the size of

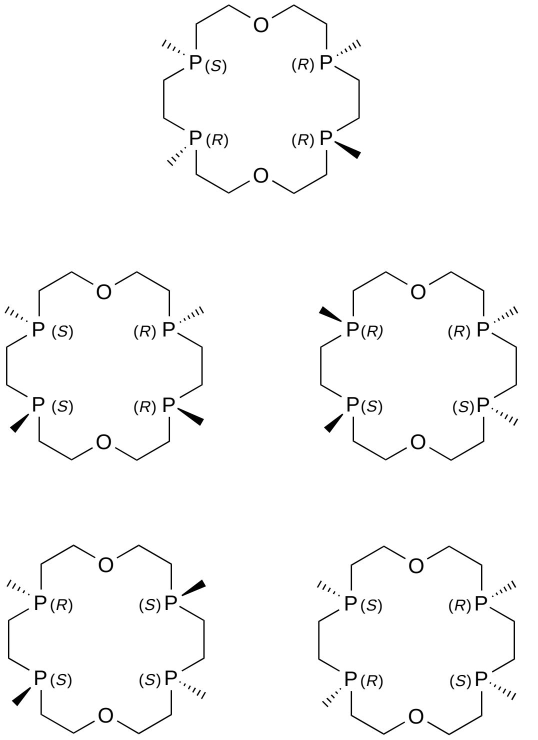


Figure 15 The five diastereoisomers of $18[ane]P_4O_2$

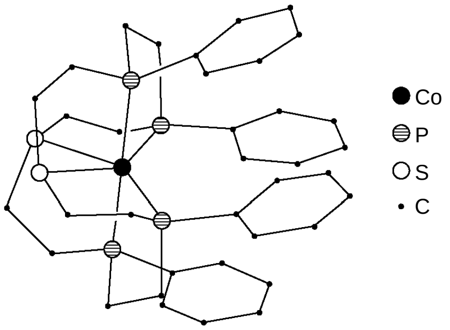

Figure 16 Structure of the complex cation of the green complex $[Co(\varepsilon\text{-}18[ane]P_4S_2)][BF_4]_2$[159]

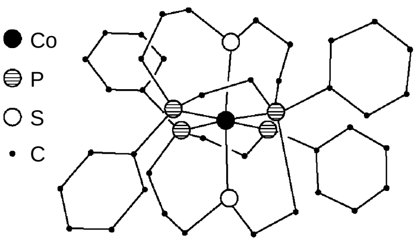

Figure 17 Structure of the low-spin complex cation $[Co(\delta\text{-}22[ane]P_4S_2)][BF_4]_2{\cdot}0.5H_2O$[160]

the ring enables the formation of complexes accommodating longer M–S bonding, for example, the low-spin Co^{II} complex with δ-22[ane]P_4S_2 (Figure 17).[160] Very recently, tripodal ligands of the 1,4,7-triphospha-cyclononane type have also been prepared with metal atoms as a template.[161] A review on related systems is available.[162]

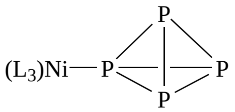
PART II
Other P-donor Ligands

5 ELEMENTAL PHOSPHORUS AS A LIGAND

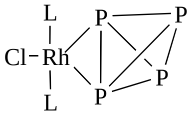
It was first demonstrated in exploratory work by the groups of Dahl,[163] Ginsburg,[164] Sacconi[165] and Huttner[166] that elemental phosphorus can play a role as a ligand for transition metals. These early contributions were followed by extremely successful systematic studies by Scherer and his collaborators, the results of which have been summarized in several review articles.[167–170] The work was also put into perspective referring to the isolobal principle (CH/P)[171] and to cluster theories.[172,173]

As a ligand, elemental phosphorus not only appears in the oligomeric forms present in its polymorphs (like P_4), but as P_n with n covering a large range from $n = 1$ to at least $n = 16$, and as the corresponding cations and anions (the polyphosphides).

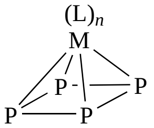
The 'natural' tetrahedral P_4 molecule can function as a monohapto two-electron donor at each of its four vertices, as, for example, in Sacconi's neutral $(L_3)Ni(P_4)$ complexes (**47**),[165] where (L_3) represents a triopodal auxiliary ligand, or as an edge-on dihapto four-electron donor as in Ginsburg's $Cl(L)_2Rh(P_4)$ compounds (**48**).[164] Upon photochemical or thermal cage-opening, P_4 can also be accommodated as a square-planar cyclic unit (**49**) or as a bicyclobutane- or butterfly-type ligand (**50**), respectively.[174,175]



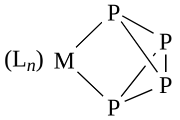
(**47**)



(**48**)



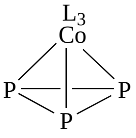
(**49**)



(**50**)

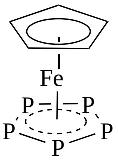
The oligomer P_3 has been trapped in a cobalt complex $(L_3)CoP_3$, in which it caps one face of an octahedron as a

triangular six-electron donor ligand (**51**),[165] and ring-opening of the P_3 triangle can lead to clusters with angular triatomic P-P-P units.[176,177]

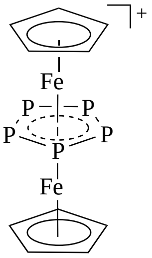


(**51**)

A fascinating analogy between cp^- and P_5^- became apparent by the isolation of the mixed ferrocene cp*Fe(P_5), where cp* represents pentamethylcyclopentadienyl and (P_5) the planar, strictly pentagonal phosphorus unit (**52**). The compound is prepared in the thermolysis of $[cp^*Fe(CO)_2]_2$ in the presence of white phosphorus. The P_5^- unit, which clearly acts as a six-electron donor in this mononuclear complex, can also function as a central unit in a cationic triple-decker cation $[(cp)Fe(P_5)Fe(cp^*)]^+$ (**53**).[178]



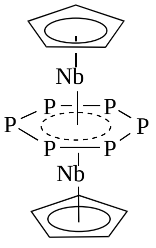
(**52**)

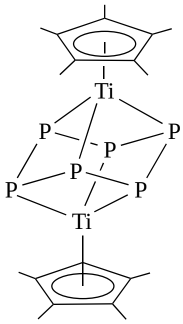


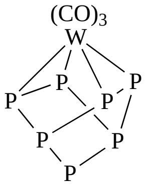
(**53**)

P_6 has been found as a planar middle-deck ligand in dinuclear complexes of niobium, for example, $[(cp^*)Nb(P_6)Nb(cp^*)]$ (**54**),[179] or – in a chair conformation – between titanium atoms in $(cp^*)Ti(P_6)Ti(cp^*)$ (**55**).[166] P_7 is present in $(P_7)[Fe(cp)(CO)_2]_3$ as a bicyclic cage reminiscent of P_4S_3.[180] The P_7 unit can also be introduced, by using K_3P_7 as a reagent, into complex anions of the type $[(P_7)M(CO)_3]^{3-}$ (**56**), in which it has a norbornane structure.[181] For information on larger P_n oligomers as ligands to transition elements and on the rich coordination chemistry of diatomic P_2, the reader is directed to reviews on the subject.[166–169]

Finally, *single phosphorus atoms* have recently been detected as multiply bonded ligands to a variety of transition metals. Triply bonded terminal phosphorus atoms were discovered in complexes of metals in higher oxidation states and with electronegative auxiliary ligands, mainly N-donors. Thus, there are tungsten complexes of the type $(NN_3)W{\equiv}P$ with (NN_3) representing a tripodal eight-electron ligand, or molybdenum complexes of the type $(R_2N)_3Mo{\equiv}P$.[182,183] Substituent-free, two-coordinate phosphorus atoms are found as linear bridges in dinuclear complexes of the type





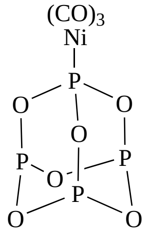


(**54**) (**55**) (**56**)

$(R_2N)_3Mo{=}P{=}Mo(NR_2)_3$.[184] P atoms may also play the role of triply bridging units, as in $(cp_2Zr)_3Cl_2(P)$.[185]

6 PHOSPHORUS OXIDES AND SULFIDES AS P-DONOR LIGANDS

In oxides or sulfides of low-valent phosphorus with their cage-type structures, like P_4O_6 or P_4S_3, the phosphorus atoms have very significant donor character and consequently the molecules can be introduced as ligands into metal complexes. Classical examples are the 1:1 complexes with nickel carbonyls, $(P_4O_6)Ni(CO)_3$ (**57**) or $(P_4O_6)[Ni(CO)_3]_2$, in which one or two P-donor sites are occupied by $Ni(CO)_3$ acceptors.[186]



(**57**)

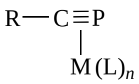
Apart from these traditional examples, the two-atomic unit PO has recently been detected as a P-bound ligand in metal complexes. Because of the direct analogy with NO, these results are of great current interest. PO can appear as a simple terminal ligand as in $(R_2N)_3Mo(PO)$,[182,183] or as triply bridging group as in $(cp'Co)_3(PO)_2$ or $(cp'Ni)_2[W(CO)_4](PO)_2$.[166,187] Analogous complexes with diatomic PS are also known.[166]

7 PHOSPHAALKYNES RC≡P AS LIGANDS

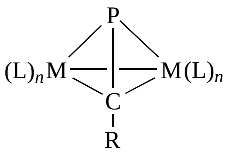
Phosphaalkynes RC≡P have become popular reagents and ligands ever since a few simple, stable compounds

of this type have become readily available.[188,189] The molecules can behave as terminal monohapto (**58**), side-on dihapto (**59**) or side-on bridging ligands in mono- and dinuclear complexes, respectively. The terminal coordination is still rare, as in the type $(PP)_2Mo(P{\equiv}CR)_2$, where (PP) is a chelating ditertiary phosphine.[190] Side-on coordination has been observed in prototypes like $(R_3P)_2Pt(RC{\equiv}P)$[31] or $(cp)_2(Me_3P)Mo(RC{\equiv}P)$.[189] Bridging RCP units can be placed between two cobalt atoms in compounds $(CO)_3Co(RC{\equiv}P)Co(CO)_3$ with a tetrahedral core structure reminiscent of the analogous alkyne complexes (**60**).[191] In these complexes the P-atom can again function as a donor center.[189]

(**58**)

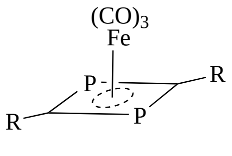


(**59**)

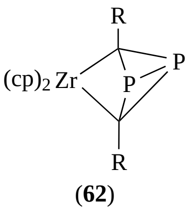


(**60**)

Phosphaalkyne molecules RC≡P can undergo oxidative coupling to form 1,3-diphospha-cyclobutadienes as new ligands in the coordination sphere of a metal. Numerous examples of this reaction have been reported leading to simple products like $(CO)_3Fe(C_2P_2R_2)$ (**61**).[192a] A different type of $(RCP)_2$ dimer is formed under reducing conditions, as in $(cp)_2Zr(C_2P_2R_2)$ (**62**). This ligand can be considered a 1,3-diphospha-cyclobutane-2,4-diyl unit with a folded structure as compared to the planar structure in the previous examples.[192b] Cocyclization of phosphaalkynes with alkynes to give four-membered ring ligands has also been observed.[189] More often than not, the metal atom may be incorporated into the phosphacycle to give a metalla-phospha-heterocyclic core unit.[189]

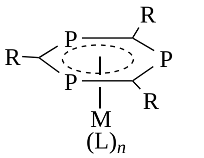


(**61**)

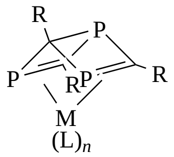


(**62**)

Cyclotrimerization has been achieved with a variety of metals. The products may contain the trimer as a flat 1,3,5-triphospha-benzene unit (**63**), or as a folded Dewar-benzene type ligand (**64**).[189] Recently, the pentamerization of a phosphaalkyne has also been reported.[193]



(**63**)

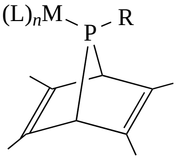


(**64**)

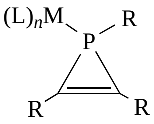
8 PHOSPHINIDENES RP AND DIPHOSPHENES RP=PR AS P-DONOR LIGANDS

Phosphinidenes RP (with a sextet of electrons at the P-atom) are isolobal with carbenes R_2C, and their dimers $(RP)_2$, with a P=P double bond, are the counterparts of the carbene dimers, the olefins $R_2C{=}CR_2$. The coordination chemistry of the two phosphorus species is far less developed, but the number of stable complexes is growing rapidly, as summarized in review articles.[194,195]

Phosphinidenes have been introduced into metal complexes as terminal and bridging ligands, M–PR and M–P(R)–M, respectively. Early examples are compounds of the terminal type $(cp)_2Mo{=}PR$ with R representing a bulky substituent like $CH(SiMe_3)_2$ or 2,4,6-$(^t Bu)_3C_6H_2$.[196] $RP{=}ML_n$ fragments, where L_n are auxiliary ligands, are generally produced as reactive intermediates by elimination from 7-phospha-norbornadiene (**65**) or phospha-cyclopropane and -propene complexes. Conversely, phosphinidenes can be trapped by alkenes and alkynes to give phospha-cyclopropanes and -propenes (**66**), respectively.[194]

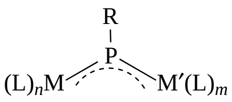


(**65**)

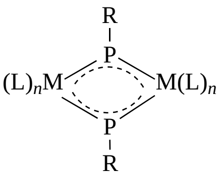


(**66**)

Dinuclear complexes with bridging phosphinidenes (**67**) can be prepared via various routes including, for example, the metallation of coordinated phosphine $M–PH_3$, primary phosphines $M–PRH_2$ or halophosphines $M–PRX_2$, and so on. Alternatively, alkali metal carbonylates can be reacted with organohalophosphines.[197] Two phosphinidenes may bridge two metal complex fragments to give four-membered ring arrays (**68**).[198]



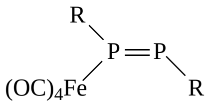
(**67**)



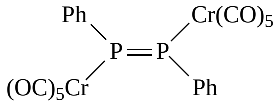
(**68**)

Phosphinidenes were finally found as units capping metal triangles and squares. The compounds were obtained upon thermolysis of dinuclear precursors.[197]

Diphosphenes R–P=P–R appear as P-donors in simple 1:1 and 1:2 complexes, an example for the former being the type R–P=P[$Fe(CO)_4$]R (**69**) with the substituents R = 2,4,6-(^{t}Bu)$_3C_6H_2$ in the trans (E) position. These complexes can be prepared using the free ligands as precursors, or by assembling the diphosphene in the coordination sphere of the metal atom(s), as demonstrated for *trans*-Ph[$(CO)_5Cr$]P=P[$Cr(CO)_5$]Ph (**70**). The diphosphene may finally also act as a π-donor via its P=P bond to give trinuclear complexes: (PhP=PPh)[$Cr(CO)_5$]$_3$. With $Cr(CO)_3$ groups, η^6-coordination to the arene rings has also been observed. A unique case demonstrating the diphosphene-alkene analogy is the tetrahedral cluster complex (^{t}Bu)$_2P_2Fe_2(CO)_6$ obtained from ^{t}BuPH$_2$ and $Fe(CO)_5$ in a multistep synthesis.[199]



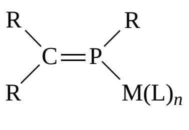
(**69**)



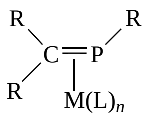
(**70**)

9 PHOSPHAALKENES $R_2C{=}PR'$ AS P-DONOR LIGANDS

Phosphaalkenes of the general formula $R_2C{=}PR'$ can function as P-bound monohapto and/or P=C-bound dihapto-ligands to metals.[200] The two modes (**71a,b**) are not always easily distinguished and the complexes may be fluxional in solution depending on the nature of the substituents and the solvent. This phenomenon was carefully investigated for the 1:1 complex ($Ph_2C{=}PMes$)Pt(PPh_3)$_2$ (Mes = mesityl).[201a] The dinuclear complex ($RP{=}CH_2$)[$Fe(CO)_4$]$_2$ is an example for a combination of both modes of coordination [R = 2,4,6-(^{t}Bu)$_3C_6H_2$].[202]

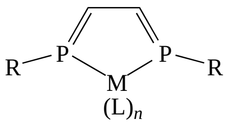


(**71a**)



(**71b**)

Two independent phosphaalkenes can be coordinated in the dihapto-mode to the same metal center, as exemplified by [$(Me_3Si)_2C{=}PCl$]$_2$Ni(CO).[200] Similarly, α, ω-difunctional phosphaalkenes can form chelate complexes (**72**).[201b] From vinylphosphines, phospha-allyl metal complexes can be generated, but this mode of coordination is not yet very common. By contrast, with phosphinyl groups attached to the carbon atom of the phosphaalkene unit, neutral or cationic 1,3-diphospha-allyl ligands can be generated that were shown to appear in a large variety of stable complexes. The situation is similar for 1,4-diphospha-butadienes, for which a selection of open-chain and chelated metal complexes have been reported.[203]



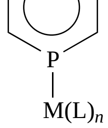
(**72**)

Transition metals complexes in which the metal atom is one of the substituents of the P-atom of a phosphaalkene, $L_nM{-}P{=}CR_2$, have been described. This chemistry was extended to dinuclear species of the types $(L_nM)_2P{=}CR_2$ and $R_2C{=}P[ML_n]_2P{=}CR_2$.[204]

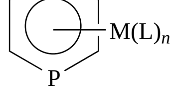
10 PHOSPHININES (PHOSPHA-BENZENES) AS LIGANDS TO METALS

Phosphinines are a special group of phosphaalkenes in which the P=C double bond becomes integrated into the aromatic system of benzene and related arenes. The majority of examples are based on the mono-phospha-benzenes, but di- and triphospha-benzenes in various substitution patterns have also been employed as ligands. The coordination chemistry of this class of ligands has been reviewed.[205]

Phosphinines can act mainly as monohapto two-electron σ-donors through the phosphorus atom(s) or as polyhapto six-electron π-donors with metal atoms centered above the ring system (**73a,b**). The σ-mode has been observed, for example, with units $Cr(CO)_5$, $Ni(PR_3)_2$, $Ni(C_2H_4)(PR_3)$, Mn(cp)$(CO)_2$, AuCl, and others. π-Complexation is achieved in most cases only after P-σ-complexation, as in (L′)[σ-$Cr(CO)_5$][π-$Cr(CO)_3$] with L′ = 4-Hex-C_5H_4P. A di(benzene)chromium analog was obtained with two molecules of 2,4,6-tri(^{t}butyl)phosphinine,[205] while a mixed complex (cp)Mn(L″) could be obtained for a phosphinine L″ with a different set of substituents.[206]



(**73a**)

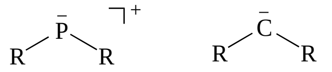


(**73b**)

There is also a rich and rapidly growing coordination chemistry of various other phosphorus heterocycles. The early work has been reviewed.[207,208]

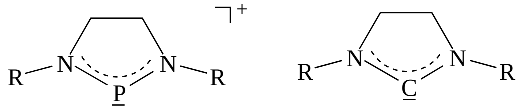
11 PHOSPHENIUM CATIONS AS P-BOUND LIGANDS

Phosphenium cations of the general formula $[R–P–R]^+$ with an electron-sextet at the phosphorus atom can formally be generated by heterolytic cleavage of the P–X bond in precursor compounds R_2PX, and in many cases the synthesis follows this route.[209] The $[R_2P]^+$ species are analogs of the neutral carbenes $[R_2C]$ and hence of great current interest (**74a,b**).



(**74a**) (**74b**)

Because of the high electron deficit at the two-coordinate phosphorus atom, phosphenium cations are only stable with electron-donating substituents R, predominantly with nitrogen donor atoms. This is an obvious parallel to the situation with 'stable carbenes' of the Wanzlick-Arduengo type. Therefore most complexes in this series are derived from diazaphospholes (**75a,b**).[209]



(**75a**) (**75b**)

A selection of typical examples includes the cations obtained from $Fe(CO)_5$ and the *N*,*N*′-dimethyl-diaza-phospholenium cation, $\{[(CH_2NMe)_2P]Fe(CO)_4\}^+$ (**76**),[210] for which open-chain analogs are also known: $\{[(Me_2N)_2P]Fe(CO)_4\}^+$.[211] Related cationic complexes with the acceptor units $(CO)_3Ni$, $(bipy)(CO)_3Mo$, or $[(MeO)_3P]_5Mo$ are also known. Neutral complexes can have the formulae $[(CH_2NBz)_2P]Mo(cp)(CO)_2$ or $[(Mes)_2P]W(cp)(CO)_2$.[209]

1 INTRODUCTION

Palladium was discovered in 1803 by Wollaston in the course of his studies on the refining of platinum. It was named after a newly discovered asteroid, Pallas, which bears the name of the Greek goddess of wisdom. Pd occurs associated with other platinum group metals and the extraction processes depend on the particular ore used. It is the second most abundant platinum group metal and its major sources are located in South Africa and Russia. Supplies of palladium in 2002 reached 5.25 million oz and sales amounted to 4.78 million oz, at an average price of $222 per ounce. The highest demand for palladium comes from the manufacturing of exhaust autocatalysts in the automobile industry, which uses a mixture of platinum group metals to effect the oxidation of hydrocarbons and CO (to CO_2) and the reduction of nitrogen oxides (to N_2). The relative demand of Pt, Pd, and Rh for this purpose is strongly affected by price and market considerations. In 2002, a total of 3.08 million oz of newly supplied Pd (56.70% of the total new demand) plus 0.37 million oz of exhaust recovered Pd were used in this manufacture. Dental palladium alloys accounted for a further 15.69%. The electronics industry represented 14.85% of the 2002 demand of Pd, used in the form of silver-palladium or pure palladium pastes for printing conductive tracks and in the production of multilayer ceramic capacitors. The rest of the supply satisfied the demand for jewelry alloys (7.43%) and the manufacture of industrial catalysts (5.33%).[1] Pd compounds are catalysts for the production of vinyl acetate monomer (VAM), and for purified terephthalic acid (PTA), while palladium catchment gauze is used in the manufacture of nitric acid.

Six naturally occurring isotopes have been found for palladium: ^{102}Pd (1.02%), ^{104}Pd (11.14%), ^{105}Pd (22.33%), ^{106}Pd (27.33%), ^{108}Pd (26.46%), and ^{110}Pd (11.72%).[2] Their nuclear properties ($I = 5/2$ for ^{105}Pd; $I = 0$ for the other isotopes) preclude the use of NMR as an observation technique for Pd. The only ^{105}Pd resonance recorded in $K_2[PdCl_6]$ has a bandwidth at half height of 25 000 Hz.

Palladium belongs to group 10 and has the ground-state electronic configuration: [Kr] $4d^{10}$. Pd chemistry bears similarity to that of Pt, its 3rd row congener, but the former is generally more reactive. Although the chemistry of palladium is dominated by the oxidation state +2 (the most stable for the element), it has also a well-established chemistry in oxidation states 0, +1, and +4. Examples of Pd(III) compounds are also known. An unstable Pd(V) complex, $[PdF_6]^-$, and a Pd(VI) compound, PdF_6,[3] have been reported but they have not been confirmed by other research groups. This reluctance to reach high oxidation states follows the observed trend in late transition metals, due to the increased stability of their d valence orbitals. The inorganic and coordination chemistry of palladium has been reviewed in several comprehensive works.[4–9]

Palladium exhibits a rich organometallic chemistry widely applied to organic syntheses, which is covered in other chapters in this encyclopedia (*see* ***Palladium: Organometallic Chemistry***; ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***; ***Oligomerization & Polymerization by Homogeneous Catalysis***; and ***Organic Synthesis Using Metal-mediated Coupling Reactions***).

2 GENERAL PROPERTIES OF THE METAL

Palladium metal is silvery-white, ductile, and malleable, crystallizing in the fcc structure (*see* ***Structure & Property Maps for Inorganic Solids***). The metal can be made into finely divided forms (including nanoparticles) that are catalytically

Table 1 Some properties of palladium

Property	Value
Abundance (earth's crust/ppm)	c. 6×10^{-4}
Electron affinity ($M \rightarrow M^-$/kJ mol^{-1})	53.7
Ionization energies (kJ mol^{-1})	
$M \rightarrow M^+$	805
$M^+ \rightarrow M^{2+}$	1875
$M^{2+} \rightarrow M^{3+}$	3177
Radii (pm)	
Metallic	137.6
Pd^{II} (six-coordinated)	86
Pd^{IV} (six-coordinated)	64
Electronegativity (Pauling)	2.2
Melting point (K)	1825
Boiling point (K)	3413
ΔH_{fusion} (kJ mol^{-1})	17.2
$\Delta H_{vaporization}$ (kJ mol^{-1})	393.3
Density (kg m^{-3})	12 020 (293 K)
Thermal conductivity (W m^{-1} K^{-1})	71.8 (300 K)
Electrical resistivity (Ωm)	10.8×10^{-8} (293 K)
Coefficient of linear thermal expansion (K^{-1})	11.2×10^{-6}

very active. Palladium on carbon is a widely used catalyst that contains dispersed Pd (Pd(0) but also Pd(II)) and variable amounts of water. Table 1 shows some properties of the element.

Perhaps, the most remarkable property of metallic palladium is its ability to absorb hydrogen, greater than for any other metal (up to 900 times its own volume). The absorption is reversible and highly selective for H_2 and D_2. The amount of gas absorbed decreases with temperature for a given pressure. This property provides a method to purify H_2 (used in the industrial production of this gas) just by passing the impure H_2 through a Pd membrane at a controlled temperature. As palladium absorbs H_2, its metallic conductivity falls and the material becomes a semiconductor for a composition close to $PdH_{0.5}$ (*see* ***Semiconductors***). However, its ductility is not lost until large quantities of H_2 have been absorbed. It seems that H_2 is first chemisorbed on the surface of the metal, but as the gas pressure increases, hydrogen enters the metallic lattice, forming a 'hydrogen dilute' or α-phase. As H_2 is added further, a hydride phase, called α' or β-phase, is formed. Inelastic neutron-scattering and vibrational techniques have been applied to the study of these phases and have shown that hydrogen atoms occupy octahedral holes in the metallic structure. A variety of Pd-rich alloys also absorb H_2. The most interesting one, Pd–Ag (20%), is utilized in the manufacture of industrial membranes as it does not undergo the volume expansion observed for pure Pd when forming the β-phase.[10]

Palladium is a noble metal, difficult to oxidize because of a combination of high sublimation energy and high ionization potential, although it is more reactive than the other platinum group metals. It is oxidized by O_2, F_2, and Cl_2 at red heat. It dissolves slowly in oxidizing acids (HNO_3 or H_2SO_4), and readily in aqua regia. Pd is also attacked by molten alkali metal oxides or peroxides.

3 SIMPLE COMPOUNDS

3.1 Hydrogen and Hydrides

In addition to the interaction between bulk palladium and hydrogen discussed in Section 2, spectroscopic studies have proved that Pd atoms react with H_2 on codeposition with H_2-doped Ar, Kr, and Xe matrices at very low temperatures. The ligand-free side-on bonded Pd(η^2-H_2) molecular–dihydrogen complex is found in Xe and Kr at 12 K, and in Ar at 9 K.[11] Some IR bands that had been assigned to the end-on bonded Pd(η^1-H_2) complex, were finally recognized to arise from $Pd(H_2)_n$ ($n = 2$, 3). The stable $(PdH)_2$ reaction product containing dissociated dihydrogen and Pd–Pd(H_2) were also detected.[11] Theoretical calculations have shown that the interaction between single Pd atoms and H_2 does not catalyze the cleavage of the H–H bond, but Pd_2 fragments (modeling a hydrogen-adsorbed palladium surface) do (*see* ***Hydride Complexes of the Transition Metals***).[12]

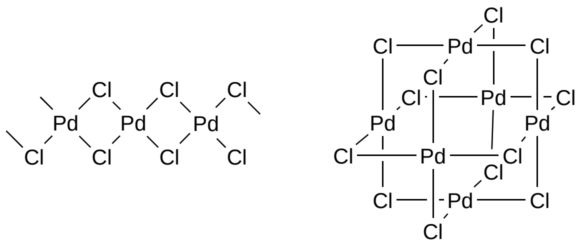
Complex hydrides of palladium have been synthesized with formally zerovalent Pd. Linear, trigonal planar, and tetrahedral 'PdH_n' units can be found in M_2PdH_2 (M = Li, Na), $NaBaPdH_3$, and M_2PdH_4 (M = Sr, Ba, Eu) respectively.[13,14] A square planar hydrido complex of Pd(II), Na_2PdH_4, has been prepared using extremely high H_2 pressure (1800 bar).[15]

3.2 Halides

Only fluorine, the most oxidizing halogen, gives binary combinations with Pd in oxidation states higher than II. The brick-red Pd(IV) fluoride, PdF_4, is formed by fluorination of 'palladium trifluoride' under strong reaction conditions (7 atm F_2, 150 °C) and is violently hydrolyzed by water. It is diamagnetic and its structure consists of edge-sharing $[PdF_6]$ octahedra.

A trifluoride of empirical formula 'PdF_3' is known. It is not a Pd(III) compound as the composition might suggest, but a mixed oxidation state derivative better represented as $Pd^{II}Pd^{IV}F_6$. It can be synthesized by treating $PdBr_2$ with BrF_3. This gives the adduct $Pd_2F_6{\cdot}2BrF_3$, which loses BrF_3 at 180 °C to yield $Pd^{II}Pd^{IV}F_6$. It is also hydrolyzed in water and its paramagnetism is due to the octahedral environment of Pd(II) (d^8), not due to the presence of Pd(III) (d^7) (*see* ***Magnetism of Transition Metal Ions***).

All divalent palladium halides are known. PdF_2, also easily hydrolyzable, is synthesized by refluxing $Pd^{II}Pd^{IV}F_6$ with SeF_4. It has a rutile type structure and Pd is six-coordinated, a situation very unusual for Pd(II). The compound shows the expected paramagnetism ($\mu = 1.90$ B.M.) for a ${t_{2g}}^6{e_g}^2$



α-$PdCl_2$ β-$PdCl_2$

Figure 1 The two structures of $PdCl_2$

configuration. $PdCl_2$ is obtained by direct synthesis from the elements or by heating $H_2[PdCl_4]\cdot nH_2O$. At about 600 °C, $PdCl_2$ sublimes and then dissociates into its elements. Two different structures (Figure 1) have been found: (1) α-$PdCl_2$, red crystals containing infinite flat chains of four-coordinated square- planar Pd atoms sharing Cl atoms; and (2) β-$PdCl_2$, which consists of Pd_6Cl_{12} cubes in which the central points of the faces and edges are occupied by the Pd atoms and by the Cl atoms, respectively.[16] When synthesized by dry methods, $PdCl_2$ is insoluble in water, but the hydrate $PdCl_2\cdot 2H_2O$ can be obtained from an aqueous solution as dark red hygroscopic crystals. $PdCl_2$ is one of the most useful starting materials in the chemistry of Pd(II). It is also easily reduced to the metal by H_2 at room temperature, or by ethyl alcohol and ethylene in warm solutions. $PdBr_2$ is obtained by direct reaction with its elements. An alternative route (similar to the synthesis of $PdCl_2$) is the treatment of the metal with a mixture of HNO_3 and HBr to form $H_2[PdBr_4]\cdot nH_2O$, which on heating loses HBr to give $PdBr_2$. The water insoluble PdI_2 is easily accessible by addition of KI to a solution of $K_2[PdCl_4]$.

3.3 Chalcogenides

There is only one stable oxide of palladium, PdO. The black, anhydrous palladium(II) oxide is insoluble in acids and can be obtained by heating the metal in oxygen below 875 °C (it dissociates above this temperature). The hydrated oxide $PdO\cdot nH_2O$ can be obtained by addition of alkali to an aqueous solution of $Pd(NO_3)_2$. It is a yellowish-brown precipitate, soluble in acids, that cannot be completely dehydrated without loss of oxygen. A Pd(IV) oxide, $PdO_2\cdot nH_2O$, is said to precipitate when alkali is added to a solution of $K_2[PdCl_6]$. It is a dark red solid, strongly oxidizing, which evolves O_2 slowly at room temperature. At 200 °C, it decomposes to give PdO. Anhydrous PdO_2 has been obtained from PdO and $KClO_3$ at high temperature and pressure, and it also loses O_2 readily. A rich structural chemistry of mixed-metal oxides, such as $M^I{}_2PdO_3$, $M^{II}{}_2PdO_3$, or $M^{II}{}_4PdO_6$, has been reported.

Palladium(II) sulfide is readily formed as a brown precipitate by bubbling H_2S through a solution of $[PdCl_4]^{2-}$, or as a greyish-black crystalline powder if palladium and sulfur are heated together. In this compound, Pd is coordinated to four sulfur atoms in a slightly distorted square-planar arrangement. PdSe and PdTe are also known and can be synthesized following analogous procedures. The disulfide PdS_2, diselenide $PdSe_2$, and ditelluride $PdTe_2$, have also been prepared. They do not contain Pd(IV), as the formulas seem to indicate, but Pd(II) and $S_2{}^{2-}$, $Se_2{}^{2-}$, or $Te_2{}^{2-}$ groups, respectively.

3.4 Compounds with Other Nonmetals

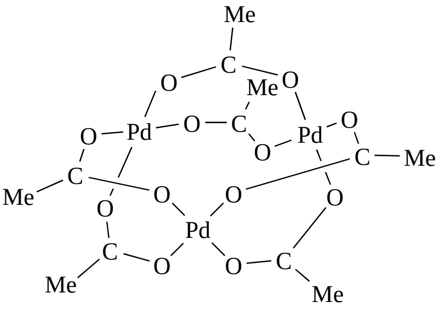
The reactions of palladium with nonmetals such as boron, silicon, phosphorus, arsenic, and antimony have been investigated. The systems are complex and nonstoichiometry is frequent although some complexes of definite, stoichiometric composition have been reported.

3.5 Other Simple Compounds

A few palladium compounds with simple anions, some of them useful as starting materials, are discussed in this section.

3.5.1 Palladium Acetate

Palladium(II) acetate is usually prepared by the reaction of Pd sponge in hot glacial acetic acid with nitric acid as oxidant. A slight excess of Pd sponge must be used to make sure that all the HNO_3 is consumed. Several other palladium(II) carboxylates can be obtained similarly. The crystal-structure determination of the acetate reveals a trimeric structure with bridging acetates in the solid state (**1**).[17] Thus, the compound is better formulated as $[Pd(\mu\text{-}O_2CMe)_2]_3$.



(**1**)

3.5.2 Palladium Acetylacetonate

$Pd(acac)_2$ can be made from acetylacetone and tetrachloropalladate salts or palladium acetate. It has a monomeric structure with a square-planar coordination of palladium to the four oxygens of two chelating acetylacetonates.

3.5.3 Palladium Nitrate

Nitrates are known for Pd(II) and Pd(IV). A hydrated Pd(II) nitrate can be prepared by dissolving the metal in nitric acid followed by crystallization. The composition of the brown crystals obtained is $Pd(NO_3)_2(H_2O)_2$ and IR studies indicate monodentate coordination for the nitrato groups. The anhydrous nitrate, $Pd(NO_3)_2$, contains bridging nitrato groups and can be prepared by reaction of $Pd(NO_3)_2(H_2O)_2$ and liquid N_2O_5 at room temperature. If the hydrated nitrate reacts with N_2O_4, the palladium(IV) nitrate $Pd(NO_3)_4$ is obtained.

4 COMPLEXES OF PALLADIUM(0)

4.1 Introduction

Palladium(0) (d^{10}) forms [PdL_n] complexes with phosphines, arsines, phosphites, cyanide, isocyanides, and olefins. The reduction of $K_2[Pd(CN)_4]$ with potassium in liquid ammonia affords the stable palladium(0) cyanide $K_4[Pd(CN)_4]$. However, the isoelectronic palladium $[Pd(CO)_4]$ is not stable in spite of the excellent π-acceptor properties of the CO ligand. Since CN^- is a good σ-donor (in addition to π-acceptor), and CO is a very bad σ-donor, the presence of some σ-donation, in addition to π-acception, helps stabilize Pd(0). For instance, CO can stabilize Pd(0) in mixed complexes with σ-donor coligands, that is, $[Pd(CO)(PPh_3)_3]$. The high ionization energies of Pd and Pt (805 and 870 kJ mol^{-1} respectively) suggest that, in the absence of significant σ donation, the metal would be reluctant to π-back-donate to the acceptor ligand. Pure σ-donors such as amines or σ-, π-donors like halides can also stabilize Pd(0) if combined with π-acid ligands (olefins or phosphines).[18]

4.2 Synthesis

A common synthetic procedure is the reduction of a Pd(II) compound or complex in the presence of an excess ligand. [PdL_n] complexes have been prepared for a large number of phosphines (mono and bidentate), phosphites, arsines, and stibines by procedures similar to those shown for the synthesis of $[Pd(PPh_3)_4]$ in Scheme 1.

The coordination number of palladium depends on L, very bulky phosphines (e.g. P^tBu_3, $P(C_6H_{11})_3$, P^tBu_2Ph, P^tBu_2Me, $P(o\text{-Tol})_3$) favoring the species [PdL_2] (linear or bent). These apparently 14-electron species show additional interactions in the solid state (C–H *Agostic Bonding* or Pd–C_{ipso}(aryl) contacts). Structurally characterized [PdL_3] species (16-electron, trigonal planar) are well known. The tetrahedral [PdL_4] complexes (18-electron) show a tendency to dissociate ligands in solution to give coordinatively unsaturated species [PdL_3] and, in a very small extent, [PdL_2]. ^{31}P NMR studies have shown that the displacement of the equilibria represented in equations (1) and (2) depends on the size and basicity of the phosphine. Generally, not all three species are observed for a given phosphine.[19]

$$[PdL_4] \rightleftharpoons [PdL_3] + L \qquad (1)$$

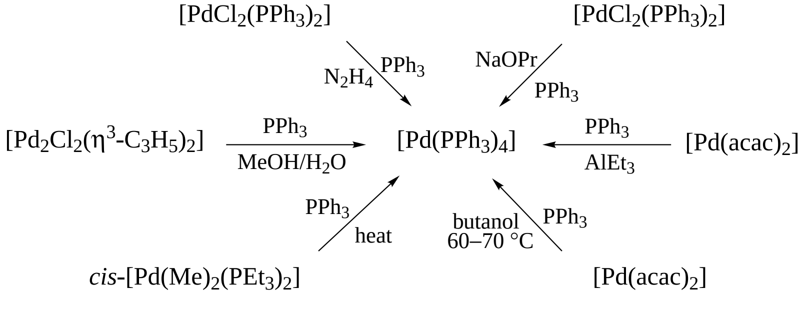
$$[PdL_3] \rightleftharpoons [PdL_2] + L \qquad (2)$$

Most Pd(0) compounds are easily oxidized in the air, but the complexes $[Pd(dba)_2]$ (better formulated as $[Pd_2(dba)_3]\cdot dba$) or $[Pd_2(dba)_3]$ (**2**, dba = dibenzylideneacetone) are stable and easy to store. Moreover, they are excellent precursors to generate $[Pd(dba)L_2]$ and [PdL_2] complexes in solution (L_2 = bidentate phosphines or two monodentate phosphines).

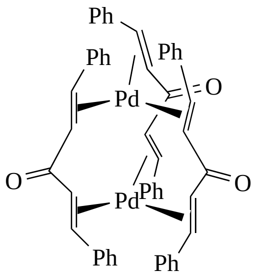
$[Pd_2(\mu\text{-dppm})_3]$ is a useful starting material for Pd-dppm derivatives in other oxidation states. Its luminescent properties have been studied and the distance between Pd atoms has been estimated to be 304.3 pm from spectroscopic studies. This suggests a weak metal–metal interaction.[20]

[PdL_2(olefin)] complexes (L_2 = diphosphine, 2 monophosphines) are very common. The complex $[Pd(PPh_3)_2(\eta^2\text{-}C_{60})]$ (**3**) is formed by reaction of C_{60} with [Pd $(PPh_3)_4$].[21]

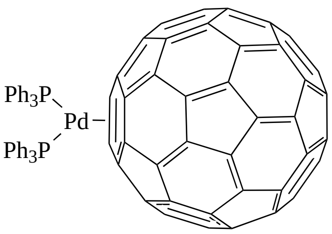
Isocyanide complexes $[Pd(CNR)_2]_n$ are prepared by reduction of a Pd(II) isocyanide complex with RNC in the presence of a strong alkali (equation 3), or by treating $[Pd(\pi\text{-}C_5H_5)(\pi\text{-}C_3H_5)]$ with RNC. Their structure is unknown but that of the corresponding Pt complexes is a triangular



Scheme 1



(**2**)



(**3**)

arrangement of three platinum atoms $[Pt(\mu\text{-}CNR)(CNR)]_3$.

$$[PdI_2(CNR)_2] + 2KOH + 3RNC \longrightarrow [Pd(CNR)_2]_n + RNCO + H_2O + 2KI + 2RNC \quad (3)$$

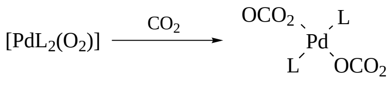
In addition, other forms of Pd(0) stabilized in less conventional ways should be cited. Catalytically active palladium colloids are obtained by reduction of palladium acetate in DMSO,[22] or in the presence of a number of polymers.[23,24] Some of the latter are easy to recycle and avoid the leaching of Pd during the catalytic runs.

4.3 Reactions

Palladium(0) complexes are prone to undergo ligand dissociation as it has already been noted. The lability of the ligands in $[PdL_n]$ complexes can be used in the synthesis of mixed ligand complexes (equation 4).

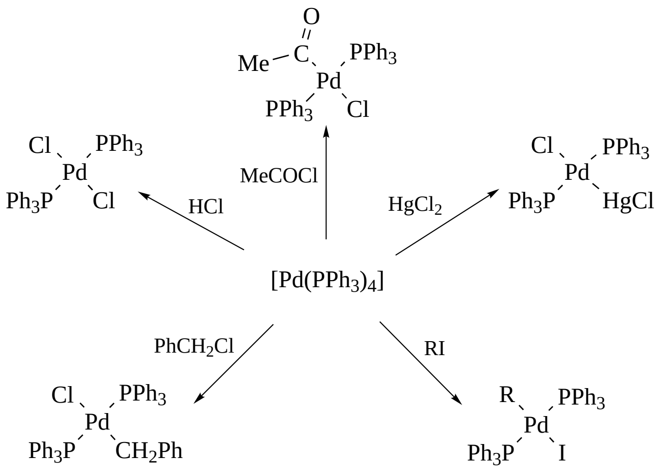
$$[Pd(PPh_3)_4] + 2SbPh_3 \longrightarrow [Pd(PPh_3)_2(SbPh_3)_2] + 2PPh_3 \quad (4)$$

$[PdL_2L']$ adducts are formed by reaction of $[PdL_4]$ with small molecules such as NO, SO_2, CS_2, or O_2. $[PdL_2(O_2)]$ species have shown to be active oxidizing agents reacting with CO_2, SO_2, NO_2, or NO to yield carbonato, sulfato, nitrato, and nitrito complexes respectively (equation 5).[25]



(5)

Oxidative Addition reactions that give palladium(II) complexes (Scheme 2) are also facile processes that occur on the



Scheme 2

coordinatively unsaturated species $[PdL_n]$ with a variety of substrates (halogens, HCl, alkyl, and aryl halides, etc.) and are involved in catalytic processes where a Pd(0) complex is added as the catalyst or is formed in the course of the reaction (*see* ***Palladium: Organometallic Chemistry***; ***Asymmetric Synthesis by Homogeneous Catalysis***; ***Carbonylation Processes by Homogeneous Catalysis***; ***Organic Synthesis Using Metal-mediated Coupling Reactions***; ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***). Some of the formally dicoordinated $[PdL_2]$ complexes with bulky ligands such as electron-rich phosphines, either isolated or formed as intermediates in Pd-catalyzed reactions, undergo easy oxidative addition reactions by RX reagents that do not work on conventional $[PdL_4]$ complexes. The application of these ligands has revolutionized the use of catalytic C–C coupling reactions with less reactive organic electrophiles such as aryl tosylates and chlorides.[26,27] Reactions with main group halides or organometallics such as $Cd(GePh_3)_2$ or $Ph_3PbPbPh_3$ give palladium(II) complexes containing Pd–M bonds.

5 COMPLEXES OF PALLADIUM(I) AND OTHER SMALL CLUSTERS

5.1 Introduction

All characterized Pd(I) compounds have Pd–Pd or Pd–M bonds. Accordingly, the paramagnetic behavior anticipated for a d^9 configuration is not found in these multinuclear diamagnetic complexes as the expected unpaired electron is in fact involved in the formation of a metal−metal bond. There are some palladium clusters in formal oxidation states ranging from 0 to +1 (metal−metal bonds do not count in the assignment of oxidation states) that will be considered here.

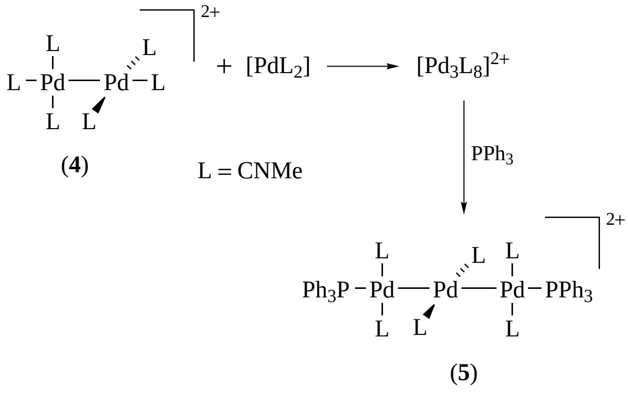
Their number, however, is small compared to the rich cluster chemistry found for other transition metals, possibly because of the lower stability of palladium carbonyls. High nuclearity clusters are dealt with in another article (*see* ***Polynuclear Organometallic Cluster Complexes***).

5.2 Complexes with Unsupported Palladium–Metal Bonds

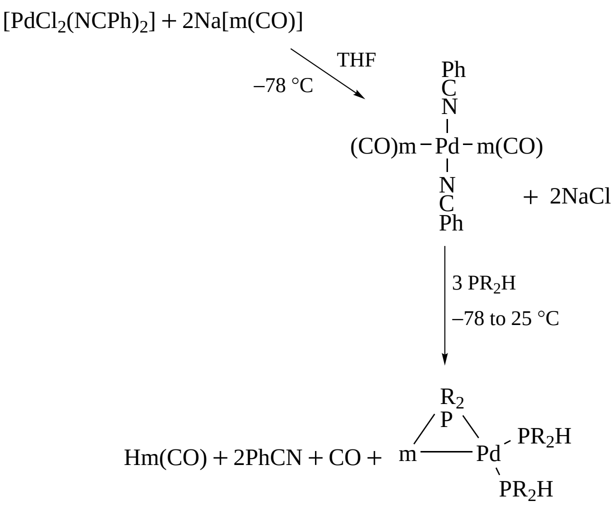
Most of the compounds with palladium–metal bonds are complexes with both metal atoms held together by small bite bridging ligands. Exceptions are the isocyanide derivatives shown in Scheme 3. An X-ray crystal-structure determination of the cationic complex $[Pd_2(CNMe)_6](PF_6)_2$ (**4**) showed only terminal CNMe ligands that adopt a staggered arrangement.[28] The Pd–Pd distance is short, 253.1 pm. In the related cation $[Pd_2(PMe_3)_6]^{2+}$, the distance increases to 259.8 pm.[29] In the unusual trinuclear cluster with linear Pd arrangement $[Pd_3(CNMe)_6(PPh_3)_2](PF_6)_2$ (**5**), each palladium atom has a square-planar environment with short Pd–Pd distances (259.2 pm).[30]

A palladium(I) complex isostructural to (**4**) and synthetically very useful is $[Pd_2(CH_3CN)_6](BF_4)_2$. It can be considered as a 'naked' unsupported $[Pd–Pd]^{2+}$ unit since easy substitution of the acetonitrile ligands leads to a variety of Pd(I) compounds and small clusters.[31]

Another class of unsupported Pd–M compounds is that of complexes of the type *trans*-$[Pd(mCO)_2L_2]$ (L = neutral ligand; mCO = $Mn(CO)_5$, $Co(CO)_4$, $CrCp(CO)_3$, $MoCp(CO)_3$, $WCp(CO)_3$), obtained by reaction of *trans*-$[PdCl_2L_2]$ with the corresponding carbonylate. Note that formally they are palladium(0) complexes, although in this case the stability of the carbonylate anions in solution strongly suggests that the mCO moieties are playing a role not very different from that of the chloro ligands in the precursor, a typical palladium(II) complex. For L = NCPh, these complexes react with PR_2H to give heterobimetallic complexes stabilized by bridging phosphido groups (Scheme 4).[32]



Scheme 3



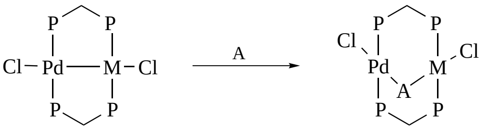
Scheme 4

5.3 Dimeric Complexes with Palladium–Metal Bonds Supported by Small Bite Ligands

A great deal of chemistry has been developed in the last three decades concerning complexes with binucleating ligands similar to 1,2-bis(diphenylphosphino)methane (dppm) and 2-pyridyldiphenylphosphine (PPh_2Py). They behave somewhat differently since a double bridge with two dppm ligands is rather flexible and can accommodate a range of Pd to Pd distances, whereas PPh_2Py ligand bridges are more rigid. The torsion angles shown by the two palladium coordination planes in the complexes also reflect this difference in flexibility and they change from 0° for the bridging PPh_2Py and related ligands, to a range of 37–72° for the dppm-type derivatives.

The derivative $[Pd_2Cl_2(\mu\text{-dppm})_2]$ (Pd–Pd bond length = 265.2 pm) can be prepared by a variety of methods including reduction of the palladium(II) complex $[PdCl_2(dppm)]$ and comproportionation of palladium(0) and palladium(II) complexes, for example, $[Pd(PPh_3)_4]$ and $[PdCl_2(PhCN)_2]$ in the presence of dppm. This method also applies to the synthesis of the heterodinuclear complex $[PdPtCl_2(\mu\text{-dppm})_2]$ from $[Pd(PPh_3)_4]$, $[PtCl_2(^tBuCN)_2]$, and dppm. For both the Pd–Pd and Pd–Pt derivatives, the metal–metal bond is very reactive and undergoes insertion of small molecules as shown in equation (6). Sulfur inserts into the M–M bond when the palladium(I) dimer (**6**, M = Pd) reacts with S_8 or $MeCHCH_2S$. The addition occurs at the expense of the metal–metal bond, producing the so-called A-frame complexes (**7**). These are formally Pd(II) complexes, where the Pd–Pd distance has

increased to 325–350 pm, depending on the inserted group.

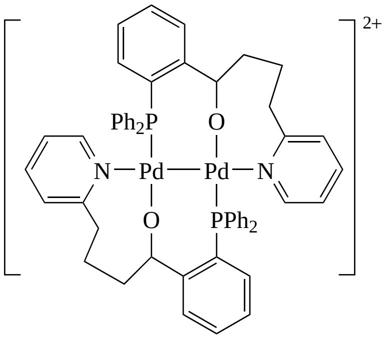


(6) (7) (6)

P⌒P = $Ph_2PCH_2PPh_2$; M = Pd, Pt; A = CO, SO_2, $MeO_2CC_2CO_2Me$

2-Pyridyldiphenylphosphine forms a number of homo- and heteronuclear palladium dinuclear clusters with short Pd–M bonds (about 260 pm). They are usually made by comproportionation of a Pd(II) complex and a second complex in a low oxidation state, for example, Pd(0), Rh(I), Ru(0). For these derivatives, head-to-head and head-to-tail isomers are possible, but the latter seems to be preferred (Figure 2). The metal–metal bonds in these derivatives are not as reactive as in the corresponding dppm complexes and insertion reactions do not occur. Some single-bridged complexes, such as $[Cp(CNR)Rh(\mu\text{-}PPh_2Py)Pd(CNR)Cl]^+$ (Pd–Rh distance 263.1 pm) are also known.

Complexes with other ligands such as $R_2PCH_2AsR_2$ and R_2PCH_2SR are similar to the dppm or PPh_2Py complexes. A cationic complex displaying a particularly short Pd–Pd bond (250.0 pm) is formed by the ligand *o*-$(PPh_2)C_6H_4CH_2O(CH_2)_3$-2-$C_5H_4N$ (**8**).[33]



(**8**)

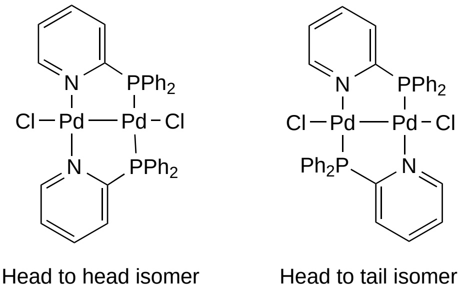


Figure 2 Isomers for two bridging 2-pyridyldiphenylphosphines

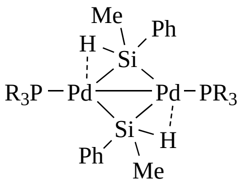
Thio- and selenophosphide complexes have also been synthesized according to Scheme 5. The Pd–Pd bond distance found for a thiophosphide complex (L = CNMe) is 260.8 pm.

The complexes $[Pd_2(\mu\text{-}P^tBu_2)_2(PMe_3)_2]$ (Pd–Pd distance 257.1 pm)[34] and $[Pd_2(\mu\text{-}P^tBu_2)_2(PH^tBu_2)_2]$ (Pd–Pd distance 259.4 pm)[35] are examples of Pd–Pd bonds supported by double phosphido bridges. The latter is a red solid easily prepared through the thermal reaction in equation (7).

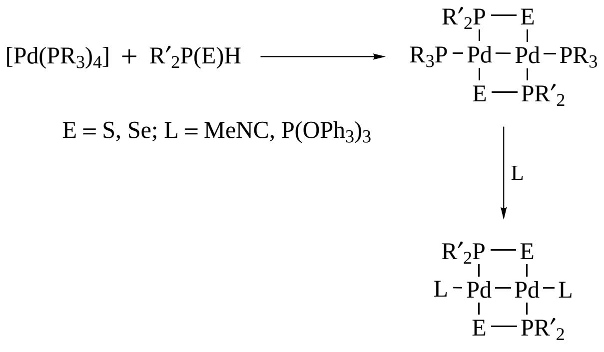
$$2CpPd(\eta^3\text{-}C_3H_5) + 4P^tBu_2H \longrightarrow [Pd_2(\mu\text{-}P^tBu_2)_2(P^tBu_2H)_2] + 2C_5H_5CH_2CH{=}CH_2 + H_2 \quad (7)$$

Palladium(I) dimeric complexes are also known where the Pd–Pd bond is supported by electron-deficient hydrido or silyl ligands. In the case of SiR_2H bridges, an agostic interaction (*see Agostic Bonding*) of one of the Pd atoms with the Si–H bond is observed (**9**).[36] The same feature has been found for some phosphido-bridged Pd(I) dimers.



(**9**)

In sandwich-type complexes supported by s-*trans*-1,3-diene ligands, a remarkably large Pd–Pd distance is observed in $[Pd_2(\mu\text{-diene})_2(PPh_3)_2]^{2+}$ (Pd–Pd = 318.52 pm) compared to the usual range of Pd(I)–Pd(I) distances (250–285 pm). This was attributed to the fact that Pd–Pd lengthening decreases the steric congestion and the Pd–Pd weakening is compensated by both back donation and donation interactions between the diene and the Pd dinuclear unit. Contributions, to a large extent, of Pd(II) resonant structures where the diene would oxidatively add to the dimer to give a bridging enediyl ligand (with elimination of the Pd–Pd bond) were discarded.[37]

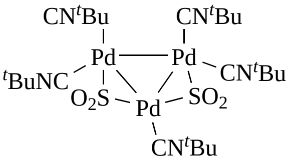


Scheme 5

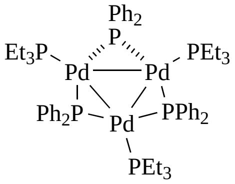
5.4 Small Clusters

Monodentate bridging ligands such as SO_2, PPh_2, and CO usually lead to nuclearities higher than two. Several examples of homo- and heteronuclear, three or four-member palladium clusters that adopt a variety of geometries are known.

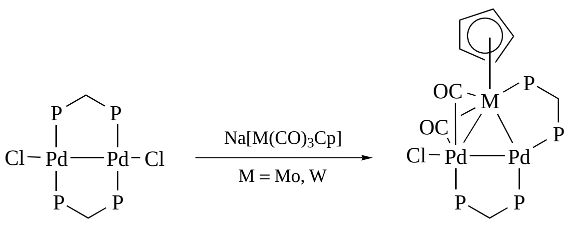
A triangulo arrangement is the most common structure for trinuclear clusters. $[Pd_3(\mu\text{-}SO_2)_2(^tBuNC)_5]\cdot 2C_6H_6$ (**10**), synthesized from $[Pd(^tBuNC)_2]_n$ and SO_2, displays the triangular arrangement of Pd atoms. The Pd–Pd distances are 276 pm for the unsupported interaction and 273.4 pm for the other two.[38] Phosphido-bridged triangulo clusters (**11**) have also been prepared, with rather large Pd–Pd distances of 290 pm. Reaction of the palladium(I) dimer (**6**) with metaloanions gives heteronuclear clusters with triangular arrangement and short Pd–M distances (equation 8).[39]



(**10**)



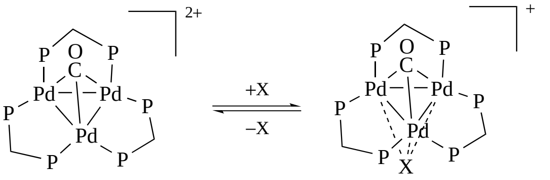
(**11**)



(**6**) (**12**)

(8)

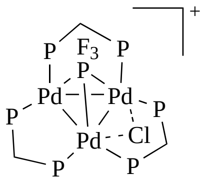
The reaction of palladium acetate with dppm and CO affords the trinuclear dicationic cluster $[Pd_3(\mu\text{-dppm})_3(\mu^3\text{-}CO)]^{2+}$ (**13**), which contains a planar triangular $Pd_3(\mu\text{-dppm})_3$ framework. The selective attachment of halide ions gives (**14**) (equation 9),[40] closely related to (**15**), which is obtained by disproportionation of $[Pd_2Cl_2(\mu\text{-dppm})_2]$ in the presence of PF_3.[41]



(**13**) (**14**)

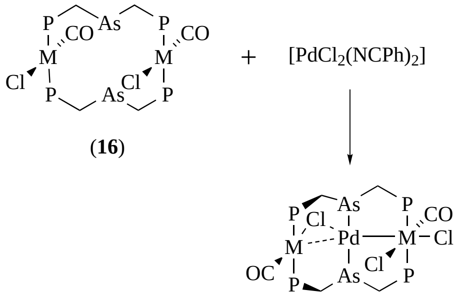
(9)

The tridentate ligand bis-(diphenylphosphinomethyl) phenylarsine (dpma) gives metallamacrocycles with Rh



(**15**)

or Ir (**16**), which react with $[PdCl_2(NCPh)_2]$ to give (**17**) (equation 10). The X-ray structure of the Rh complex shows a Rh–Pd distance of 269.9 pm, whereas the Cl-bridged Rh···Pd distance of 316.6 pm is not indicative of a metal–metal bond.[42]



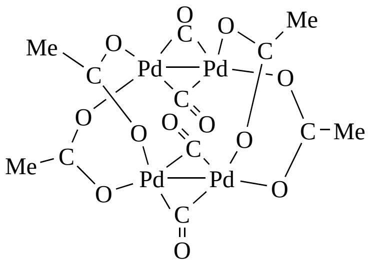
(10)

(**17**)

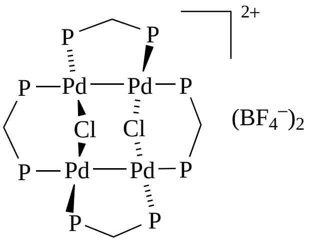
Complexes with the formula $[Pd(O_2CR)(CO)]\cdot nRCO_2H$ ($n = 0$, 0.5; R = Me, Et, Ph) have been prepared from the Pd(II) carboxylates and CO in carboxylic acid/benzene solution. These compounds are actually tetrameric clusters (**18**) with two short (266.3 pm) and two long (290.9 pm) Pd–Pd distances, and are better regarded as two dimeric Pd(I) units linked by acetate bridges.[43] The structurally related (**19**) is also known.[44] The four palladium atoms in complexes $[Pd_4(\mu_3\text{-}S)(\mu\text{-}SO_2)_2L(PBz_3)_4]$ (L = CO, CNR) show a tetrahedral arrangement with a capping μ_3-sulfido and two bridging SO_2 ligands,[45] while a rectangular structure is found in $[Pd_4(\mu\text{-}Cl)_2(\mu\text{-dppm})_4](ClO_4)_2\cdot$bpe.[46]

Carbonylation of different palladium complexes, often in the presence of phosphines, led to the synthesis of a variety of clusters including halocarbonyl clusters of unknown nuclearity $[PdX(CO)]_n$ (X = Cl, Br), and phosphine–carbonyl clusters from tetrameric $[Pd_4(CO)_5(PR_3)_4]$ to high nuclearity compounds such as $[Pd_{38}(\mu^3\text{-}CO)_4(\mu^2\text{-}CO)_{24}(PEt_3)_{12}]$.[47] From these preformed clusters, nanosized cluster compounds of higher nuclearity such as $[Pd_{69}(CO)_{36}(PEt_3)_{18}]$ can be prepared.[48]

When SO_2 is bubbled through a solution of $[Pd_8(CO)_8(PMe_3)_5]$, the cluster $[Pd_5(\mu^2\text{-}SO_2)_2(\mu^3\text{-}SO_2)_2(PMe_3)_5]$ is formed in high yield. Rather than being isostructural and isoelectronic with $[Pt_5H_8(PR_3)_5]$ (tbp arrangement for the platinum atoms), its structure consists of a rhombus of palladium atoms with a fifth palladium atom bridging the internal Pd–Pd bond of the rhombus. This is due to the fact that two of the SO_2 ligands are acting as four-electron bridging



(**18**)



(**19**)

ligands using one oxygen lone pair (*see* ***Electronic Structure of Clusters***).[49]

6 COMPLEXES OF PALLADIUM(II)

6.1 Introduction

Pd(II) is a second row, d^8 transition metal center. Considering the splitting of the d orbitals in crystal fields of different symmetry (*see* ***Coordination & Organometallic Chemistry: Principles***), the four-coordinated square-planar geometry is energetically the most favorable. Indeed, it is by far the most frequently found geometry, and therefore the Pd(II) complexes are diamagnetic. However, there are exceptions to this behavior, depending on the ligands. In a few cases involving bulky ligands, the complex is apparently three-coordinated, but this initial impression is usually corrected when additional interactions (for instance, C–H agostic bonds, or Fe–Pd bonds) are considered.[50] One case of tetrahedral paramagnetic Pd(II) complex is known. The compound PdF_2 is a rare example of a six-coordinated Pd(II) (see Section 3.2). Finally, the formation of five-coordinated complexes is more frequent, either with a bpt structure, a square pyramidal structure or, very often, intermediate geometries. Five-coordinated complexes are the usual nonobserved intermediates in associative ligand substitution reactions, but a good number of stable compounds, both in solution and in the solid state, are also known.

Palladium(II) is a class b or a soft metallic center. Accordingly, it forms numerous stable complexes with soft ligands. A vast palladium(II) coordination chemistry is found for S-, N-, P-, and As-donor ligands. Pd(II) also shows a higher affinity for the heavier halogens. Ligand-exchange reactions with alkali metal salts are favorable when moving from $[PdX_nL_{4-n}]^{(2-n)+}$ to $[PdX'_nL_{4-n}]^{(2-n)+}$, provided X′ is heavier than X. The reverse exchange can be forced with silver or thallium salts, the formation of the more insoluble Ag or Tl halide (that with the heavier halide) being the driving force (equation 11).

$$[PdX_nL_{4-n}]^{(2-n)+} \underset{MX}{\overset{M'X'}{\rightleftharpoons}} [PdX'_nL_{4-n}]^{(2-n)+} \qquad (11)$$

X′heavier than X

M = Ag, Tl; M′ = alkaline metal

Complexes containing O–donor ligands are less abundant and monodentate ligands of this type readily undergo substitution reactions by other ligands. However, the *Chelate Effect* is important in favoring the final stability of a complex, and there is a well-developed chemistry for bidentate O-donors and also for chelating ligands that combine a soft and a hard-donor center.

Substitution reactions in palladium(II) complexes are a common preparative route to new types of derivatives. Halocomplexes are often employed as starting materials. These reactions are usually noticeably faster for palladium than for platinum and proceed through associative mechanisms whenever organometallic ligands are not present.[50] It has been proved that even in the case of sterically very hindered complexes, where the reaction rates can depart from the order predicted by the n_{Pt} scale, when this occurs, it is because of steric factors that overcome the usual electronic control, but the mechanism remains associative.[51] It is generally possible to predict the leaving ligand in a substitution reaction considering the relative *Trans Effects* of the different ligands in the complex. The lability of palladium(II) complexes makes it often difficult to isolate unstable isomers, and fast isomerization to the more stable isomer is frequently found. Therefore, few examples of kinetically stable pairs of cis and trans isomers are known.

In the following sections, the coordination chemistry of palladium(II) will be illustrated with selected examples. They are roughly organized according to the number of donor atoms in the ligand and the binding mode to the metal. More information can be found in the comprehensive works and monographs cited.[5–9] *Coordination Chemistry Reviews* often offers surveys of the recent palladium literature.

6.2 Complexes with Monodentate Ligands

Palladium(II) complexes with monodentate ligands are widespread. Table 2 illustrates the most important types. Besides, there are a large number of compounds that combine different L (neutral) or X (monoanionic) ligands, that is,

Table 2 Palladium (II) complexes with monodentate ligands

Stoichiometry	X	L
$[PdX_4]^{6-}$	$\underline{S}O_3{}^{2-}$	
$[PdX_4]^{2-}$	Cl, Br, I, CN, $\underline{S}CN$	
$[PdX_3L]^-$	Cl, Br	PR_3, SR_2
	Cl	NH_3
$[PdX_2L_2]$	Cl, Br	NR_3H_{3-n}, RCN, py, PR_3, $P(OR)_3$, E = PPh_3 (E = O, S, Se), ER_2 (E = S, Se), $DM\underline{S}O$,
	I	PR_3, $P(OR)_3$
	CN, N_3	PR_3
	$\underline{S}CN$	NH_3, py, PR_3, $AsPh_3$, $SbPh_3$,
	$SC\underline{N}$	PR_3, $AsPh_3$
	$GePh_3$, $PbPh_3$	PR_3
$[PdYL_3]$	$\underline{S}O_3$	NH_3
$[PdXL_3]^+$	Cl	NMe_3, $P(OR)_3$
	Cl, Br, I	PR_3
$[PdL_4]^{2+}$		H_2O, $DMS\underline{O}$ + $DM\underline{S}O$, $\underline{S}C(NH_2)_2$, NR_3H_{3-n}, MeCN, PR_3

[PdXX′LL′], although there is a strong tendency to give fast equilibria with their symmetrization compounds $[PdX_2L_2]$, $[PdX'_2L'_2]$, and so on.[52] Complexes of group 15 (specially P- and As-donors) and S-donor ligands are by far the most numerous.

$PdCl_2$ and halo complexes are useful starting materials for the preparation of Pd(II) complexes. $[PdCl_4]^{2-}$, easily prepared from $PdCl_2$ and a soluble chloride salt in MeOH or HCl(aq), is commonly used. When substitution of the halogen cannot be easily accomplished, it can be forced by creating a vacant coordination site on the metal. The use of soluble silver(I) salts ($AgBF_4$, $AgNO_3$) in a non or weakly coordinating solvent (CH_2Cl_2, acetone, THF) eliminates the halogen from the Pd coordination sphere in the form of an insoluble AgX salt. The 'vacant' coordination site (usually solvent coordinated) is then more available to the incoming ligand. Similarly, metathesis reactions, for example, treatment of the $[PdCl_nL_{4-n}]^{(2-n)+}$ derivatives with M^IX ($X^- = Br^-$, I^-, CN^-, SCN^-, etc.), provide access to other $[PdX_nL_{4-n}]^{(2-n)+}$ derivatives. The fluorocomplexes of palladium are scarce: $[PdF(PEt_3)_3](BF_4)$,[53] and $[PdF_2(diapp)]$ (diapp = dialkylphosphinopropane),[54] in addition to some organometallic derivatives $[PdFAr(PR_3)_2]$.[55] The latter are a convenient source of 'naked fluoride' and have proved to be interesting fluorinating reagents. Ultrasound-promoted reaction of AgF with the appropriate iodo precursor is a convenient preparation method for $[PdFAr(PR_3)_2]$. Reaction of XeF_2 with $[PdMe_2(diapp)]$ was used to prepare $[PdF_2(diapp)]$.

CN^- is probably the strongest anionic monodentate ligand toward palladium(II). The coordination mode of SCN^- has been extensively studied by infrared spectroscopy and X-ray crystallography.[56] Both N and S linked SCN^- complexes are found for Pd (see table 2 for a few examples). These forms are very similar in stability. Therefore electronic differences, introduced by other ligands coordinated to Pd, and steric effects (coordinated $\underline{N}CS$ is linear but $\underline{S}CN$ is bent, M–S–C angle about 105°) may determine which donor atom is attached to the metal. Linkage isomerism has been observed for nitro complexes as well. The fluxional behavior of $[Pd(NO_2)_2(diphos)]$ has been studied by ^{15}N NMR and is due to exchange between the N- (nitro) and O-bound (nitrito) forms of the NO_2 ligand.

Oxygen-containing solvents such as water, alcohols, ethers, or ketones are hard donors, and few palladium(II) complexes have been isolated although they are probably intermediates in substitution reactions carried out in these solvents. It is possible to isolate $[Pd(solv)_4]^{2+}$ complexes for solv = DMSO, H_2O and $[PdL_2(solv)_2]^{2+}$ for L_2 = bidentate phosphine and solv = H_2O, $DMS\underline{O}$, acetone. $[Pd(H_2O)_4]^{2+}$ has been used to selectively cleave polypeptides.[57] DMSO is capable of linkage isomerism and $[Pd(DMSO)_4]^{2+}$ is better represented as $[Pd(DM\underline{S}O)_2(DMS\underline{O})_2]^{2+}$. The solv ligands are easily replaced by other species. Attempts at isolating these species for EtOH produce reduction to the Pd metal. $[Pd(H_2O)_4]^{2+}$ is stable only in strongly acidic solutions of noncoordinating acids like $HClO_4$. The complex is acidic and it readily undergoes hydrolysis to give hydroxo species, rarely isolated. Studies on *trans*-$[Pd(H)(H_2O)(PCy_3)_2]X$, obtained by oxidative addition of strong acids $[H_3O^+][BF_3OH^-]$ or $[H_3O^+][BF_4{}^-]$ to $Pd(PCy_3)_2$ suggest that the acidity of the hydridic hydrogen is higher than that of the hydrogens of the coordinated water.[58]

Many Pd(II) complexes with amines, nitriles, and heterocyclic N-containing ligands (pyridines, imidazoles, etc.) are known, $[PdX_2L_2]$ being the commonest type. These are usually trans, although cis isomers can also be obtained by careful choice of the preparation procedure. Nitrile complexes $[PdCl_2(NCR)_2]$ (R = Me, Ph) and $[Pd(NCMe)_4]^{2+}$ are used as starting materials for other complexes, as they are soluble in most organic solvents and RCN ligands are easily substituted by other ligands. The complexes of Pd(II) derivatives with peptides and nucleosides–nucleotides have been reviewed,[59] and may be relevant to the mechanism of anticancer action of transition metal compounds such as *cis*-$[PtCl_2(NH_3)_2]$ (*see* ***Platinum-based Anticancer Drugs***).[60] Tetraamine complexes $[PdL_4]X_2$ are also common. Among them, the salts $[Pd(NH_3)_4][PdCl_4]$ and $[Pd(NH_3)_4][PtCl_4]$ are noteworthy for their solid-state structure, similar to $[Pt(NH_3)_4][PtCl_4]$, where the square-planar ions are stacked vertically. The short axial metal–metal distances (325 pm) seem responsible for the anomalous visible spectra and the semiconductivity and photoconductivity that arise from a filled

and empty band structure created from the overlap between the p_z and d_z2 orbitals.[61]

Although amido palladium complexes are less abundant than amino complexes, they play an important role in the catalytic amination of organic compounds. The same applies to alkoxy ligands for the Pd-mediated synthesis of organic ethers. Terminal amido or alkoxy Pd complexes are usually rather reactive due to the high nucleophilicity associated with the lone pairs on the heteroatom. For this reason, bridging amido or alkoxy groups, where these lone pairs are involved in bonding, often lead to more stable complexes.

The numerous P-donor ligand complexes are found as cis and trans isomers. The relative stability of the two isomers depends on the actual ligands and on the solvent if the stability in solution is being considered.[62,63] Solvation effects are very important and favor the polar cis form in solution. Bulky ligands tend to favor the trans form. The cis–trans isomerization is favored by addition of excess PR_3. Phosphines play an important role in stabilizing organometallic palladium(II) derivatives, and hence PR_3 complexes are often used as catalyst precursors for the transformation of organic substrates. Most of the palladium hydrides known also contain phosphines as ancillary ligands, for example, $[PdHX(PR_3)_2]$ (X = Cl, OPh, $GePh_3$) or [PdHX(diphos)] (X = SiR_3, SnR_3), $[PdH(triphos)]^+$ (exception is the homoleptic $[PdH_4]^{2-}$, see Section 3.1).

In connection with the wide applicability of palladium in catalytic processes, much work has been devoted to the synthesis of palladium complexes with ligands attached to a support (silica or a polymer), which should combine the advantages of homogeneous and heterogeneous catalysis.[64] These ligands very often bind Pd through phosphine ends, although other types of donor atoms (N, As) have also been used (*see* ***Supported Organotransition Metal Compounds***).

A homoleptic square-planar palladium(II) carbonyl complex $[Pd(CO)_4](Sb_2F_{11})_2$ that displays ν(CO) at 2259 cm^{-1} (the value for free CO is 2143 cm^{-1}) has been recently prepared. This is an exceptional complex, dubbed by the authors as 'superelectrophilic metal carbonyl'. The very high value of ν(CO) shows that the carbonyl ligands behave as σ-donors (*see* ***Carbonyl Complexes of the Transition Metals***). Additional data (e.g. ν(M–C)) and stability data support that this ligand is very weakly coordinated as only a σ-donor.[65]

Isocyanides are excellent ligands for Pd(II) and Pt(II), to the point that they can be used in the synthesis of thermotropic liquid crystals. Some $[MX_2(isocyanide)_2]$ complexes are liquid crystals (discotic) at room temperature.[66] The thermal properties depend very much on the cis or trans geometry of the complex. For X = I, the trans geometry is favored, whereas for X = Cl, cis complexes are formed.

The complexes referred to so far are four-coordinated square planar, the normal geometry for Pd(II). As stated above, some palladium(II) complexes deviate from this trend. Since early times, conductimetric and electronic spectral measurements provided evidence for five-coordinated species of the type $[PdXL_4]X$ in solution for L = N, N' disubstituted thio- and seleno-ureas.[67] $[PdX_2(ER_3)_3]$ (E = P, As, Sb) have also been isolated when ER_3 is a ligand with suitable steric requirements (e.g. $PBzMe_2$ or 5-ethyl-5H-dibenzophosphole). The geometry of these derivatives is distorted tetragonal pyramidal with an apical X group. $[Pd\{P(OR)_3\}_5]^{2+}$ complexes have been synthesized in the presence of excess $P(OR)_3$, but recrystallization in the absence of phosphite results in the loss of the fifth ligand to give $[PdL_4]^{2+}$.

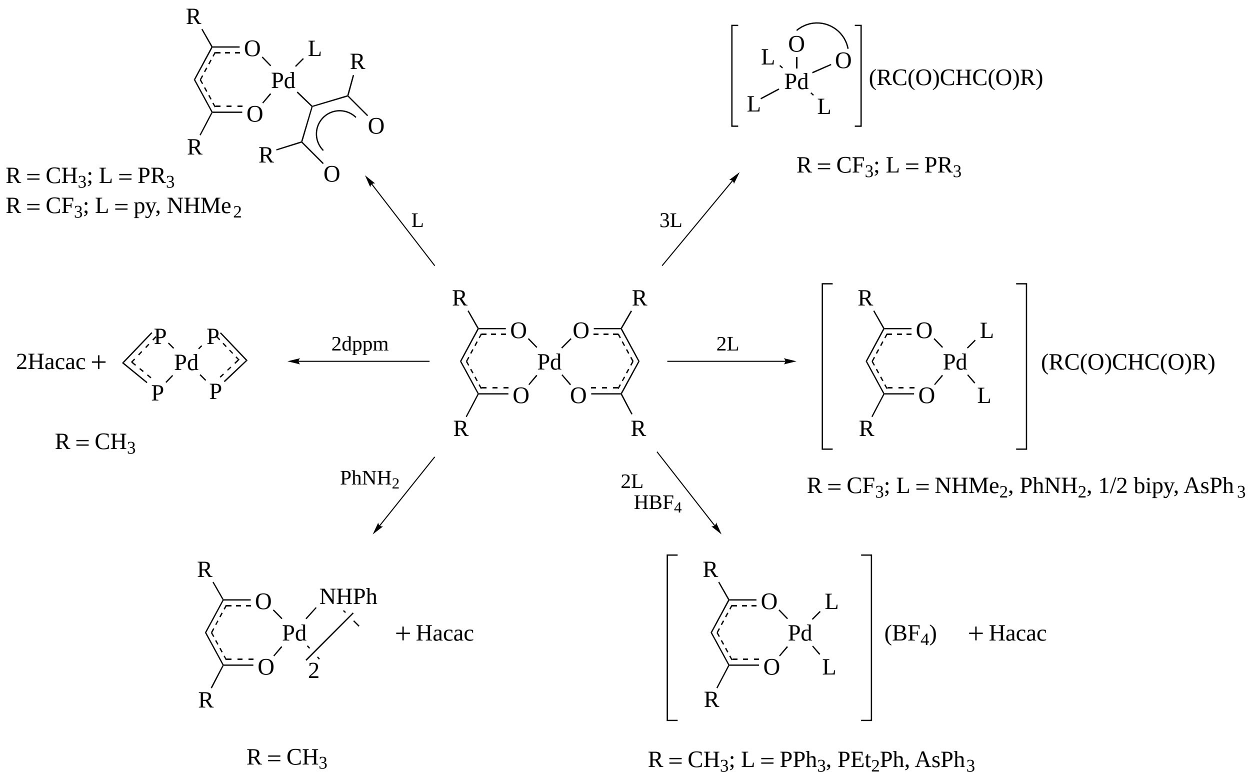
6.3 Complexes with Bi- or Polydentate Chelating Ligands

In mononuclear palladium derivatives with ligands bearing two or more donor atoms, the geometric and steric requirements of the ligand are determinant of the number of donor atoms that will coordinate, the final geometry and stability of the metallic species. For most bidentate ligands, a cis arrangement of their donor atoms is adopted, and the highest stability is reached for a five-membered metallacycle, although four- and six-membered rings are not uncommon.

The main general types of derivatives with bidentate ligands (representing as X a monoanionic donor, and as L a neutral donor end) are: 1) $[Pd(X–X)_2]^{2-}$ (X–X = oxalate; malonate; dithiooxalate; 1,1-dithiolate); 2) $[Pd(X–L)_2]$ (X–L = β-diketonate; glycinate-N,O-; dioximate-N,O-; *o*-aminophenolate-N,O-; salicylaldiminate-N,O-; thioether–thiolate; dithiocarboxylate; *o*-$C_6H_4(AsR_2)S^-$); 3) $[PdX_2(L–L)]$ and 4) $[Pd(L–L)_2]^{2+}$ (L–L = bidentate amine; α-diimine; 2,2′-bipy; phen; bidentate phosphine; substituted amines $Ph_2ECH_2CH_2NH_2$, E = P, As; bis-thioethers). Besides, many chiral and nonchiral bidentate ligands have been developed that combine two different donor atoms (N, O, P, As, S) and are either anionic or neutral. Many of their palladium complexes are useful in catalytic processes such as the polymerization of olefins,[68] and others.[69]

The influence of the ligand backbone on the geometry of the metal derivative is clearly seen for bidentate phosphines and arsines. Diphosphines $R_2P(CH_2)_nPR_2$ usually form cis complexes $[PdX_2(L–L)]$, if $n = 2$, 3. For $n = 1$, cis chelating ligand complexes are rare and dppm prefers to bridge two metals or to act as a pendant η^1-ligand, for example *trans*-$[Pd(CN)_2(\eta^1\text{-dppm})_2]$. Large values of n give *trans*-$[PdX_2(L–L)]$ derivatives (L–L = ${}^tBu_2P(CH_2)_nP^tBu_2$; $n = 10$) or dinuclear complexes with bridging phosphine.

Palladium(II) β-diketonates give a complex substitution chemistry due to the many coordination modes adopted by these ligands: O,O′-chelate, Pd–C through the γ-carbon, singly O-bonded, and so on. Some of this chemistry is summarized in Scheme 6. The use of acetylacetonate as an easy leaving group by protonation is noticeable. Thus, $M(acac)_2$ deprotonates diphosphines $Ph_2PCHRPPh_2$ to give $M(Ph_2PCRPPh_2)_2$, and $ArNH_2$ to give $[Pd_2(\mu\text{-NHAr})_2(acac)_2]$.

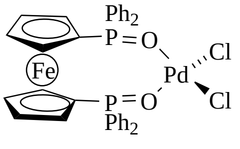


Scheme 6

The related volatile hexafluoroacetylacetonate, Pd(hfacac)$_2$, and several mixed allyl diketonates, including the liquid [Pd(C_3H_5)(Bu^{t}C(O)CH(CO)C_3F_7)], are used for chemical vapor deposition on surfaces (CVD) and subsequent reduction to Pd. The mechanism of formation of a Pd film on a copper surface by thermal decomposition of deposited Pd(hfacac)$_2$ has been studied in detail.[70,71] Reduction with H_2 can also be used and it produces polycrystalline Pd.

Among the numerous S-donor chelating ligand complexes, the 1,2-dithiolene derivatives are peculiar since these ligands are redox active and therefore easily and reversibly oxidized and reduced. This makes it often difficult to assign oxidation states to the metal (*see Dithiolenes* and Section 7).[72]

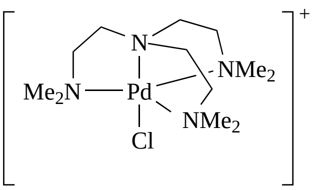
The preference for chelation in some bidentate ligands can lead to a departure from the normal square-planar coordination. Thus, a small distortion of the square-planar structure toward a tetrahedral geometry has been observed for [Pd(2,2′-bipy)(NO_3)$_2$]·H_2O due to steric constrain. The complex [PdX(L–L)$_2$]$^+$ (X = halogen; L–L = 2, 9-dimethyl-1, 10-phenantroline) has a trigonal bipyramidal structure, and [PdCl(*o*-phen)(PPh_3)$_2$]$^+$ has a distorted square pyramidal structure with a long apical Pd–N distance (268 pm).[73] An interesting family thoroughly investigated is that of the trigonal bipyramidal Pd or Pt compounds containing a coordinated alkene, [M(N–N)(C_2H_4)XY].[74] The reasons for their stability have been discussed on the basis of quantum-mechanical calculations. Six-coordination in the solid state is observed for the *o*-phenylene derivatives [PdX_2(L–L)$_2$] (X = halogen, L–L = *o*-C_6H_4(EMe_2)E′Me_2, E, E′ = P, As, Sb). The X-ray crystal-structure determination carried out for [PdI_2{*o*-C_6H_4(AsMe_2)$_2$}$_2$] shows an hexacoordinated Pd atom with long *trans*-Pd–I bonds. However, in solution five-coordinated species [PdX(L–L)$_2$]$^+$ are formed. Perhaps, the most extraordinary distortion is observed in [PdCl_2(dppfO_2-*O*,*O*′)]. This complex, bearing a chelating ligand with a large *bite angle*, is actually tetrahedral (**20**). The dihedral angle between the {PdCl_2} and {PdO_2} planes is 84.2°. According to its tetrahedral structure, the complex shows a magnetic moment of 2.48 μ_B, consistent with paramagnetic Pd(II) with two unpaired electrons and in sharp contrast with the diamagnetic behavior of other Pd(II) complexes.[75]



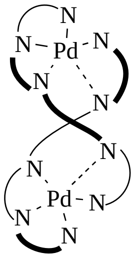
(**20**)

Tri- and tetradentate ligands coordinated to palladium usually contain group 15 donor atoms. The tridentate amine *N*-(2-aminoethyl)-1,2-diaminoethane (dien) gives [PdX(dien)]X

and [PdL(dien)]X_2 complexes. N,N'-Di(2-aminoethyl)-1,2-diaminoethane (trien) acts as tetradentate in [Pd(trien)]X_2. The four N atoms bind palladium in a trapezoidal arrangement as shown in the structure determination of its PF_6^- derivative, with Pd–N distances between 1.95 and 2.08 Å. The tripod ligand tris[2-(dimethylamino)ethyl]amine is tetracoordinated in alkaline media to give the five-coordinated complex (**21**). A number of other five-coordinated palladium complexes containing N-donor atoms are known. Particularly remarkable is the double-helical dinuclear structure of $[Pd_2(quinquepy)_2]^{4+}$ where each palladium is in an irregular five-coordinated environment with four short contacts to a terpyridyl fragment of one quinquepy and a terminal pyridine of a second quinquepy. The coordination sphere is completed by a long contact (260 pm) to the remaining pyridine of the second ligand (**22**).[76]

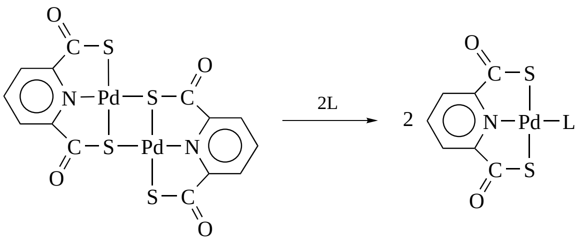


(**21**)



(**22**)

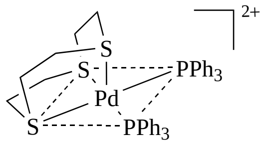
Symmetric pincer ligands take three positions of the square coordination plane in Pd, while the ligands in the fourth position can be varied. This allows complexes that are nonsusceptible to isomerization to be built, with a dipolar moment in the direction defined by the fourth ligand and the central donor atom of the pincer (equation 12).[77]



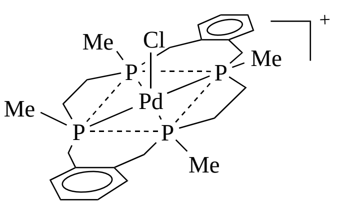
(12)

Tridentate phosphines and arsines are also known to give [PdXL]X complexes. Mixed P,N,N or P,S,S neutral ligands, however, form [PdX_2L] derivatives with one donor atom uncoordinated. The tetraphosphine $Ph_2PCH_2CH_2PPhCH_2CH_2PPhCH_2CH_2PPh_2$ forms a planar complex $[PdL][PF_6]_2$ while the tripod ligand $P(CH_2CH_2PR_2)_3$ (R = neopentyl), which cannot adopt a planar structure, acts as tridentate in $[PdXL]^+$ with an uncoordinated PR_2 group. Five-coordinated complexes [PdXL]X are also formed for the tetraarsine ligands $Me_2AsCH_2CH_2AsPhCH_2CH_2AsPh$-$CH_2CH_2AsMe_2$ and $As(o\text{-}C_6H_4AsR_2)_3$ (R = Me, Ph).

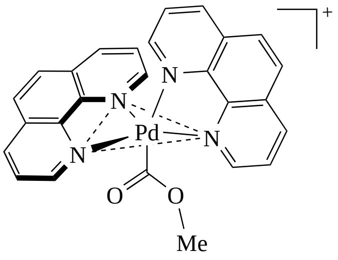
Overall, the formation of pentacoordinated complexes is favored by chelating and particularly by polydentate macrocyclic ligands. A search in the Cambridge Structural Database reveals that many of the structurally characterized five-coordinated Pd(II) compounds contain macrocyclic or rigid polydentate ligands, S, N, and P donor atoms being dominant. Complexes (**23**), (**24**) and (**25**) are typical examples.



(**23**)



(**24**)



(**25**)

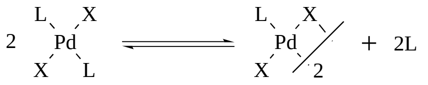
6.4 Complexes with Bridging Ligands and without Pd–Pd Bonds

Palladium atoms can be held together by ligands with a donor atom having at least two electron pairs or by a ligand containing at least two donor atoms. These cases lead to electron precise bridges, and to the absence of Pd–Pd interactions unless these are forced by severe steric constraints. When a bridging ligand shares a one-electron pair with both metals, an electron-deficient bridge is formed. This is possible for R (hydrocarbyl) and for H. Although few bridging R or hydrido palladium(II) complexes are known, they play an important role in some organometallic transformations. Only nondeficient bridges will be dealt with in this section.

Double bridges $Pd_2(\mu\text{-}X)_2$ are formed very frequently, but less stable single bridges $Pd_2(\mu\text{-}X)$ are also known. Dimeric compounds are the most abundant, but trimeric derivatives $[L_2Pd(\mu\text{-}X)_2Pd(\mu\text{-}X)_2PdL_2]^{2+}$ and compounds with higher nuclearity have been prepared.

Halogens and pseudohalogens are the simplest and most common bridging ligands. Complexes with $[Pd_2(\mu\text{-}X)_2X'_4]^{2-}$, $[Pd_2(\mu\text{-}X)_2X'_2L_2]$, and $[Pd_2(\mu\text{-}X)_2L_4]^{2+}$ stoichiometries (X = halogen or pseudohalogen; X′ = monoanionic ligand; L = neutral ligand) have been prepared. The only complex bearing bridging fluoride, $[Pd_2(\mu\text{-}F)_2Ph_2(PR_3)_2]$, has been

recently reported.[78] Chelating ligands also give $[Pd_2(\mu\text{-}X)_2(L{-}L)_2]^{2+}$. Halogen bridge-splitting by an incoming ligand is a facile process and offers a synthetic way to monomer derivatives. There are some examples of monomer–dimer equilibrium (or terminal-bridging halogen equilibrium) in solution (equation 11). Labile dimeric compounds with unsupported halide single bridges are also known.



(13)

L = RCN, RSO_2; X = Cl, Br

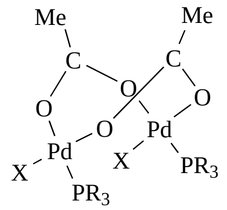
Hydroxide can also behave as a bridging ligand, for example, in $[Pd(\mu\text{-}OH)_2L_4]^{2+}$, $[Pd(\mu\text{-}OH)_2(L{-}L)_2]^{2+}$, and so on. The OH group can be easily protonated and displaced by acidic ligands, and reacts with CO_2 to give hydrogen carbonato complexes.[79] Amines can also protonate hydroxo bridges leading to remarkably stable amido-bridged palladium compounds.

Thiolates have a very strong tendency to act as bridges. Simple thiolato palladium compounds $Pd(SR)_2$ (R = alkyl, aryl) are oligomers or polymers with bridging SR^- groups between metal atoms. Thiolato complexes containing ancillary ligands are rarely monomers, and dimeric derivatives analogous to the halogen-bridged derivatives are known. Thiolate bridges are very strong and bridge splitting is difficult to accomplish. Sulfide and selenide are also prone to act as bridging ligands binding two or even three palladium atoms.

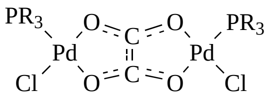
Phosphido-bridged dimers $[Pd_2(\mu\text{-}PR_2)_2X_2(PR_2H)_2]$ can be obtained by reaction of secondary phosphine complexes $[PdX_2(PR_2H)_2]$ with a base. HX elimination is easier in the order $PPh_2H > PPhEtH > PEt_2H$.

Small bite bidentate ligands usually prefer to bridge two palladium(II) atoms, as this arrangement is more stable than the strained chelating form. The systems $\mu\text{-}\underline{S}C\underline{N}^-$, $\mu\text{-}SO_3$, μ-dppm, and μ-carboxylates are examples of these types of ligands. CN bridges act as a C,N-donor and the linearity of the two bonds produces tetrameric single-bridged complexes when these are forced to be cis, or polymers for trans complexes. In contrast to halide single bridges, cyanide single bridges are rather strong.

Double-bridged carboxylate derivatives adopt a butterfly conformation (**26**), which usually leads to Pd···Pd interactions.[80] Pyrazolate ligands form similar structures, although in this case, the higher rigidity of the boat shaped double bridge keeps the two Pd atoms apart. Polydentate species such as oxalate or biimidazolate can act as bridging and chelating ligands simultaneously (**27**).



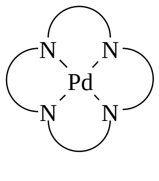
(**26**)



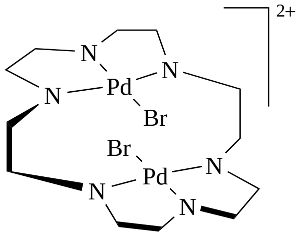
(**27**)

6.5 Complexes with Macrocyclic Ligands

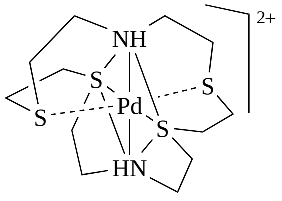
Palladium gives complexes with many macrocyclic ligands containing N, S, and O heteroatoms. Some have already been mentioned for their ability to stabilize five-coordinated Pd(II), and others will be mentioned in Section 7. In general, the strong preference of Pd (II) for square-planar coordination has to be balanced against the coordination ability and structural requirements of the ligand. Porphyrins and similar $(N_4)^{n-}$ ligands offer a square-planar bonding cavity and give very stable complexes (**28**), but other types of complexes are formed when this match does not occur and a compromise has to be reached, as in structure (**29**). Sometimes apparently minor changes in the ligand, such as replacing H (**30**) for Me (**31**), produce dramatic changes in the coordination mode, from $S_2N_2{+}S_2$ quasi-octahedral (two Pd to S distances are long, 295.4 and 300 pm) to S_4 square planar. In this case, space-filling models show that the steric bulk of the NMe groups is big enough to prevent the meridional S–N–S binding adopted in (**30**).[81]



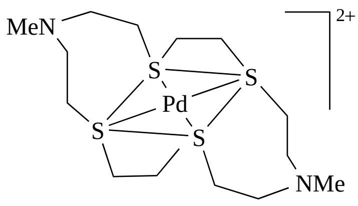
(**28**)



(**29**)



(**30**)



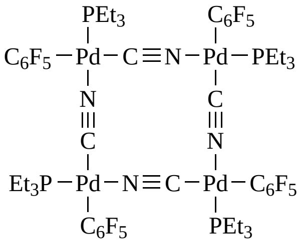
(**31**)

6.6 Pd(II) As a Tool for Self-assembly

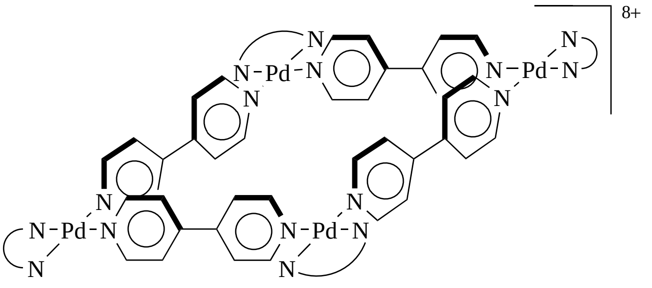
In recent years, there has been an enormous development in the construction of extended self-assembled structures with the participation of metal atoms, either in the corner or in the edges of molecular triangles, squares, rectangles, and cages. *Cis*-'PdL_2' can be used to define corners in square and triangular structures, using the two available

coordination sites, while *trans*-'PdL_2' moieties can participate to define linear edges. Excellent reviews of the topic are available.[82,83]

To give a simple example of this use, the linearity in the bonds formed by CN and by 4,4′-bipy leads to similar tetrameric structures for $[Pd_4(\mu\text{-}CN)_4(C_6F_5)_4(PEt_3)_4]$ (**32**),[84] and for$[\{Pd(en)(4,4'\text{-bipy})\}_4][NO_3]_8$ (**33**).[85] The short length of the bridging ligands in (**32**) does not allow accommodating anything in the square cavity, whereas (**33**) recognizes organic molecules in aqueous media.

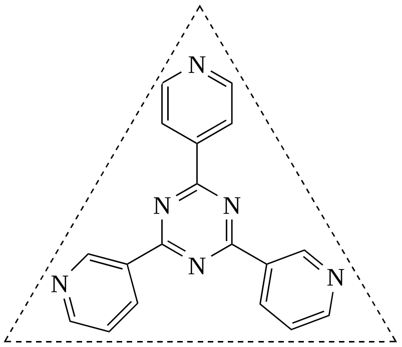


(**32**)



(**33**)

Planar exo-multidentate ligands (molecular panels, e.g. **34**) coordinate to palladium to give a variety of polyhedra.[86] Molecular cages have also been assembled using *cis*-'PdL_2' corners (*see* ***Self-assembled Inorganic Architectures***).

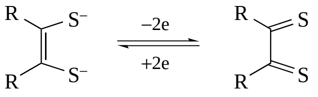


(**34**)

7 COMPLEXES OF PALLADIUM(III)

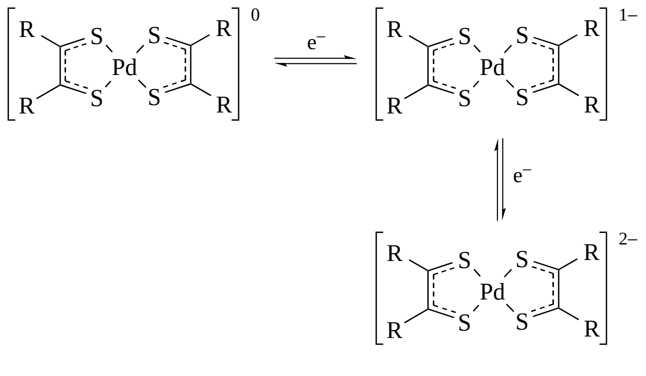
There is a certain reluctance to assign the oxidation number +3 to palladium, whereas there is not much trouble in assigning it +4 in other complexes. Thus, Pd(III) candidates are looked at with suspicion, not because it is difficult to accept that Pd can have charge densities midway between Pd(II) and Pd(IV), but probably because in many instances where a formal oxidation state +3 can be assigned, either the complex has some noninnocent ligands which do not allow a clear decision, or the complex is a dimer or a higher polymer and can be assigned mixed oxidation states.

The first case is best exemplified by the 1,2-dithiolene complexes (*see Dithiolenes*).[72,87] Bis(1,2-dithiolene) complexes of palladium of the types represented in Scheme 7 are known. The monoanionic complexes are assigned as Pd(III) complexes if (as applied in Scheme 7) the two ligands are considered in its reduced dianionic dithiolene form (**35**) (equation 14). However, very different oxidation states can be assigned to the metal if one or two ligands are considered in their oxidized neutral dithiabutadiene form (**36**) (equation 14). Obviously, the ambiguity in oxidation number affects the three complexes, and not only the Pd(III) candidates. Molecular orbital calculations favor the dithiolene structure (**35**). The EPR spectra of the monoanionic complexes, which are monomeric and paramagnetic, show hyperfine splitting (sextet) caused by the interaction of the unpaired electron with the ^{105}Pd nuclei. The stacking properties and solid-state systems involving these complexes have been reviewed.[72]



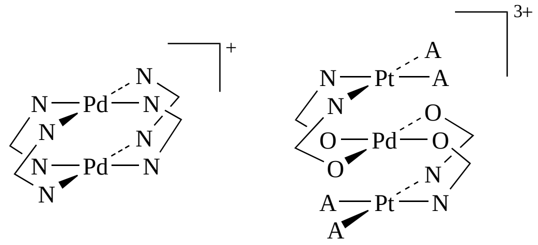
(**35**) (**36**) (14)

The paramagnetic complex $[Pd_2(\mu\text{-form})_4]PF_6$ (form = (p-Tol)NCHN(p-Tol)) (**37**), is obtained by oxidation of $[Pd_2(\mu\text{-form})_4]$ with $AgPF_6$, but the EPR spectrum indicates that the odd electron is located in a ligand-based orbital.[88] Similarly, for the mixed blues (*see* ***Mixed Valence***



Scheme 7

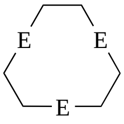
Compounds) *cis*-$[A_2Pt(\mu\text{-}L)_2Pd(\mu\text{-}L)_2PtA_2]X_3$ (A = amine; L = 1-methyluracilato, 1-methylthyminato; $X^- = NO_3^-$, ClO_4^-) (**38**), which can be formally considered $Pt^{II}{}_2Pd^{III}$, it is difficult to rule out the possibility of ligand oxidation rather than metal oxidation.[89]



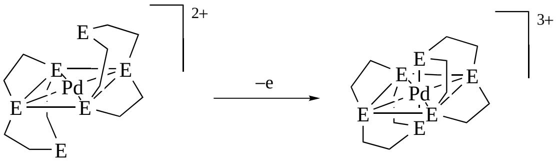
(**37**) (**38**)

Complexes containing linear-chains ···Pd···X···Pd···X···(X = halide), for example, those formed by the partial oxidation of $[PdL][ClO_4]_2$ (L = tetradentate planar ligand, two bidentate ligands, or four monodentate ligands, usually amines) with X_2, have Peierls-distorted structures (*see Peierls Distortion*) and are better regarded as having Pd atoms alternating in oxidation states and bridged by nonequidistant halogen atoms, that is, $[Pd^{II}L][Pd^{IV}LX_2][ClO_4]_4$.[90]

The tridentate macrocyclic ligands 1,4,7-triazacyclononane and 1,4,7-trithiacyclononane (**39**, E = NH, S, respectively), act as bidentate chelates toward Pd(II) to give square-planar complexes $[Pd^{II}L_2]^{2+}$ with two pendant E donor atoms (**40**). The complexes can be oxidized chemically or electrochemically to $[Pd^{III}L_2]^{3+}$ (**41**) (equation 15), which show tetragonally elongated octahedral coordination, as expected for a Jahn–Teller distorted d^7 complex.[91,92] Interestingly, electrochemical studies on the Pd(II) complexes (**30**) and (**31**) (Section 6.5) show that only the second can be reversibly oxidized to Pd(III).



(**39**)



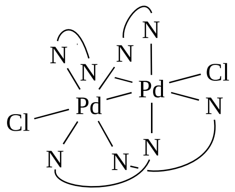
(**40**) (**41**)

(15)

The Pd(II) complex with mixed donor atoms $[Pd([9]aneNS_2)_2](BF_4)_2$ ($[9]aneNS_2$ = 1, 4-dithia,7–azacyclononane) has a primary NS coordination, but presents a purple–blue color due to long-range interactions to the two remaining S donors. Its cyclic voltammetry study shows two one-electron oxidations assigned to Pd(II)–Pd(III) and Pd(III)–Pd(IV) couples. Quantitative electrochemical oxidation affords orange solutions of $[Pd\ ([9]aneNS_2)_2]^{3+}$ in MeCN, which is shown by electron spin resonance (ESR) to contain a d^7 Pd center.[93]

The present overall picture seems to suggest that oxidation to Pd(III) requires to be electronically counterbalanced by an increase in coordination numbers to a distorted octahedral geometry, as found in the latter complexes discussed. In its absence, Pd(III) will withdraw more electron density from the ligands in a square-planar coordination (e.g. 1,2-dithiolenes), and the oxidation will become more ligand based.

A dinuclear complex of Pd(III), $[Pd_2(hpp)_4Cl_2]$ (hpp = the anion of 1,3,4,6,7,8-hexahydro-2H-pyrimido[1,2-α]pyrimidine), has been reported. The four bridging hpp ligands describe a paddle wheel–type structure. This compound presents the shortest Pd–Pd distance ever reported (239.1 pm), shorter than all reported Pd(I)–Pd(I) bonds, and 36 pm shorter than the Pd–Pd distance in the metal itself (**42**, N^N = hpp).[94]



(**42**)

8 COMPLEXES OF PALLADIUM(IV)

8.1 Introduction

Palladium(IV) is a hard metal center and therefore it requires strong σ-donor ligands to give stable species that are six-coordinated and octahedral. Pd(IV) complexes are usually prepared by oxidation of the analogous Pd(II) derivatives and halogens or nitric acid are generally used as oxidants. Thus, the dissolution of Pd in aqua regia and subsequent treatment with alkaline chloride affords $M_2[PdCl_6]$ complexes, which thermally decompose to give the stable Pd(II) chloropaladates. Although Pd(IV) compounds are not particularly difficult to attain, they are usually labile toward *Reductive Elimination*. Hence, species that have a trans-X configuration are easier to handle than the corresponding cis-X configuration, since the former are more resistant to the elimination of X_2 and to give Pd(II) derivatives.

8.2 Palladium(IV) Complexes Containing Group 17 and 16 Donor Atoms

Besides PdF_4 and the mixed valence compound $Pd^{II}[Pd^{IV}F_6]$ (see Section 3.1), the known halogen derivatives of Pd(IV) are the halocomplexes $[PdX_6]^{2-}$ (X = F, Cl, Br, I). Obtained by halogen oxidation (or, for $[PdI_6]^{2-}$, addition of excess CsI to $[PdCl_6]^{2-}$), they have been crystallized with a variety of alkali metal cations. $Cs_2[PdI_6]$ has been also obtained in the solid state by application of pressure to samples of $Cs_2[PdI_4]{\cdot}I_2$.[95]

Some Pd(IV) complexes with oxoanions have been prepared, including the hydroxide $[Pd(OH)_6]^{2-}$ and periodate or tellurate derivatives. S-containing anionic ligands such as dithiocarbamates have generally been more efficient in giving stable Pd(IV) complexes than the neutral donors, because of their higher basicity. However, stable $(NR_4)[PdX_5(EMe_2)]$ derivatives (R = alkyl; X = Cl, Br; E = S, Se) have been prepared. ^{77}Se NMR studies support the presence of Pd(IV) by the high-field shifts of the Se resonances in comparison with the corresponding Pd(II) complexes.

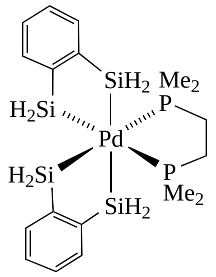
8.3 Palladium(IV) Complexes Containing Group 15 Donor Atoms

Amines and heterocyclic N-donor ligands form palladium(IV) complexes that have the stoichiometry $[PdCl_4L_2]$ (L = NMe_3, $NMeH_2$, piperidine, pyridine, α-picoline, etc.; L_2 = bipy, phen, biguanidine). They are prepared by chlorine oxidation of the corresponding Pd(II) complexes. The bromo derivatives are also known for the amines, although they are more difficult to obtain for the heterocyclic ligands (py, bipy). These complexes are thermally unstable and eliminate X_2 on heating. An X-ray crystal-structure determination of $[PdCl_4(bipy)]$ confirmed the expected cis octahedral geometry for the complex. $[PdCl_2(NH_3)_4]Cl_2$ and $(NR_4)[PdX_5L]$ (L = NMe_3, Py) have also been prepared. See also Section 7 for mixed valence complexes of the type $[Pd^{II}L][Pd^{IV}LX_2]Y_4$.

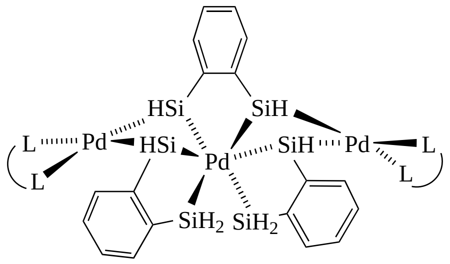
Palladium(IV) complexes with ligands containing heavier group 15 donor atoms are less stable than those with the harder N-donor ligands. Careful control of the oxidation conditions enables the synthesis of a number of $[PdCl_4L_2]$ (L = monodentate phosphine or arsine) or *cis*-$[PdCl_4(L{-}L)]$ (L–L = bidentate phosphine or arsine) complexes. *Trans*-$[PdX_2(L{-}L)_2](ClO_4)_2$ (X = Cl, Br; L–L = *o*-$C_6H_4(AsMe_2)_2$, *o*-$C_6H_4(PMe_2)_2$, *o*-$C_6F_4(PMe_2)_2$, $Me_2PCH_2CH_2PMe_2$) complexes have also been prepared and their trans octahedral geometry has been confirmed for the diarsine derivative by an X-ray diffraction study. The anions $[PdX_5L]^-$ are also known for phosphine and arsine ligands, and as for the N-derivatives, they are more stable than the neutral compounds.

8.4 Palladium(IV) Complexes Containing Group 14 Donor Atoms

Organometallic Pd(IV) complexes are not dealt with in this section (*see* ***Palladium: Organometallic Chemistry***). $[Pd(CN)_6]^{2-}$ has been prepared by metathesis of $[PdCl_6]^{2-}$ with KCN. The crystal-structure determination of $Cd[Pd(CN)_6]$ shows a perfect octahedral environment for Pd with Pd–C distances of 2.07(2) Å.[96]



(**43**)



(**44**)

The silylpalladium(IV) complex (**43**), which has also been structurally characterized by X-ray diffraction, is obtained by reaction of $[PdMe_2(dmpe)]$ with three equivalents of 1,2-disilyl-benzene. This reaction must involve oxidative addition steps of Si–H to Pd(II).[97] Closely related to this complex is the unusual, formally Pd(VI) complex $[Pd_3(H_2SiC_6H_4SiH_2)_3(L{-}L)_2]$ (L–L = diphosphine) (**44**).[98] The X-ray diffraction study of this complex revealed two short Si–Si contacts. Thus, the complex can also be understood as a Pd(II) derivative, as supported by theoretical calculations.

Glossary

Heck reaction: the palladium-catalyzed reaction of an aryl or vinyl halide with an alkene to give an arylated or vinylated alkene
Stille reaction: the palladium-catalyzed reaction of an aryl or vinyl halide with an organotin reagent, where one of the organic groups is alkynyl, aryl, or vinyl, to give a cross coupled product
Suzuki reaction: the palladium-catalyzed reaction of an aryl or vinyl halide with an aryl boronic acid to give an arylated or vinylated arene. In some cases, primary alkyl halides can react in place of the aryl or vinyl halides
Wacker process: the palladium-catalyzed oxidation of ethene to acetaldehyde by oxygen

1 INTRODUCTION

The organometallic chemistry of palladium is one of the most extensive and varied fields of transition metal organometallic chemistry. In many respects, the chemistry of palladium parallels that of platinum, as one would expect from its place in the periodic table. However, where a given compound might be a stable species in platinum chemistry, it will often be a reactive intermediate in some palladium-catalyzed process. Many of the more than 1000 research articles that are published each year in organopalladium chemistry deal with applications of palladium complexes to organic synthesis. These applications arise because palladium complexes readily form reactive adducts with many common, inexpensive classes of organic molecules, such as alkenes, alkynes, dienes, CO, and alkyl, aryl, and, vinyl halides. The resulting compounds, in turn, can be used to introduce new functional groups into organic molecules or change the framework of the organic moiety through carbon–carbon bond formation.

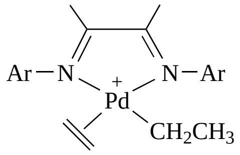
Four oxidation states of palladium are encountered in organometallic chemistry (*see* ***Palladium: Inorganic & Coordination Chemistry***).[1,2] In order of importance, they are Pd^{II}, Pd^{0}, Pd^{IV}, and Pd^{I}. With the reduction of palladium from Pd^{II} to Pd^{0}, the metal changes its reactivity from electrophile to nucleophile. However, unlike main group nucleophiles such as thiolates or cyanide, Pd^{0} complexes react with both alkyl halides and aryl or vinyl halides. Reactions of Pd^{0} complexes with these latter sp^2 halides generate new Pd^{II} aryl or vinyl bonds through the process of oxidative addition.

Derivatives of Pd^{II} are normally prepared from $PdCl_2$. This salt is insoluble in organic solvents, and nearly so in water. Thus, it is normally used in a solubilized form. Addition of MCl to $PdCl_2$, where M = Li, Na, or K, gives M_2PdCl_4, which is soluble in water and low-molecular weight alcohols. The Li salt is also soluble in a number of organic solvents. For increased solubility in organic media, $PdCl_2(PhCN)_2$ is a common starting material. It can be prepared simply by heating palladium chloride in benzonitrile. Upon cooling the solution, yellow–brown crystals of the complex are deposited.

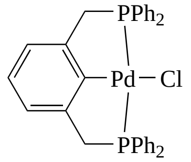
The more electrophilic reagent $Pd(OAc)_2$ is another useful reagent in organopalladium chemistry. It is monomeric in benzene at 80 °C, but is trimeric at room temperature in benzene. For even greater reactivity, $Pd(O_2CCF_3)_2$ can be used. Both the acetate and trifluoroacetate are soluble in organic solvents. Reaction of palladium acetate with acetylacetone produces $Pd(acac)_2$. This acetylacetonate and especially the hexafluoroacetylacetonate, $Pd(hfac)_2$, are useful as volatile sources of palladium in metalorganic chemical vapor deposition.

The organic derivatives of Pd^{II} include palladium alkyls, such as $PdMe_2(bpy)_2$ (bpy = 2,2′-bipyridine); π-allyl complexes, such as $Pd(\eta^3-C_3H_5)_2$ and $[Pd(\eta^3-C_3H_5)Cl]_2$; diene complexes including (1,5-cyclooctadiene)$PdCl_2$, cationic metal alkyls (**1**), and cyclometalated or cyclized diene complexes (*see Cyclometalation*) in which the palladium is in a chelate ring, bound to one or more ligand atoms such as N or P and also σ-bonded to a carbon, as typified by complex (**2**).

Pd^{II} is classified as a soft metal center.[3] Thus, it readily coordinates to polarizable ligands such as alkenes, dienes,



(**1**)

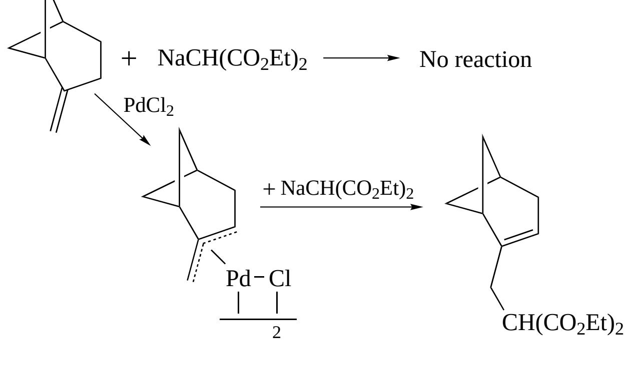


(**2**)

phosphines and phosphites, CO, σ-arenes, and σ-alkyls. In the case of alkene and π-allyl complexes, palladium coordination is able to reverse the reactivity profile of the organic ligand. While alkenes normally react with electrophiles such as H^+, Br_2, or R^+, when alkenes (or π-allyl complexes derived from alkenes) are coordinated to Pd^{II}, they undergo reactions with nucleophiles such as water, amines, and carbon nucleophiles including Pd^{II}-R groups and malonic ester anions (Scheme 1). This polarity reversal in the reactions of coordinated ligands is a major reason organopalladium compounds play such an important role in modern organic synthesis (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***).

The kinetics of reactions at Pd^{II} centers is an additional reason for the numerous synthetic applications of organopalladium complexes. The stereochemistry of Pd^{II} is almost exclusively square planar. When the rates of substitution at isostructural Ni^{II}, Pd^{II}, and Pt^{II} complexes are compared (equation 1), the relative rates of reaction are Ni^{II}, 5×10^6; Pd^{II}, 1×10^5; and Pt^{II}, 1.

$$\textit{trans}\text{-}(Et_3P)_2M(o\text{-tolyl})Cl + py \longrightarrow \textit{trans}\text{-}(Et_3P)_2M(o\text{-tolyl})py^+ + Cl^- \quad (1)$$



Scheme 1

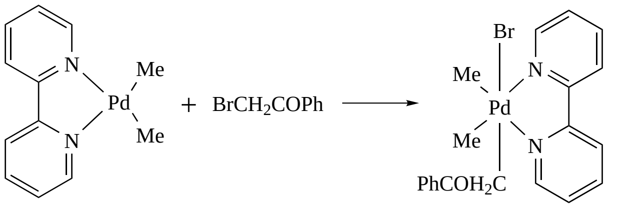
Thus, for many systems, compounds that would be reactive intermediates in palladium chemistry are stable species in platinum chemistry (*see* ***Mechanisms of Reaction of Organometallic Complexes***). Coupled to the kinetic lability of palladium versus platinum complexes is the thermodynamic advantage of bonds to the heavier element. In at least one case, bond dissociation energies of Pd–CH_3 bonds in an isolable compound ([Pd(bpy)Me_2]) are estimated to be 10% lower than the bond dissociation energy of a Pt−CH_3 bond in an isostructural compound (approximately 130 kJ mol^{-1} for Pd^{II} vs 145 kJ mol^{-1} for Pt^{II}) (*see* ***Bonding Energetics of Organometallic Compounds***).[4]

Complexes of palladium in the zero oxidation state are easily prepared and are important catalysts for transformations in organic synthesis. The tetrakis(triphenylphosphine)Pd^0 complex is one of the most used Pd^0 reagents. It can be synthesized from $PdCl_2(PPh_3)_2$ and hydrazine hydrate in DMSO. The yellow solid can be handled briefly in air without extensive decomposition, but it is best handled under an inert atmosphere. Solutions are rapidly oxidized by exposure to air. A second important source of Pd^0 is 'bis(dibenzylideneacetone)palladium(0)'. In fact, the stoichiometry of this preparation is $[Pd_2(dba)_3]$dba. The alkenes of the dibenzylideneacetone ligands bridge the two Pd^0 sites in this complex, leading to a short Pd−Pd distance of approximately 324 pm. Molecules with such contacts are generally deeply colored, and $[Pd_2(dba)_3]$ is a brown solid that gives purple solutions. An advantage of this Pd^0 reagent is that, as a solid and in solution, it is relatively insensitive to oxygen, but the organic ligands are easily displaced by many different ligands. For example, rather than trying to isolate a species such as $Pd(Pt\text{-}Bu_3)_2$, one adds two equivalents of $Pt\text{-}Bu_3$ to a $Pd_2(dba)_3$ solution. Since many palladium-catalyzed organic reactions go through a Pd^0−Pd^{II} catalytic cycle, the Pd^0 species is generated in situ. For example, a reaction is charged with a Pd^{II} compound such as $Pd(OAc)_2$ and ligands. One of the substrates in the reaction acts as a reducing agent, transiently producing a L_nPd^0 species.

Unlike Ni^0, Pd^0 does not form a stable binary carbonyl. When $PdCl_2$ is carbonylated in acetic anhydride, reduction takes place to give the polymeric $[Pd(CO)Cl]_n$. However, $Pd(CO)_4$ can only be prepared and studied using matrix-isolation techniques.

There is continuing interest in the organometallic chemistry of Pd^{IV}.[5] This oxidation state has often been invoked as an intermediate in the reactions of Pd^{II} species with reactive acyl or alkyl halides. Spectroscopic evidence has been obtained for this hypothesis. When phenacyl bromide reacts with dimethylpalladium(II) complexes, such as $PdMe_2$(bpy), a complex can be isolated at 0 °C, which is shown, by ^{1}H NMR and X-ray crystallography, to be $PdBrMe_2(CH_2COAr)$(bpy) (equation 2). The same complex reacts with MeI to form $PdIMe_3$(bpy). The d^6 Pd^{IV} complexes are expected to exhibit

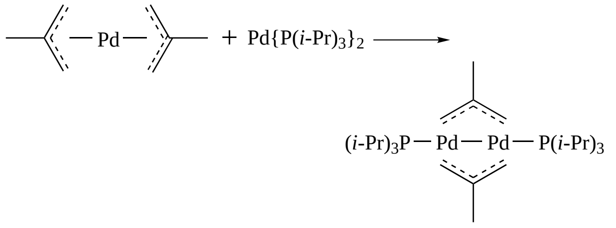
octahedral geometries and to be kinetically inert.



(2)

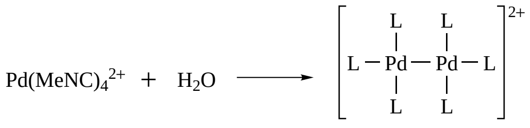
There is one report of a formally hexavalent Pd^{VI} complex.[6] Heating 1,2-$C_6H_4(SiH_3)Pd^{II}$(dmpe), where dmpe = 1,2-bis(dimetylphosphino)ethane, in toluene gives a trinuclear complex with the central palladium ligated to six silicon atoms. Two of the Pd–Si distances are normal, ~240 pm, while four of the Pd–Si distances are considerably longer, ~250 pm. This asymmetry could be explained if the central Pd atom is a bis σ-complex of Pd^{II} with two Si–Si bonds, instead of a Pd^{VI} derivative.

The organometallic chemistry of Pd^{I} has expanded considerably over the last few decades. Because Pd^{I} has the d^9 electronic configuration, a monomeric complex would be paramagnetic. However, the reported Pd^{I} organometallic complexes are dimeric, with Pd^{I}–Pd^{I} bond lengths on the order of 260 pm, twice the covalent radius of palladium. Many Pd^{I} compounds are synthesized by mixing an equimolar amount of a Pd^{II} and Pd^{0} compound. A number of Pd^{I} dimers exist with bridging Cp or π-allyl ligands. For example, the reaction of the $Pd^{II}\pi$-allyl compound $[CH_2C(Me)CH_2]_2Pd$ with the Pd^{0} complex Pd(P-i-$Pr_3)_2$ gives the Pd^{I} dimer $\{[CH_2C(Me)CH_2](P\text{-}i\text{-}Pr)_3Pd\}_2$ (equation 3).



(3)

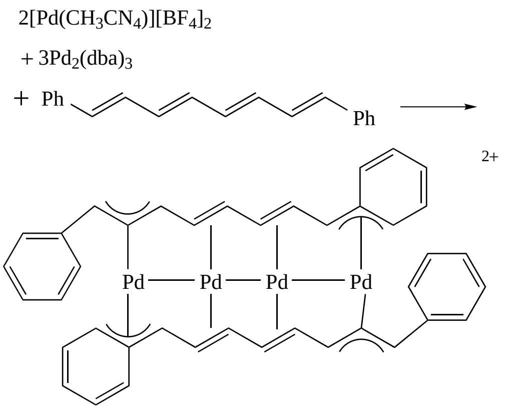
Isocyanide ligands have been found to promote the formation of Pd^{I} dimers. When an aqueous solution of $[Pd(MeNC)_4]^{2+}$ is prepared, disproportionation to produce $(MeNC)_3Pd$–$Pd(MeNC)_3{}^{2+}$ takes place (equation 4). Several different isocyanides can be used in this reaction, and PPh_3 will displace one or two of the isocyanide ligands. The unsupported metal–metal bond is not particularly reactive, but irradiation at 315 nm will generate the reactive metal radical $Pd(MeNC)_3{}^{+}$.



(4)

L = MeNC

Metal–metal bonded chains of $Pd_n{}^{2+}$ units form in good yield when a combination of one Pd^{II} species and $(n-1)Pd^{0}$ species are sandwiched between two polyene chains (equation 5). With the appropriate polyene, chains of three to five palladium atoms can be constructed.



(5)

The numerous palladium-catalyzed organic reactions have a relatively small number of elementary steps. *Oxidative Addition*, *Reductive Elimination*, ligand coordination, and addition to coordinated ligands (either intramolecular or intermolecular) are the most important classes of transformations in most palladium catalytic cycles. The exact nature of the species within the coordination sphere of palladium and the order in which the steps take place are responsible for the variety of the organic products produced. Four representative and important palladium-catalyzed reactions are briefly discussed here to illustrate the range of organopalladium reactions.

The oxidation of ethene by palladium salts in water to give acetaldehyde has been known for 100 years (*see* ***Oxidation Catalysis by Transition Metal Complexes***). It is often called the *Wacker Process*, after Wacker Chemie GmbH, which first developed the process. The key steps in this oxidation are shown in Scheme 2.[7] Palladium catalyzes the nucleophilic addition of water to ethene, leading to the reduction of Pd^{II} to Pd^{0}. Then the palladium is reoxidized back to Pd^{II} with Cu^{II} salts, giving Cu^{I}, which in turn is oxidized by oxygen.

A more detailed catalytic cycle is shown in Scheme 3, which takes into account the other ligands on the metal. Even in a scheme as detailed as Scheme 3, some information is lacking. For example, it is not made clear whether attack of water on the ethene double bond is cis to the metal or trans.

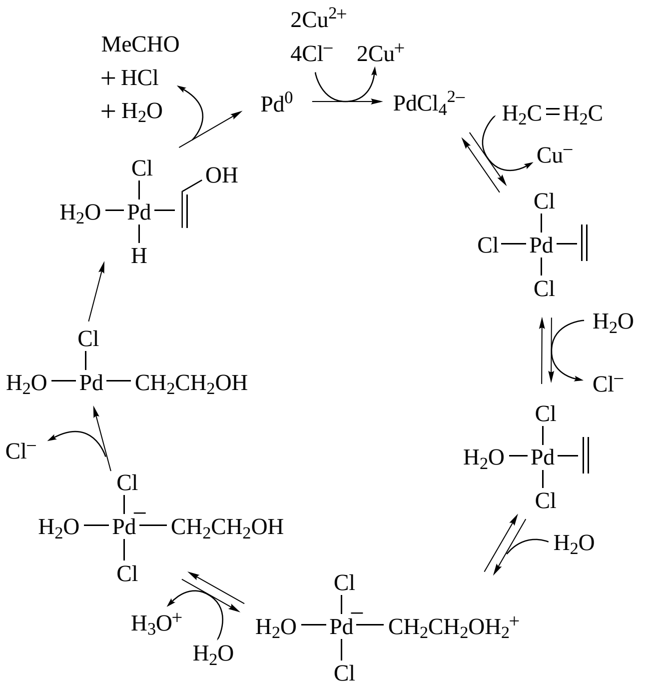
$$H_2O + H_2C{=}CH_2 + Pd^{II} \longrightarrow MeCHO + Pd^{0} + 2H^{+}$$

$$Pd^{0} + 2Cu^{II} \longrightarrow Pd^{II} + 2Cu^{I}$$

$$2Cu^{I} + \frac{1}{2}O_2 + 2H^{+} \longrightarrow 2Cu^{II} + H_2O$$

$$H_2C{=}CH_2 + \frac{1}{2}O_2 \longrightarrow MeCHO$$

Scheme 2

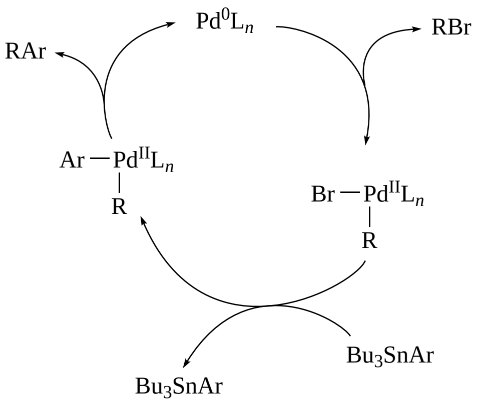


Scheme 3

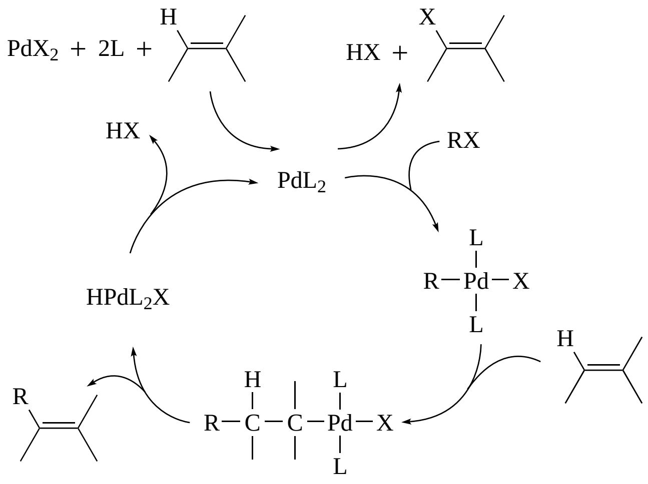
Evidence exists for both possibilities, as will be discussed in Section 9.

A second important palladium-catalyzed process is cross coupling of an aryl or alkenyl tialkyltin reagent with an alkyl or aryl halide. In this reaction, one carbon–palladium bond is generated by transmetalation of Pd^{II}-X with Bu_3Sn-R, while the other carbon–palladium bond is formed by oxidative addition of an organic halide with a Pd^0L_n species. This reaction, which is tolerant of many organic functional groups, is normally known as the Stille Reaction (Scheme 4).[8]

The *Heck Reaction* is the name given to the palladium-catalyzed vinylation of organic halides.[9] It is applicable to a wide range of alkenes, although it is limited to aryl and vinyl

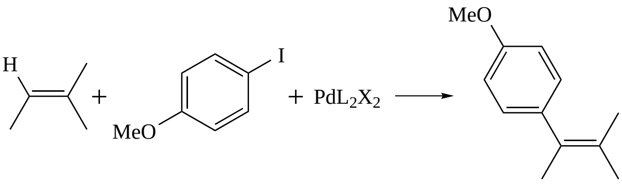


Scheme 4



Scheme 5

halides or tosylates (equation 6). A simplified catalytic cycle is shown in Scheme 5. The reason for the limitation to aryl and vinyl halides is due to the facile *β-Elimination* of hydrogen from palladium alkyls. For many processes, *β*-elimination is competitive with reductive elimination of carbon groups.



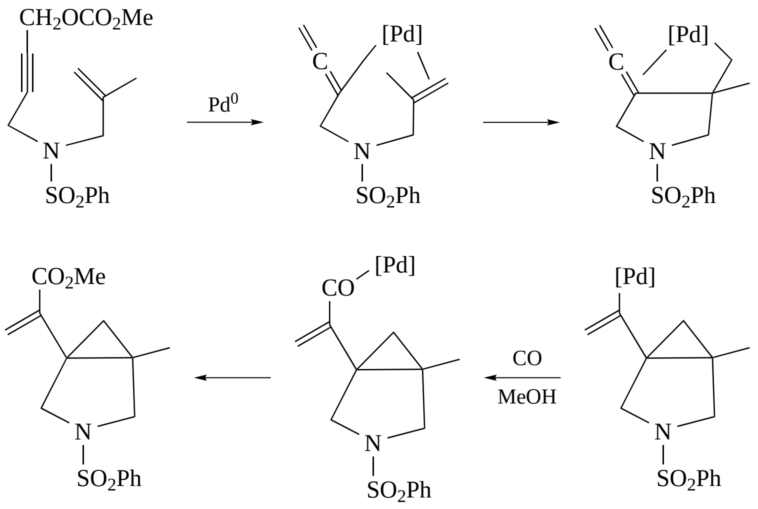
(6)

Palladium catalysts are increasingly used to make complex organic structures, where several framework carbon–carbon bonds are formed in one flask. Many of these processes are examples of 'atom economy' in synthesis, where a catalyst promotes addition reactions, and all of the atoms in the starting materials appear in the products.[10] The process in Scheme 6 illustrates this principle. A Pd^0 nucleophile reacts with a propargylic carbonate to give a σ-allenyl intermediate, where [Pd] indicates a Pd species with undetermined ligands. Sequential insertion of the [Pd]–C bond into coordinated alkenes leads to a σ-vinyl complex. Carbon monoxide inserts into the Pd–vinyl bond, giving a palladium acyl, which reacts with methanol to give the ester final product in 80%.

2 STRUCTURE AND SPECTROSCOPY OF ORGANOPALLADIUM COMPOUNDS

2.1 Structural Aspects of Organopalladium Compounds

The coordination geometry of organopalladium compounds is quite regular (*see* ***Coordination Numbers & Geometries***).



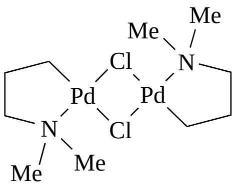
Scheme 6

Complexes of zero-valent palladium (d^{10}) are tetrahedral if the coordination number is four, trigonal if the coordination number is three, and linear if the coordination number is two. For Pd^{II} (d^8), the geometry is square planar, unlike Ni^{II}, which is normally octahedral, but like Pt^{II}. With a very bulky ligand, 14-electron three-coordinate T-shaped species can be stabilized and structurally characterized. For example, the complex Pd(Ar)I[P(t-Bu)$_3$], where Ar = 2,4-xylyl, can be isolated and the aryl group is opposite the open coordination site.[11] For the few Pd^{IV} (d^6) complexes that have been structurally characterized, octahedral geometry is found.

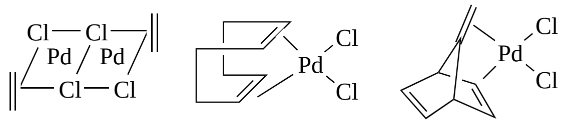
Bonds between palladium and carbon groups are covalent, as their Pauling electronegativities would predict (Pd; 2.2; C; 2.5; H; 2.1). The covalent radius of palladium is 128 pm. This leads to expected bond lengths of 207 pm for Pd–C(sp^3) bonds, 196 pm for Pd–C(sp^2) bonds, and 190 pm for Pd–C(sp) bonds. In general, the experimentally determined bond lengths are within a few percent of these values. The bond lengths for Pd^{II}–Me bonds and Pd^{IV}–Me bonds are essentially the same, which suggests that the covalent radii for these two oxidation states are the same.

All carbon groups have a strong *Trans Influence*, which means groups trans to the Pd–C bond are lengthened relative to most other groups. For example, in the simple chelate (**3**), the Cl trans to the CH_2 group has a Pd–Cl bond length of 252 pm, while the Cl trans to the tertiary amine has a Pd–Cl length of 234 pm. Acyl groups are especially strong trans influence groups.

Alkene and diene complexes of Pd^{II} have the C–C axis of the double bond perpendicular to the palladium square plane, as in (**4**) and (**5**). Steric, rather than orbital factors, favor this coordination geometry for d^8 metals. With a properly designed ligand, such as 7-methylenebicyclo[2.2.1]hept-2-ene, one alkene can be constrained to lie in the coordination plane (**6**). Coordination lengthens the carbon–carbon alkene bond by 3–6%. Buckminsterfullerene, C_{60}, forms isolable complexes with up to six Pd(PEt$_3$)$_2$ units. The palladium atoms lie over a 6–6 ring junction, with the carbon and phosphorus atoms in the same plane and the C–C bond lengths increased ~7pm.



(**3**)

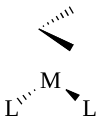


(**4**) (**5**) (**6**)

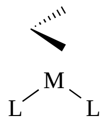
Most stable Pd–alkyne complexes are of Pd^0 species with electron-poor alkynes. Dimethyl acetylenedicarboxylate forms Pd(MeO$_2$CC$_2$CO$_2$Me)(PPh$_3$)$_2$, which has a trigonal geometry, with both P atoms and both alkyne carbons coplanar. The C–C–CO$_2$Me angle is decreased to 145° and the alkynic C–C bond is lengthened to 128 pm. The bridging alkyne complex Pd$_2$(C$_5$Ph$_5$)$_2$(μ-C$_2$Ph$_2$) has also been structurally characterized. Bridging by the alkyne group increases the C–C bond to 133 pm.

Palladium forms many complexes with η^3-allyl, or π-allyl, ligands. In these complexes, the π-allyl ligand and the other groups coordinated to palladium adopt a

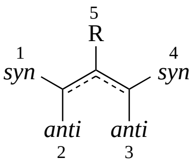
square-planar geometry (**7a**) as opposed to a tetrahedral geometry (**7b**). In symmetric complexes, such as $Pd_2Cl_2(\eta^3\text{-}C_3H_5)_2$, the carbon–carbon bonds have equivalent lengths of approximately 136 pm. The Pd–C1 and Pd–C3 distances in structure (**8**) are equal, at 212 pm, but in most cases C2 is closer to the metal. The plane containing the C_3H_5 group is not strictly perpendicular to the Cl_2Pd plane, but is tilted to make an angle of approximately 111°. The anti groups in (**8**) are tilted slightly toward the palladium center, as is the group on carbon C2. The syn groups are tilted slightly away from the metal.



(**7a**)

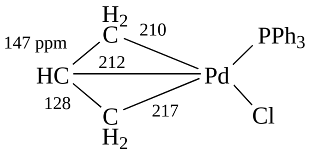


(**7b**)



(**8**)

In the asymmetrically substituted π-allyls, such as $Pd(\eta^3\text{-}C_3H_5)Cl(PPh_3)$ (**9**), the greater trans influence of PPh_3 versus Cl leads to marked asymmetry in the bonding of the C_3H_5 group. The Pd–C bond trans to PPh_3 is lengthened, and the associated carbon–carbon bond length is shortened. Numerous structural and molecular mechanics studies have been carried out on π-allyl complexes with chiral ligands, such as CHIRAPHOS ($Ph_2PCHMeCHMePPh_2$). The object has been to establish the chiral environment around palladium in order to understand and develop new catalysts for enantioselective reactions.[12]



(**9**)

2.2 Infrared Spectroscopy of Organopalladium Compounds (*See Transition Metal Carbonyls: Infrared Spectra*)

Matrix-isolation techniques permit the isolation of $Pd(CO)_4$ in a CO matrix. This unstable species exhibits a ν_{CO} of 2066 cm^{-1}. The analogous $Pt(CO)_4$ gives ν_{CO} of 2044 cm^{-1} and the ν_{CO} of $Ni(CO)_4$ is 2037 cm^{-1}. The increase in ν_{CO} is further indication that $d_\pi - p_\pi$ bonding decreases in the order Ni > Pt > Pd. In general, platinum carbonyls have a lower ν_{CO} value than isostructural palladium complexes.

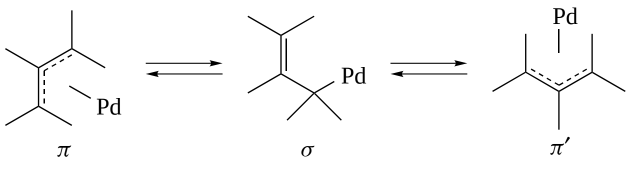
Terminal Pd–H groups will normally be observed in the range 2060–1950 cm^{-1}; however, the assignment of such a band should be confirmed by NMR or investigation of the analogous Pd–D compound, if carbonyl ligands are present. IR spectroscopy can aid in the identification of some Pd–C groups. Palladium acyls generally have a strong absorption between 1630 and 1720 cm^{-1}. σ-bonded palladium alkynes have an absorption band of variable intensity between 1950 and 2125 cm^{-1}, and σ-alkenes have $\nu_{C=C}$ between 1535 and 1630 cm^{-1}.

As with CO, coordination of an alkene to palladium lowers the stretching frequency of the unsaturated group, but to a lesser extent than in the analogous platinum compound. In $Pd_2Cl_4(C_2H_4)_2$, the coordinated ethene group has a $\nu_{C=C}$ of 1527 cm^{-1}, compared to 1623 cm^{-1} for free ethene and 1516 cm^{-1} for the analogous Pt complex.

2.3 NMR Spectroscopy of Organopalladium Compounds (*See Stereochemical Nonrigidity of Organometallic Complexes*)

The ^{105}Pd nucleus (22.2% natural abundance) is, unfortunately, not a useful nucleus for NMR measurements, given the fact that it is spin 5/2, with a large quadrupole moment. ^1H and ^{13}C NMR, however, have been used extensively in structural and mechanistic studies of organopalladium compounds. The NMR spectra of π-allyl complexes illustrate these applications. In $Pd_2Cl_2(\eta^3\text{-}C_3H_5)_2$, the proton at C_2 is seen at 5.42δ the syn protons (syn to C2 substituent) at 4.11δ, and the anti protons (anti to C2 substituent) at 3.06δ. In general, groups in the anti position of a π-allyl complex are more shielded. A σ-allyl is expected to produce an $ABCX_2$ spin system. If there is dynamic equilibrium, the protons on C1 and C3 can all exchange, leading to an AX_4 spin system (Scheme 7). If the π-allyl system is asymmetric, each proton can exhibit a distinct chemical shift.

Coupling constants are a valuable aid in structure assignment of π-allyls. $J_{1,2}$ is very small, less than 1 Hz. The trans coupling, $J_{2,5}$ or $J_{3,5}$, is larger, on the order of 12 Hz, compared to the cis coupling of $J_{1,5}$ or $J_{4,5}$, which is near 7 Hz. The ^{13}C NMR of the π-allyl carbons gives very different chemical shifts for C2 versus C1 and C3. In $Pd_2Cl_2(C_3H_5)_2$, for example, C1 and C3 occur at 55.8δ while C2 is at 113.5δ. The simplest rationale comes from resonance theory, where the π-allyl can be thought of as a resonance hybrid of two σ-allyl structures, which gives C1 and C3 some single bond character. 2-D NMR techniques such as NOESY can be used to establish the solution structure of organopalladium compounds. For complexes with phosphorus ligands, 2D ^{31}P-^1H correlation



Scheme 7

spectroscopy is useful for resonance assignments in complex cases.

3 STABILITIES OF ORGANOPALLADIUM COMPOUNDS

3.1 Bond Dissociation Enthalpies[13]

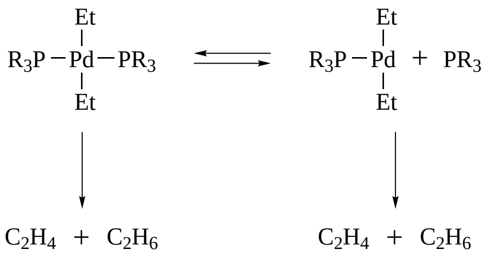
Relatively few bond dissociation enthalpies for organopalladium compounds have been obtained. For (Pd–C_3H_5) in the dimer $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$, a value of 105 kJ mol^{-1} was obtained using differential scanning calorimetry. In $Pd(Cl)_2$(1,5-cod), a Pd–Cl bond dissociation enthalpy of 215 kJ mol^{-1} was calculated, and Pd−(1,5-cod) was calculated to be 169 kJ mol^{-1}. An estimate for the mean Pd–CH_3 bond dissociation enthalpy in $PdIMe_3$(bpy) was 136 kJ mol^{-1}. Energetics of bond dissociation energies for fragments in the gas phase give values of 247 ± 21 kJ mol^{-1} in Pd–CH_3^+. The N-heterocyclic carbene *cyclo*-C[N*t*-BuCH]$_2$, NHC, dissociated from Pd(NHC)(Ac)Cl with an enthalpy of 107 kJ mol^{-1}. The average bond dissociation energy in $PdMe_2$ was calculated to be 158 kJ mol^{-1}, using the generalized valence bond approach. Most theoretical calculations on organopalladium bond dissociation enthalpies use simplified ligands, such as PH_3 or NH_3. Different levels of theory can produce qualitatively different results (*see* ***Bonding Energetics of Organometallic Compounds***).[14]

3.2 Reactions of Pd–C Bonds via Reductive Elimination and β-elimination

If inorganic palladium salts are treated with C_2H_5Li, one obtains a mixture of ethane, ethene, and butane. The ethane and ethene arise from β-elimination reactions, while the butane arises from reductive elimination. For β-elimination to take place, there must be a vacant coordination site on palladium to accept the β-hydrogen of the alkyl group. The nature of the ligands on palladium determine the stability and course of the decomposition of palladium alkyls. In addition, alkyl groups in a chelate ring are resistant to β-elimination. The ring prevents a conformation in which the metal and β-hydrogen can interact.

In the case of *trans*-$[PdEt_2(PR_3)_2]$, where the phosphines include PEt_3, PMe_2Ph, and $PEtPh_2$, warming to between 25 and 32 °C caused decomposition to equimolar amounts of ethane and ethene.[15] Essentially, no butane is formed. Added phosphines had little effect on the rate of the reaction. Kinetic studies are consistent with the mechanism shown in Scheme 8, in which β-elimination takes place predominately from the four-coordinate complex, with only minor reaction from the partially dissociated species $[PdEt_2(PR_3)]$.

Using the complex $[PdEt_2(bpy)]$, thermolysis at 80 °C also produces ethane and ethene. However, addition of methyl



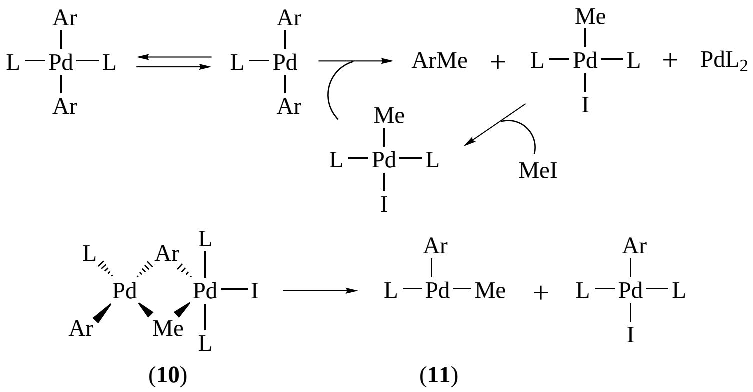
Scheme 8

acrylate reverses the product composition, and leads to butane formation. In the absence of the alkene, the complex is 16-electron, and thus, a vacant coordination site is available for β-elimination. In the presence of the alkene, the complex is 18-electron, and C–C reductive elimination is the preferred reaction path. The greater steric bulk of the phosphine ligands in Scheme 8 prevents the formation of an 18-electron complex when excess phosphines are added.

The presence of halide ions can influence whether β-heteroatom or β-hydride elimination occurs. When palladium alkyls of the type $PhCH_2CH[Pd^{II}]CH_2OAc$ were generated by insertion of an allylic acetate into a $[Pd^{II}]$–Ph bond, β-hydride elimination to give $PhCH{=}CH{-}CH_2OAc$ was the exclusive product. However, in the presence of excess LiCl, the major product was $PhCH_2CH{=}CH_2$ from β-elimination of –OAc. The role of LiCl may be to form highly charged $RPdX_4^{3-}$ complexes that promote an E2-like mechanism for β-heteroatom elimination.

Theoretical studies of Pd^{II} dimethyl complexes indicate that reductive elimination of ethane requires a cis arrangement of alkyl groups on palladium. In the four-coordinate complexes, increasing the σ-donating capability (*see σ-Donor*) of the leaving groups promotes reductive elimination. Thus, reductive elimination of CH_3 groups should be more facile than CH_2F groups, for example. Stronger donor ligands trans to the leaving groups are predicted to increase the barrier to elimination. In addition, reductive elimination from a three-coordinate $[PdMe_2(PR_3)]$ species with adjacent methyl groups had a lower activation energy than reductive elimination from a four-coordinate complex, a result supported by experimental results.[16] The hybridization of the group undergoing reductive elimination affects the ease of reductive elimination. Formation of an R–H bond typically has a lower activation energy than formation of an R–R bond, and reductive elimination of two sp^2 groups is more facile than two sp^3 groups. This arises from the shape of the orbitals on the groups undergoing reductive elimination. The greater the *s* character to the orbital, the more spherical, less directional, it is. Thus, the orbital can have more multicentered bonding in the transition state, leading to lower activation energies for reductive elimination.

Reductive elimination in palladium complexes can take place through intermolecular exchange of organic groups.



Scheme 9

Reaction of *trans*-[$PdAr_2(PEt_2Ph)_2$] with MeI gives good yields of ArMe. Mechanistic studies show that most of the elimination product arose not from a Pd^{IV} intermediate, but from a cis Pd^{II}-aryl methyl complex (**11**), which comes about from exchange in a complex such as (**10**), as shown in Scheme 9.

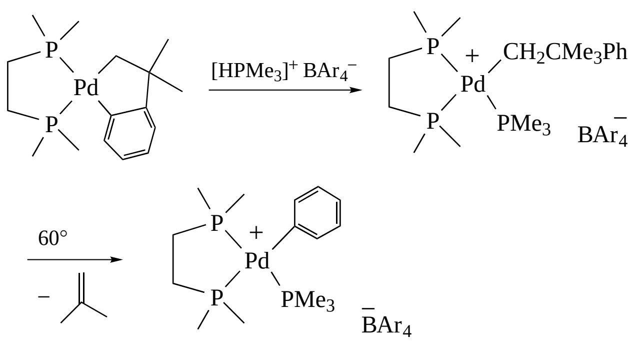
For palladium complexes with chelating diphosphine ligands, the bite angle of the ligand has a major influence on the rate of reductive elimination.[17] In $P_2PdMePh$ complexes where P_2 was either 1,3-(diphenylphosphino)propane (dppp), 1,1′-(diphenylphosphino)ferrocene (dppf), or 1,1′-(diphenylphosphino)ruthenocene (dppr), the species with the largest bite angle, the dppr complex, underwent reductive elimination the fastest (rapid decomposition above −5 °C). In contrast, the (dppp)PdMePh complex was stable for hours at room temperature. The nature of the $C_{sp}{}^3$ group also influenced stability, since the σ-vinyl complexes were less stable than the phenyl complexes.

The reagents used to generate a PdR_2L_2 species can have a controlling effect on the outcome of reductive elimination. A stoichiometric reaction between LiC_2-*t*-Bu and $PhPd(PPh_3)_2I$ gave the coupling product PhC_2-*t*-Bu via formation of the mixed Pd dialkyl followed by reductive elimination. However, when a catalytic reaction is attempted between PhI and LiC_2-*t*-Bu, using $Pd(PPh_3)_4$ in catalytic amounts, no coupling to give PhC_2-*t*-Bu occurs. Nevertheless, a catalytic reaction using $Pd(PPh_3)_4$, PhI, and $ClZnC_2$-*t*-Bu as the acetylide source gives PhC_2-*t*-Bu in 90% yield. An excess of the nucleophilic LiC_2-*t*-Bu caused the formation of $Li_2Pd(C_2$-*t*-$Bu)_4$. This complex does not readily decompose to give *t*-BuC_2–C_2-*t*-Bu. The less nucleophilic zinc reagent does not form the $PdR_4{}^{2-}$ species, which accounts for its successful use in the catalytic coupling reaction.

3.3 Decomposition Pathways for Pd^{II} Alkyls Lacking β-hydrogens

Several decomposition pathways exist for monoalkylpalladium(II) complexes, which lack β-hydrogens.[18] The compound *trans*-$Pd(CH_2Ph)(Cl)(PPh_3)_2$ (**12**) can be heated for 8 h in benzene at reflux. However, the addition of $PdCl_2(PhCN)_2$, which acts as a phosphine sponge, causes the quantitative formation of $PhCH_2Cl$. When Ag^I is used to abstract Cl^- from (**12**) in $CD_3C_6D_5$ solution at 85 °C, a 1:1 mixture of *o*- and *p*-$CD_3C_6D_4CH_2C_6H_5$ is produced. No radicals appear to be generated in this reaction. When the cationic complex $Pd(PPh_3)_2(CD_3CN)(CH_2Ph)^+ BF_4^-$ (**13**) is prepared and heated to 65 °C in C_6D_6–$CDCl_3$, a mixture of $C_6H_5CH_3$ and $C_6H_5CH_2CH_2C_6H_5$ is obtained, indicating that heating (**13**) generates benzyl radicals. Apparently, for arene alkylation to take place, it is necessary for the arene to be coordinated to the metal. Thus, the alkyl group in $Pd(PPh_3)_2(CD_3CN)(CH_2Ph)^+ BF_4^-$ behaves as a carbocation to coordinated arenes, but undergoes Pd–R bond homolysis in the absence of coordinated arene.

When the methyl complex $Pd(PPh_3)_2(I)(Me)$ is treated with Ag^I in C_6D_6 at 85 °C, the only product is PPh_3Me^+. No benzene alkylation takes place. Heating the cationic $Pd(PPh_3)_2(CD_3CN)(Me)^+$ also produces only PPh_3Me^+. The relative instability of methyl radical probably accounts for the different reaction paths of the benzyl and methyl cationic complexes. When phosphonium salt formation is not possible, for example, in the neopentyl complex



Scheme 10

cis-Pd(bpy)(CH_3CN)(CH_2CMe_3)$^+$ BF_4^-, heating at 70 °C gives only CMe_4. This product presumably arises from the neopentyl radical, since a carbocation would give rearrangement products.

Reductive elimination of C_{alkyl}–C_{aryl} bonds can take place when β-hydride elimination is blocked. As shown in Scheme 10, β-aryl reductive elimination occurs in neophyl, –CH_2CMe_2Ph, complexes. This reaction is a rare example of unstrained C–C bond activation in organopalladium chemistry.

4 COMPLEXES WITH Pd–C σ-BONDS

4.1 Formation of Pd–C Bonds

4.1.1 Transmetalation of Pd–X by R–M Reagents

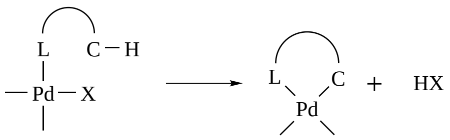
A large number of basic R–M reagents, where M can be various metals, will transfer an alkyl, aryl, vinyl, or acetylide group to Pd (normally Pd^{II}), displacing a halide or pseudohalide group. Reagents most often used are R_3B, $RB(OH)_2$, R_4Sn, RMgBr, RLi, $LiCuR_2$, and aluminum alkyls. A sample of palladium complexes with Pd–C σ-bonds prepared in this way is given in Table 1.

Most transmetalations with basic organometallics are done in ether or THF solvents at 0 °C to −78 °C. In general, alkyl *Grignard Reagents* will displace only one halide from L_2PdX_2 complexes, while lithium reagents will replace both halides. Chelating ligands, such as $Ph_2PCH_2CH_2PPh_2$ or 2,2′-bipyridyl, favor the isolation of derivatives with alkyl groups possessing β-hydrogens, although such compounds will often slowly decompose in solution at or slightly above room temperature. R_4Sn and $RB(OH)_2$ transfer alkyl groups and are unreactive with most functional groups.

Many transmetalation reactions take place as part of a catalytic cycle. For example, aryl (as well as heterocyclic and vinyl) halides, tosylates, and triflates form biaryls with numerous aryl-metal partners.[19] The cross-coupling reactions (which are increasingly being used to prepare other products besides biaryls) are usually named after the chemists who developed the reaction. The most important of these name reactions are summarized in Table 2.

4.1.2 Cyclometalation

The reaction of palladium reagents with amines, phosphines, and other organic ligands to produce chelated complexes with Pd–C bonds is the *Cyclometalation* reaction (equation 7).[20] It has been used to synthesize thousands of complexes with Pd–alkyl and Pd–aryl bonds. These complexes are beginning to be used as very stable, high turnover number catalysts and as intermediates in the synthesis of complex natural products. The scope and limitations of this reaction are detailed in Section 8.



(7)

4.1.3 Oxidative Addition

The reaction of Pd^0 complexes (such as $Pd(Ph_3P)_4$) with organic halides and related compounds has been used to prepare a number of stable Pd^{II} alkyl and vinyl compounds. This reaction with alkyl halides has the characteristics of an S_N2 reaction. Primary halides react faster than secondary halides. Also, when a chiral halide is used, such as (*S*)-(+)-benzyl-α-D chloride, the benzyl palladium product is formed with inversion of configuration at the benzylic carbon (equation 8). With vinylic halides, retention of configuration at the double bond is observed

Table 2 Palladium-catalyzed biaryl couplings: ArM + Ar′X → Ar–Ar′

Aryl-metal source	Reaction name
ArMgBr	Kumada

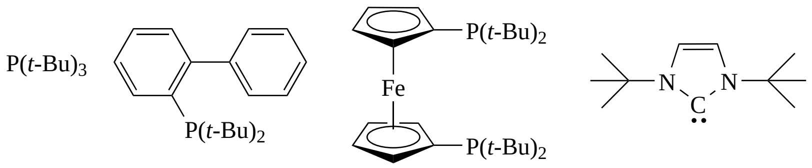
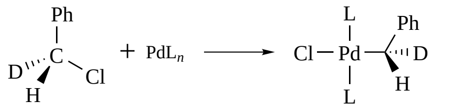
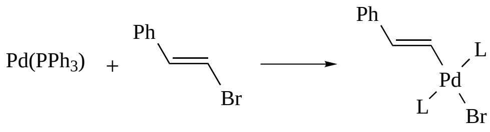


Scheme 11

(equation 9). Aryl halides reactivity with Pd^0 complexes is normally ArI > ArBr, ArOTf > ArCl.[21] Since aryl chlorides are much cheaper than the other derivatives, it was a major advance to find ligands for Pd^0 that promoted oxidative addition of ArCl at 25–100 °C. Major types of ligands that promote ArCl oxidative addition are electron-rich, bulky trialkylphosphines, dialkylbiphenylphosphines, and N-heterocyclic carbene ligands.[22] Pd^0 complexes of these phosphine ligands for catalytic reactions are often prepared by adding one or two equivalents of the ligand to $[Pd_2(dba)_3]$. Representative ligand structures are given in Scheme 11. It is usually assumed that L_2Pd^0 or LPd^0 species are the species undergoing oxidative addition with these bulky ligands in catalytic reactions. However, many reactions are carried out in the presence of strong bases, such as NaO-*t*-Bu. A $[LPd(OR)]^-$ anion can be the kinetically important species in such reactions. The aryl and vinyl Pd^{II} compounds that result from oxidative addition are useful reagents in organic synthesis for cross-coupling reactions, as described in Sections 4.2 and 10.



(8)

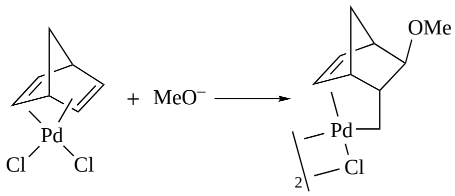


(9)

Acylpalladium complexes are readily prepared through oxidative addition of Pd^0 complexes to acid chlorides.[23] PdL_4 compounds, where L is a tertiary phosphine, react with acid chlorides at room temperature to give *trans*-$L_2Pd(COR)Cl$ complexes. Since carbon monoxide does not insert into palladium acyl bonds, $Pd(COCO_2R)$ complexes are made from oxidative addition of oxalyl chloride monoesters.

4.1.4 *Addition of Nucleophiles to Palladium-coordinated Alkenes, Dienes, and Related Compounds*

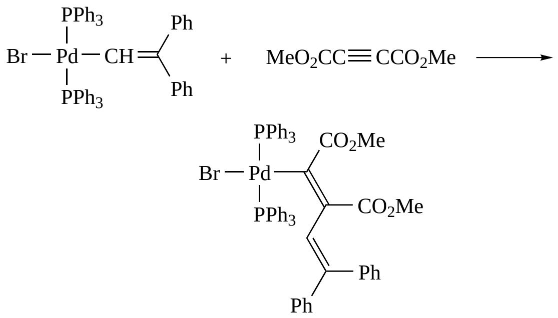
A reaction of considerable generality is the attack of a nucleophile (such as an alkoxide, alcohol, amine, or enolate) on an alkene–Pd^{II} complex. One example is given in equation (10). This reaction will be discussed in detail in Section 5.



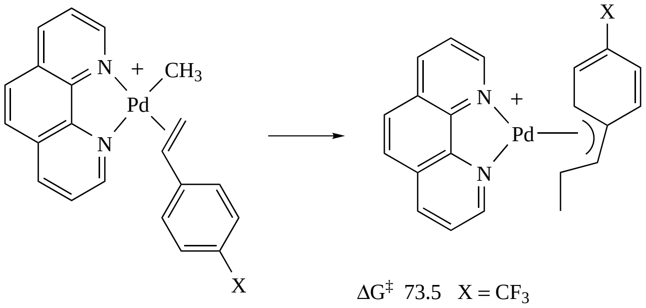
(10)

4.1.5 *Addition of Pd–R to Alkenes and Alkynes*

Complexes with a Pd–C bond will add across alkynes to form vinyl complexes. Alkynes with electron-withdrawing groups are the most reactive in such additions, such as dimethyl acetylenedicarboxylate and hexafluoro-2-butyne. The stereochemistry of addition is cis. Examples exist of alkyl, aryl, and alkynyl Pd^{II} complexes undergoing reaction (equation 11). The addition of a Pd–R group across an alkene can also be seen as the migratory insertion of an alkene into a Pd–C bond. The addition of palladium and carbon is cis and the alkyl group is added preferentially to the less-hindered carbon. Alkenes with electron-withdrawing groups tend to insert fastest (equation 12).[24]



(11)



$\Delta G^{\ddagger}$ 73.5 X = CF_3
$kJ\ mol^{-1}$ 76.0 X = H
76.9 X = CH_3

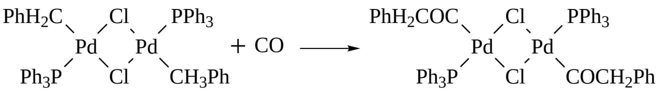
(12)

4.1.6 Addition of Pd–H to Unsaturated Groups and Alkene Isomerization

As with Pd–C bonds, Pd–H will add to unsaturated functional groups (*see* ***Hydride Complexes of the Transition Metals***). In the case of alkynes, the Pd–H addition is cis, to give vinyl complexes. The addition of a Pd–H bond to an alkene will normally generate a Pd^{II} alkyl with β-hydrogens, which can undergo further β-elimination. This process can lead to alkene isomerization. However, palladium complexes have not proved as useful as those of other transition metals for alkene isomerization. While 1,5-cyclooctadiene can be isomerized to 1,3-cyclooctadiene with $PdCl_2(PhCN)_2$, palladium on charcoal is a more convenient and active catalyst for this isomerization.

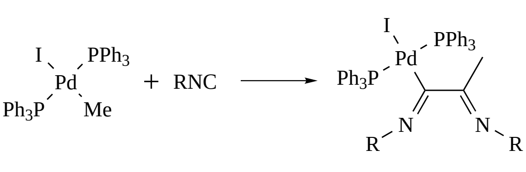
4.1.7 Insertion of CO and Isonitriles into Pd–C Bonds (See ***Carbonylation Processes by Homogeneous Catalysis***)

The insertion of CO into palladium–carbon bonds is a common step in many palladium-catalyzed carbonylation reactions and polymerizations.[25] This reaction takes place under moderate CO pressure (1–3 atm). From the range of compounds that can be carbonylated, it can be inferred that CO will insert into alkyl, aryl, and alkynic bonds (equation 13). One of the few types of Pd–C bonds inert to CO insertion is the Pd–acyl bond, thus only single carbonylations are normally observed. However, a few examples of double carbonylation have been reported. In the case of palladium-catalyzed formation of $PhCOCONEt_2$ from PhI, CO, and $NHEt_2$, reductive elimination from a bisacyl complex has been established as the mechanism, rather than CO insertion into a Pd–acyl bond.



(13)

Unlike CO, isocyanides can insert into Pd–C bonds once, twice, or even three times, to give isolable complexes (equation 14). The Pd/RNC molar ratio, the nature of the ligands on palladium, and the isocyanide determine what product is formed

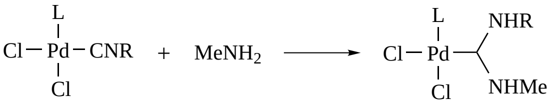


(14)

When CO inserts into a palladium–carbon bond, the resulting acyl can be hydrolyzed to an ester if methanol or another alcohol is present in the reaction. This overall reaction is termed hydroesterification when the alkyl is derived from an alkene. Alternatively, if ethene is present, and bidentate phosphine ligands are used, one can achieve alternating copolymerization of CO and C_2H_4 to produce polyketones.

4.1.8 Palladium Carbene Complexes

Palladium isocyanide complexes react with amines and alcohols to give palladium ***Carbene Complexes*** (equation 15) in a reaction that is a nucleophilic attack on the isonitrile carbon. These complexes easily lose a halide if it is trans to the carbene ligand, since the carbene carbon has a high trans influence. The structures of these compounds have the carbene carbon and its two heteroatom groups in one plane, which is perpendicular to the coordination plane of the Pd.



(15)

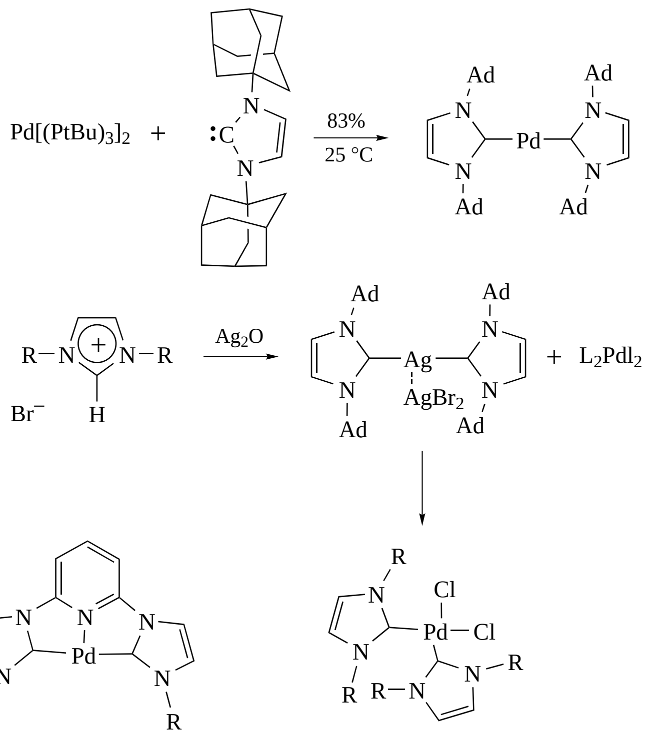
N-Heterocyclic carbenes are relatively stable, electron-rich ligands and can be made sterically demanding.[26] They are σ-donor ligands with little π-acid properties, like trialkylphosphines. These new ligands are readily available by deprotonation of azolium precursors, and the deprotonation can be carried out in the presence of palladium salts to generate the complexes directly (Scheme 12).

4.1.9 Other Routes to Pd–C Bonds

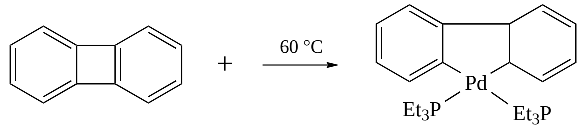
The C–H bonds of arenes can react with electrophilic palladium cations to generate new Pd^{II}-Ar derivatives, in a process that is basically an electrophilic aromatic substitution.[27] For example, mixing $Pd(OAc)_2$ in trifluoroacetic acid generates the powerful electrophile $[PdO_2CCF_3]^+$ that reacts with electron-rich arenes at room temperature (equation 16). This reaction can form the basis for the conversion of benzene derivatives to benzoic acids. Mixing 10% $Pd(OAc)_2$ in trifluoroacetic acid with chlorobenzene and $K_2S_2O_8$ as an oxidant under 1 atm of CO at room temperature gave p-chlorobenzoic acid in 100% yield. The advantage of using arenes over aryl halides is that no HX is produced that must be disposed of.

$$Pd(OAc)_2 + CF_3CO_2H \longrightarrow [PdO_2CCF_3]^+ + ArH \longrightarrow ArPdO_2CCF_3 \qquad (16)$$

Strained carbon–carbon bonds can undergo reaction with electron-rich complexes such as $Pd(PEt_3)_3$. Biphenylene reacts to form two new C–C bonds with $Pd(PEt_3)_3$ in a reaction that is undoubtedly aided by the formation of two strong Pd–C_{sp^2} bonds as well as by the strain of the bond being broken (equation 17).[28]



Scheme 12



(17)

4.1.10 Formation of Palladium Carbonyl and Isonitrile Complexes

The reduction of $Pd(acac)_2$ with $AlEt_3$ in the presence of CO and PPh_3 gives the Pd^0 carbonyl complex $Pd(CO)(PPh_3)_3$. This spontaneously loses PPh_3 in solution to yield $Pd_3(PPh_3)_4(CO)_3$. In toluene, this trimer gives, reversibly, $Pd_3(PPh_3)_3(CO)_3$. Carbonylation of $Pd_3(PPh_3)_3(CO)_3$ at 500 atm of CO converts the complex into $Pd(CO)_3PPh_3$, which decomposes at atmospheric pressure.

As with Pd^0, there are relatively few examples of Pd^{II} carbonyl complexes that have been isolated. Since palladium is an active catalyst for scores of carbonylation reactions, this lack arises from facile insertion reaction of CO into Pd–C bonds, and the ease of displacement of CO from Pd^{II} centers by other ligands, rather than a lack of interaction between Pd^{II} and CO. Reaction of $Pd(\eta^5\text{-}C_5H_5)Cl(PPh_3)$ with $AgClO_4$ followed by CO gives $[Pd(\eta^5\text{-}C_5H_5)CO(PPh_3)]ClO_4$. This compound exhibits a ν_{CO} at $2113\,cm^{-1}$. Isostructural Ni and Pt complexes each give lower energy ν_{CO} bands at $2081\,cm^{-1}$ and $2093\,cm^{-1}$, respectively. This result is further evidence that Pd^{II} is less effective at π-donation to the CO ligand than either Ni^{II} or Pt^{II}.

A much wider range of palladium isonitrile complexes have been isolated compared to the palladium carbonyls. Isonitriles will displace both acetonitrile ligands from $Pd(CH_3CN)_2Cl_2$, which offers a convenient synthesis of $Pd(RNC)_2Cl_2$. The corresponding $Pd(RNC)_2I_2$ reacts with KOH in the presence of RNC to give the zero-valent $Pd(RNC)_4$. RNC is a better σ-donor ligand and a worse π-acceptor than CO, which accounts for the formation of $Pd(RNC)_4$.

4.1.11 Organopalladium(IV) Compounds

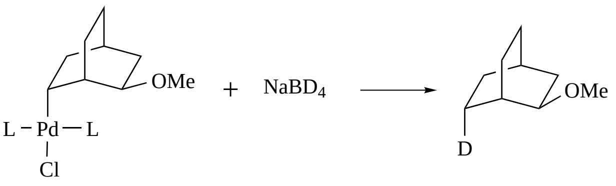
There are a relatively small number of organopalladium(IV) compounds isolated.[29] One of the first examples was prepared by oxidizing $PdCl(C_6F_5)(bpy)$ with Cl_2 to give $PdCl(C_6F_5)(bpy)$ (bpy $= 2,2'$-bipyridyl). Subsequently, it was discovered that reactive halides such as methyl iodide or benzyl halides undergo oxidative addition to Pd^{II} complexes with chelating nitrogen ligands (especially 2,2′-bipyridine, 1,10-phenanthroline and tris(pyrazol-1-yl)methane). In this way, complexes such as $PdBrMePh(CH_2Ph)(bpy)$ can be prepared. These additions seem to be standard S_N2 reactions. Reductive elimination of alkyl groups requires a vacant coordination site, which is usually generated by ionization of a halide. Where different alkyl groups are present on the Pd^{II} atom, there is a preference for coupling of two methyl groups. In acetone solution, slightly above room temperature, $PdBrMePh(CH_2Ph)(bpy)$ decomposes to give toluene and $PdBr(CH_2Ph)(bpy)$. Differential scanning

calorimetry of reductive elimination in solid Pd^{IV} alkyls, where one assumes the heat absorbed corresponds to the bond enthalpies being broken, suggests the Pd^{IV}–CH_3 bond enthalpy is ~130 kJ mol^{-1} and the Pd^{IV}–CH_2Ph bond enthalpy is ~123 kJ mol^{-1}.

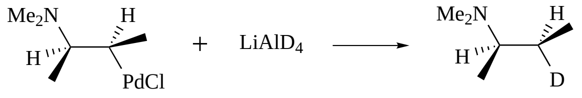
4.2 Reactions of the Pd^{II}-Carbon Bonds

4.2.1 Reduction

Compounds with Pd^{II}–C bonds will undergo reduction by H_2 or D_2, $NaBH_4$, $LiAlH_4$, or $NaCNBH_3$. This reaction provides a convenient way to remove palladium from an organometallic molecule formed from addition to a coordinated alkene or diene (equations 18 and 19). The hydride reagents work by replacing one of the halides with H, leading to reductive elimination of RH. Because of the stability of $Pd(CN)_4{}^{2-}$, aqueous cyanide solutions will break Pd–C bonds, releasing C–H. Basic alcohol solutions will also decompose organopalladium compounds, depositing palladium metal.



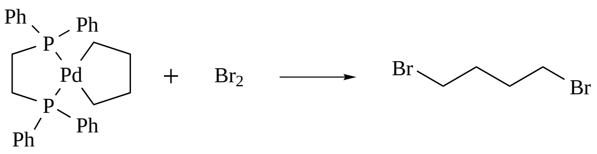
(18)



(19)

4.2.2 Reactions with Acids, Electrophiles, and Oxidants

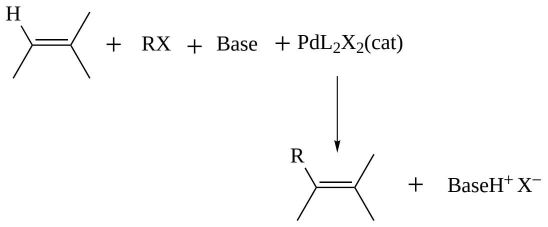
Addition of HCl (as a solution in $CHCl_3$) to compounds with Pd–C bonds results in rapid cleavage to the corresponding RH and Pd–Cl species. Bromine will cleave Pd–C bonds at temperatures between −78 °C and 20 °C to produce the corresponding RBr (equation 20). In the case of palladium acyls, an acid bromide is produced, and running the cleavage reaction in the presence of alcohols or amines leads to the formation of esters or amides. Occasional reports have described the oxidations of palladium alkyls with peracids or C_6F_5IO to give alcohols. Hydrogen peroxide in the presence of an iron porphyrin catalyst (*meso*-tetrakis(pentafluorophenyl)porphyrinatoiron(III) chloride) is reported to oxidize Pd–C bonds as well.[30]



(20)

4.2.3 Reaction of Organopalladium Species with Alkenes

A number of important reactions involve the addition of R–Pd across an alkene double bond. The palladium-catalyzed vinylation or arylation of organic halides, the Heck reaction (also known as the Mizoroki–Heck reaction), was introduced in Scheme 5 (equation 21). In this reaction, an aryl, vinyl, or benzylic halide undergoes oxidative addition to a Pd^0 species, usually generated in the reaction from a catalytic quantity of $Pd(OAc)_2$, $PdCl_2$, or $(PR_3)_2PdX_2$. Other types of halides have β-hydrogens that lead to β-elimination products instead of vinylation. The reaction is run in solvents such as DMF or acetonitrile at temperatures of 70 to 150 °C. After addition of Pd–R across the double bond, reductive elimination of L_nPd–H regenerates the double bond. Since one equivalent of acid is generated, a base is required. Common choices are K_2CO_3, Cs_2CO_3, and tertiary amines. The orientation of addition of the R group to the alkene depends on the other groups, on the double bond, and the structure of the R group.[31]

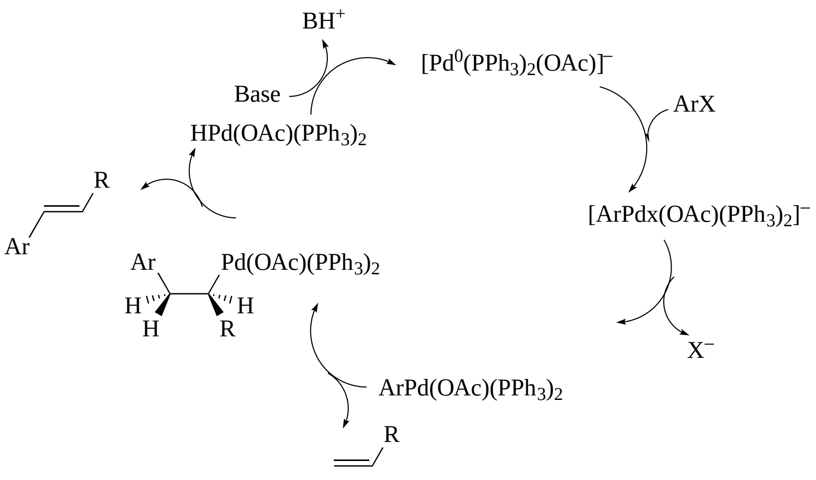


(21)

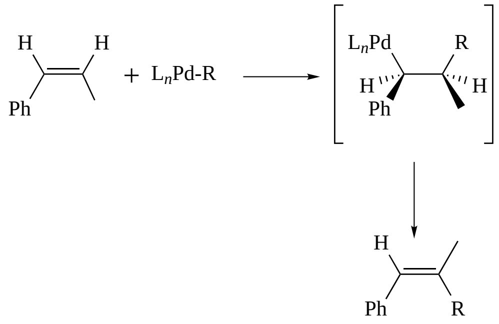
Under standard reaction conditions, the mechanism of the Heck reaction is more complicated than the textbook pathway shown in Scheme 5. The active catalyst responsible for oxidative addition of the ArX substrate is an anionic Pd^0 species, either L_2PdCl^- or $L_2Pd(OAc)^-$, depending on the starting palladium compound, where L is triphenylphosphine.[32] Reduction of the starting palladium salt to a Pd^0 species is carried out by the phosphine. A mechanism that is consistent with spectroscopic and electrochemical data is given in Scheme 13.

In general, the alkyl group is added to the less-substituted carbon atom of the double bond. If an electron-withdrawing group is attached to the alkene, the alkyl group usually attaches β to it. Changing from a monodentate to a bidentate ligand can sometimes reverse the regioselectivity of the addition. (Scheme 14).

The addition of R–Pd to the double bond and the elimination of Pd–H from it are both syn. Thus, the relative stereochemistry of the double bond is inverted (equation 22). Mixtures of stereoisomers are in fact produced, since the β-elimination reaction is reversible. Lower reaction temperatures and higher phosphine concentrations increase the stereoselectivity of the reaction.



Scheme 13

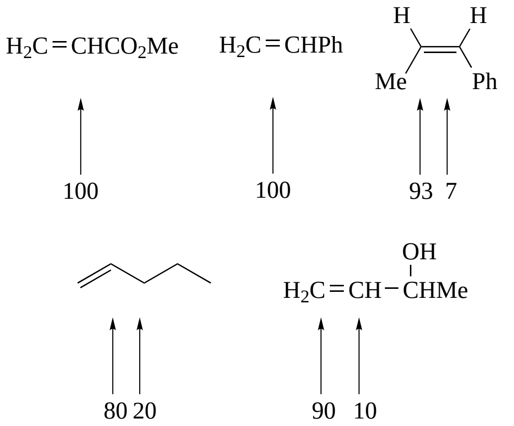


(22)

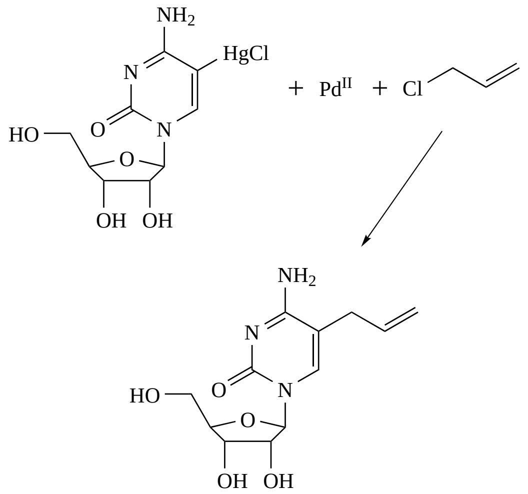
Steric hindrance is tolerated in the organic halide component of the reaction. The reaction of 2,5-diisopropyliodobenzene with methyl acrylate proceeds in 79% yield at 125 °C, for example. The alkene component, conversely, is sensitive to the number and size of the substituents on the alkene. Useful yields of product are only obtained for ethene and mono- and disubstituted alkenes. If the alkene is unreactive, the RX component is dimerized to R–R as the major reaction.

Intramolecular Heck reactions take place and can produce medium and large size rings. The new double bond can be formed exocyclic or endocyclic to the new ring, depending on the conformational freedom in the approach of the alkene to the Pd–C bond (Scheme 15). If one uses a chiral ligand, such as (S)-BINAP, chiral products can result (Scheme 16).[33]

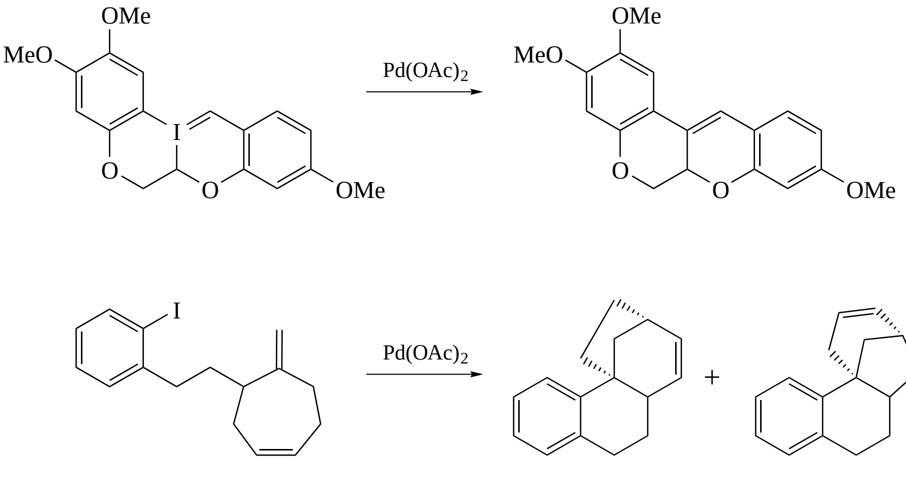
Other reagents can serve as the source of Pd–R in addition to organic halides. Organomercurials readily transfer organic groups to Pd^{II} at 25 °C, permitting the vinylation to take place at a lower temperature, although the reaction is stoichiometric. In addition, a wider range of carbon groups can be transferred, including methyl, carboalkoxy, neopentyl, and neophyl. More sensitive compounds can thus be coupled to alkenes via mercurials. 5-Chloromercuricytosine can be converted to 5-allylcytosine in 77% yield. In this reaction, β-elimination of Pd–Cl takes place in preference to Pd–H elimination (equation 23).



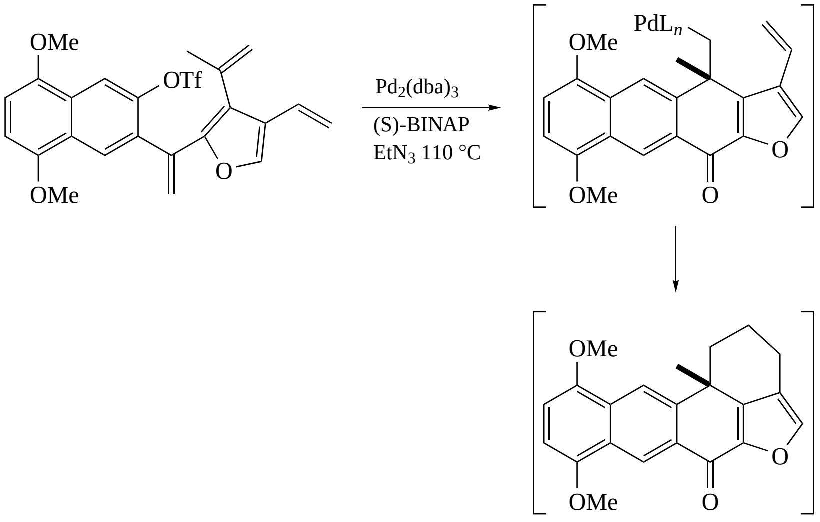
Scheme 14



(23)



Scheme 15

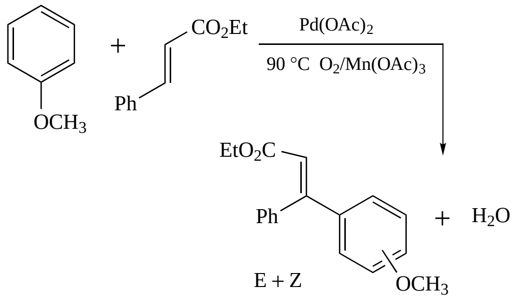


82% 68% ee

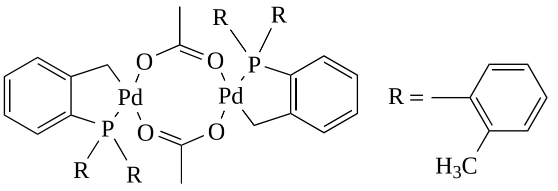
Scheme 16

The search for more stable or more reactive catalysts has produced many new leads. One of the most promising is represented by the palladacycle (**14**), known as Hermann's catalyst. This can be used in Heck reactions at high temperatures (above 140 °C), which leads to high turnover numbers of up to 10^6 with electron-poor aryl bromides.[34]

Because stoichiometric amounts of base-HX salts are produced in a Heck reaction, alternative sources of aryl groups have been investigated. Carboxylic acid anhydrides were found to react with a PdC_2/NaBr catalyst system, where the by-products were CO and a carboxylic acid. *p*-Nitrophenylbenzoates were also found to be aryl donors in a decarbonylative Heck reaction.[35] An arylation of cinnamates was discovered using $Pd(OAc)_2$ to activate the C–H bonds of electron-rich benzene derivatives. This reaction took place in toluene and used $Mn(OAc)_3/O_2$ to reoxidize the Pd^0 produced to close the catalytic cycle (equation 24).



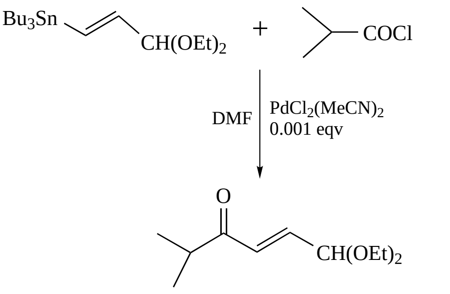
(24)



(**14**)

4.2.4 *Catalytic Cross Coupling with Organostannanes and Organosilanes, the Stille and Hiyama Reactions*

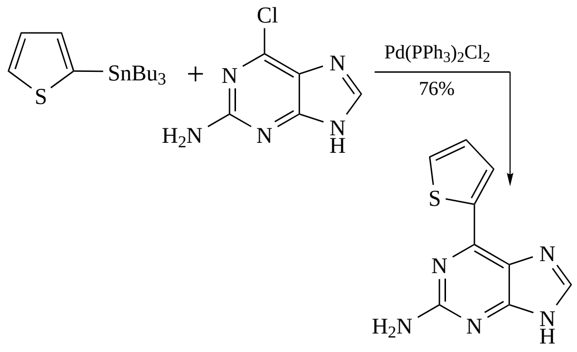
The general mechanism for the cross coupling of organostannanes and aryl halides (the Stille reaction) is given in Scheme 4.[36,37] The transmetalation step takes place through a cyclic, four-center transition state. In general, the rate of ligand transfer from tin to palladium is alkyne > vinyl > aryl > allyl, benzyl > methyl > butyl. Originally, acyl halides were used as the electrophile (equation 25). The major side reaction in that case is decarbonylation, but running the reaction under CO retards decarbonylation.



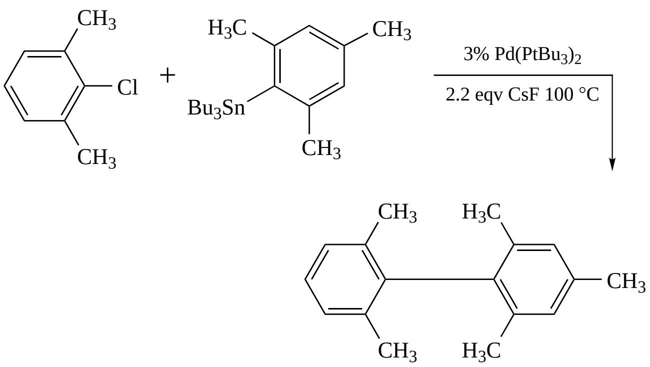
(25)

Subsequently, it was found that aryl and vinyl iodides, bromides, and triflates were excellent substrates in Stille couplings. In general, the rate for oxidative addition of ArX is X = I > Br > OTf > Cl. In addition, haloheterocycles such as 2- and 4-chloropyridines and 6-chloropurines react with standard $Pd(PPh_3)_4$ catalysts. Alkyl substrates tend to undergo β-elimination prior to coupling. Frequently an additive, such as Et_4NCl or CsF, is used. These, especially the fluoride salts, form transient five-coordinate R_4SnX^- species, which are more reactive in the transmetalation step. Fluoride in the reaction mixture also leads to formation of insoluble Bu_3SnF, which makes the otherwise difficult removal of organotin residues easy (equation 26). Recently, the use of hindered phosphine Pd^0 catalysts in conjunction with CsF cocatalysts has been found to activate simple aryl chlorides for biaryl couplings (equation 27).

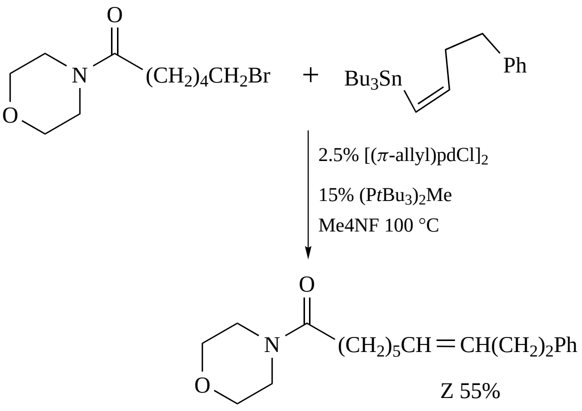
These PdL_n complexes also have been found to couple vinylstannanes to alkyl bromides. Assaying a number of different hindered phosphines, including $P(t\text{-}Bu_3)_3$, $PCy_2(t\text{-}Bu)$, and $P(t\text{-}Bu)_2Et$, only $P(t\text{-}Bu)_2Me$ and PCy_3 gave coupled products instead of β-elimination.[38] This work illustrates the remarkable sensitivity individual catalytic reactions have to ligand size and electronic properties (equation 28).



(26)

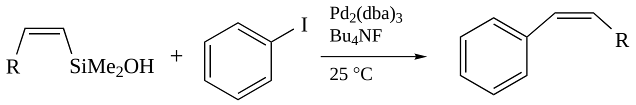


(27)

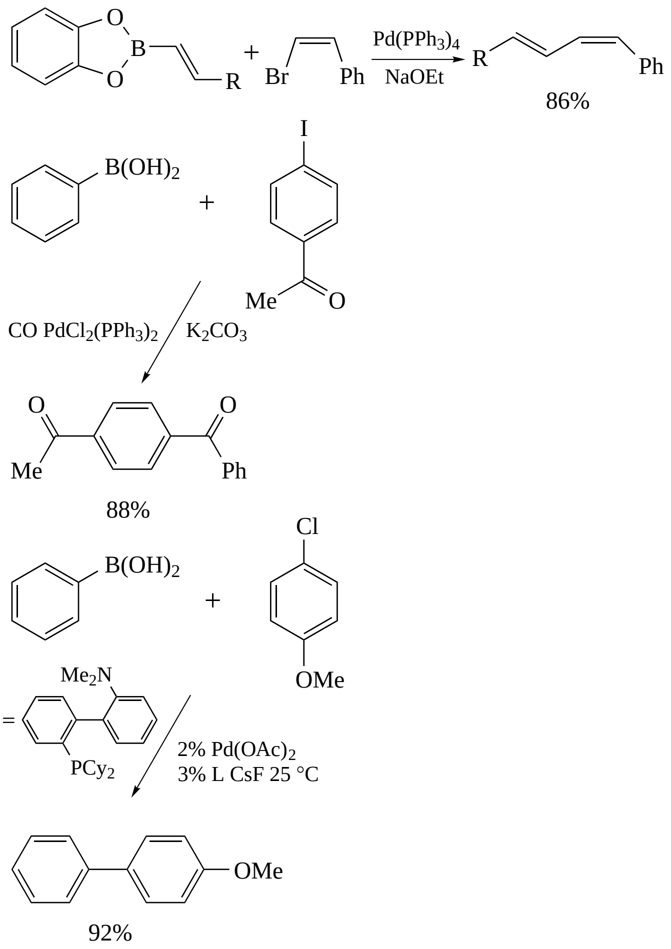


(28)

Coupling of organosilane derivatives to RX species is known as the Hiyama reaction. This process is seen as more difficult to catalyze than the Stille reaction since a C–Si bond is less reactive than a C–Sn bond. However, addition of additives, such as Bu_4NF or CsF, that form hypervalent silicon intermediates, or the use of more reactive silane precursors, such as $Me_3SiSiMe_3$, $ArSiMe_2OH$, or Cl_2MeSi(vinyl), can overcome this limitation (equation 29).



(29)



Scheme 17

4.2.5 Catalytic Cross Couplings with Organoboranes, the Suzuki or Suzuki–Miyaura Reaction

The palladium-catalyzed coupling of boronic acids (as well as other boron derivatives) with aryl and vinyl halides and pseudohalides is known as the Suzuki or Suzuki–Miyaura reaction.[39] Because boron is nontoxic, this reaction has been used in pharmaceutical syntheses. In addition, hydroboration or borate substitution allows for the synthesis of virtually any desired coupling partner. For these reasons, as well as the high yields and functional group compatibility, the Suzuki reaction is the first reaction to consider for carrying out a cross coupling. Representative substrates and catalysts are shown in Scheme 17. The various bases are used to generate four-coordinate boron ‘ate’ complexes that are more reactive in transmetalation.

An extremely useful variant of Suzuki reaction uses B-alkyl substrates with aryl or vinyl halides.[40] The B-alkyls are prepared by hydroboration of an alkene with 9-BBN-H. With appropriate palladium ligands, reductive elimination takes place faster than β-hydride elimination of alkyl groups. The major limitation is that alkyl groups must be primary, since secondary and tertiary alkyls undergo β-hydride elimination exclusively. Intermolecular and intramolecular examples are shown in Scheme 18.

4.2.6 Catalytic Cross Couplings with Grignard, Organozinc and Related Reagents, the Kumada and Negishi Reactions

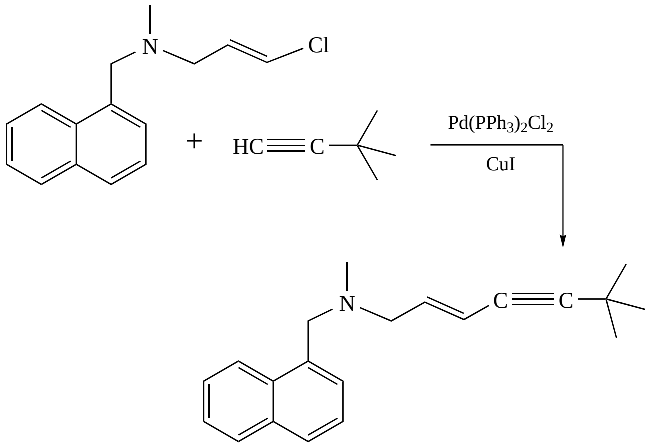
The palladium-catalyzed coupling of Grignard reagents with aryl or vinyl halides is known as the Kumada, or alternatively, the Kharasch reaction. It is perhaps the original transition metal catalyzed cross-coupling reaction, and works with both Pd and Ni catalysts. This reaction is used extensively to synthesize biaryls. Because of the basicity of Grignard reagents, there is no need to add additional bases to this coupling reaction.

The Negishi reaction, which couples aryl and vinyl halides with organozinc reagents, is potentially more useful than

the Kumada reaction because of the greater functional group tolerance of organozinc compounds.[41] If functional group compatibility is not a consideration, aryl zinc compounds can be made in situ from Grignards and catalytic quantities of $ZnCl_2$. The use of $PdCl_2$(dppf) (dppf = 1,1-bis(diphenylphosphino)ferrocene) or Pd(P*t*-Bu_3)$_2$ permits coupling of ArZnX to ArCl at temperatures at or below 100 °C. Other organometallics that can be used in palladium-catalyzed cross couplings include RHgX, Cp_2RZrCl, AlR_3, and RCu.

4.2.7 *Catalytic Cross Couplings to Terminal Alkynes, the Sonogashira Reaction*

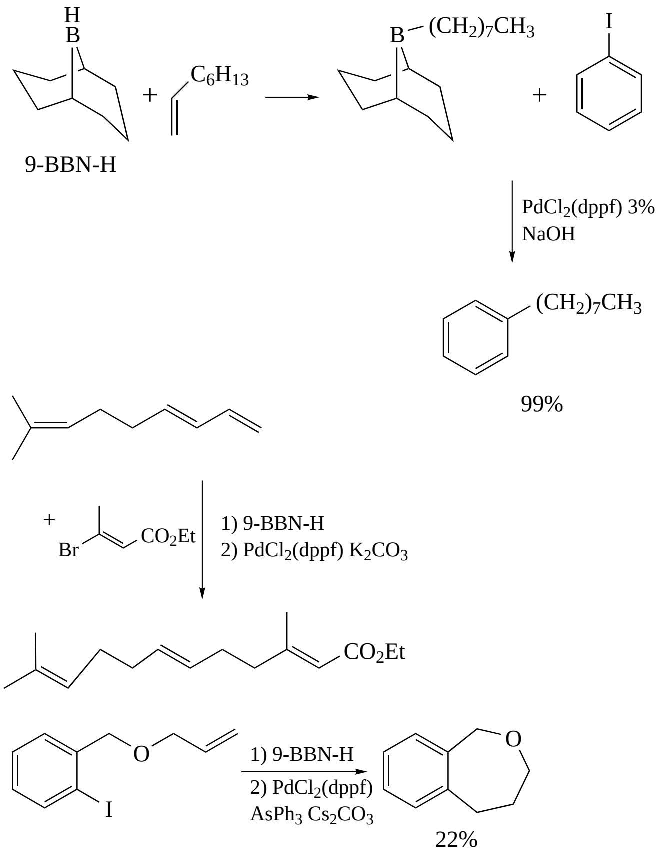
Coupling terminal alkynes with aryl or vinyl halides using palladium and copper cocatalysts is known as the Sonogashira reaction.[42] The copper is needed to activate the alkyne C–H. The industrial synthesis of the active ingredient in Lamisil®, the antimycotic agent Terbinofin, involves a Sonogashira coupling (equation 30).



(30)

4.2.8 *Catalytic Cross Couplings of Aryl Halides with Enolates*

Active methylene compounds, such as malonates, malononitrile, and aliphatic nitro compounds are coupled efficiently to aryl and heteroaromatic halides.[43] The best ligands, as is the case for many other cross couplings, are bulky phosphines such as 2-(di-*t*-butylphosphino)-2′-methylbiphenyl (see Scheme 11). Enolates of less acidic carbonyl compounds, such as ketones, esters, and amides, also undergo α-arylation using these hindered ligands. This reaction depends on the base used to generate the enolate, as well as the phosphine, with NaO-*t*-Bu, KN(SiMe)$_2$, Cs_2CO_3, and K_3PO_4 being preferred. Characteristic examples are collected in Scheme 19.



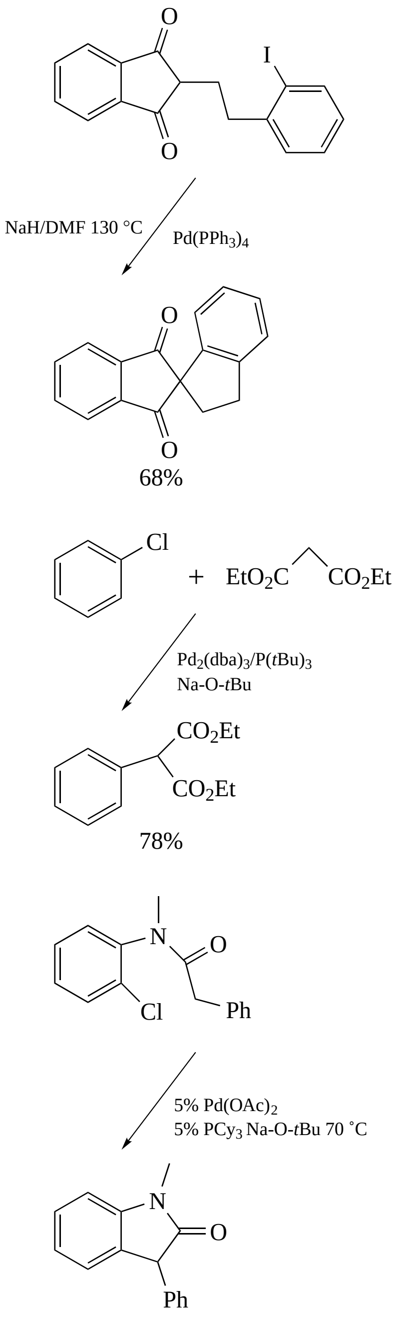
Scheme 18

4.2.9 *Catalytic Cross Couplings of Aryl Halides to Nitrogen and Oxygen Nucleophiles, the Buchwald–Hartwig Reaction*

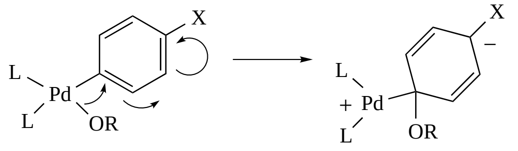
Palladium-catalyzed amination and alkoxylation of aryl halides have been developed only since the mid-1990s.[44,45] The catalytic cycle is similar to other cross-coupling reactions (Scheme 20).

Two problems had to be solved for these reactions to be made useful. First, reductive elimination to form C–N and C–O bonds was not a well-known reaction with classical ligands such as PPh_3.[46] Second, β-hydride elimination is very facile for primary and secondary heteroatom substrates. As with other cross-coupling reactions, the use of hindered, basic phosphines turned out to be crucial. Amination reactions tend to give better yields, since reductive elimination is faster for more basic groups. For example, the base used in catalytic aminations is Na-O-*t*-Bu, but the product is the aryl amine.

For aromatic ether formation, electron-withdrawing groups on the arene accelerate the rate of reductive elimination. Further, the more basic alkoxide groups form ethers faster than phenoxides. These facts have led to the proposal that, in addition to the usual concerted reductive elimination mechanism, some substrates can undergo reductive elimination via a Meisenheimer type intermediate (equation 31).

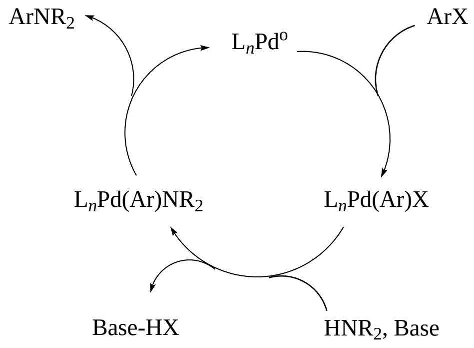


Scheme 19

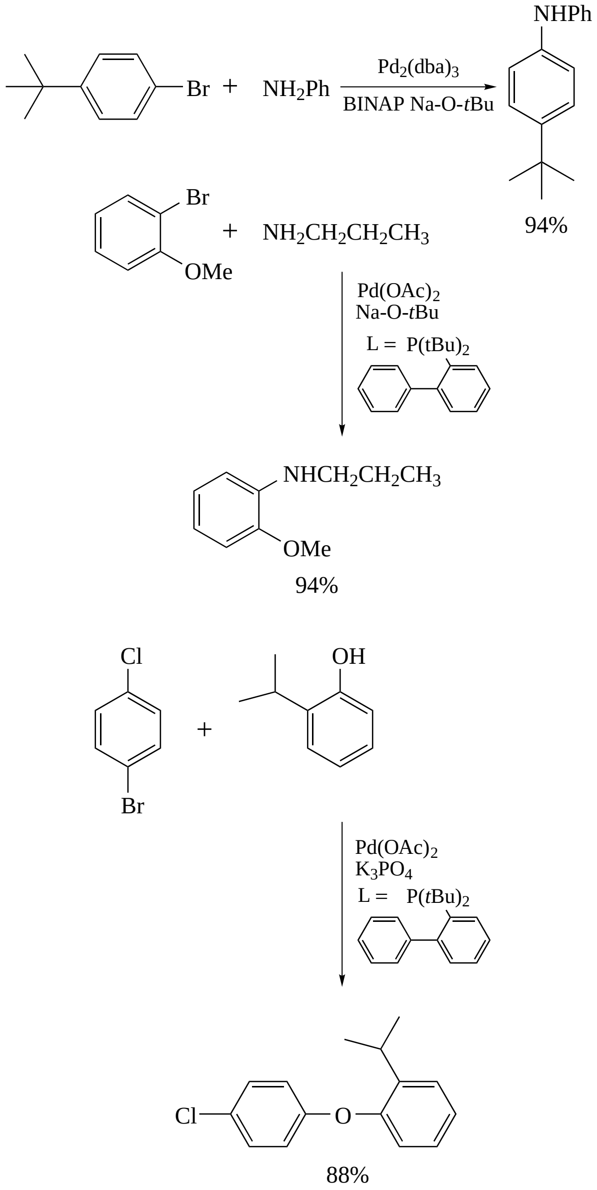


(31)

Examples of amination and alkoxylation reactions are given in Scheme 21. Synthetic equivalents of ammonia, such as $Ph_2C{=}NH$, can be used to prepare anilines and t-$BuMe_2SiONa$ reacts to give protected phenols.[47]



Scheme 20



Scheme 21

5 ALKENE AND ALKYNE COMPLEXES OF PALLADIUM

5.1 Synthesis of Monoalkene and Monoalkyne Complexes

Alkene complexes of Pd^0 are very unstable unless the double bond is substituted with electron-withdrawing groups. Condensation of palladium atoms with ethene gives $(\eta^2\text{-}C_2H_4)_3Pd$. Reduction of $[PdCl_2(1,5\text{-cod})]$ with $Li_2C_8H_8$ gives the unstable $Pd(1,5\text{-cod})_2$. The most commonly used Pd^0 alkene complex, and one that can be stored and handled in air, is $Pd_2(\text{dibenzylideneacetone})_3$, which can be prepared from K_2PdCl_4, dibenzylideneacetone, and sodium acetate in ethanol.[48] The dibenzylideneacetone ligands are easily displaced by phosphines, and because of its stability, the complex serves as a useful precursor to PdL_4. Mixed phosphine/alkene complexes of Pd^0 have been prepared by reducing $Pd(acac)_2$ with Et_2AlOEt in the presence of phosphines (equation 32).

$$Pd(acac)_2 + Et_2AlOEt + PR_3 \longrightarrow Pd(C_2H_4)(PR_3)_2 \qquad (32)$$

Zero-valent complexes of palladium with both phosphine ligands and alkynes substituted with electron-withdrawing groups, $PdL_2(RC_2R)$, are known. Alkynes have been found to bridge two Pd^I centers in the dinuclear complex $[Pd_2(\mu\text{-}PhC_2Ph)(\eta^5\text{-}C_5Ph_5)_2]$, which is synthesized from $Pd(OAc)_2$ and diphenylacetylene in methanol. Unusual asymmetric alkyne-bridged complexes derived from the paramagnetic compound $[Pd_2(\mu\text{-}PhC_2Ph)(\eta^5\text{-}C_5Ph_5)_2]^+$ have been made, including $[Pd_2(bpy)(P(OPh)_3)(\mu\text{-}PhC_2Ph)(\eta^5\text{-}C_5Ph_5)_2]^+$.

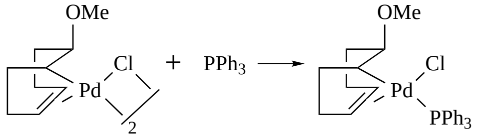
Two general routes are used to synthesize isolable alkene complexes of Pd^{II}. In the first route, $(PhCN)_2PdCl_2$ is reacted with alkenes such as styrene, cyclohexene, isobutene, or ethene to give the monoalkene chlorine-bridged dimers $[(alkene)PdCl_2]_2$. The same starting material reacts with vinyl ethers and 1,2-dimethoxyethane to give the vinyl ether complexes (vinyl ether)$PdCl_2$. Because vinyl ethers are much better σ-donors than π-acceptors, this result supports the observation that σ-donation is more important than π-acceptor ability in determining the stability of Pd^{II}–alkene complexes. Alternatively, one alkene may displace a second from $[(alkene)PdCl_2]_2$. The stability of these alkene complexes decreases in the order *cis*-2-pentene > 1-pentene > *trans*-2-pentene. The ease with which nucleophiles add to alkenes coordinated to Pd^{II}, together with the tendency for palladium to form π-allyl complexes, accounts for the limited number of stable Pd^{II}–alkene complexes. There are also only few examples of Pd^{II}–alkyne complexes that have been isolated. The bulky alkyne di-*t*-butylacetylene reacts with $Pd_2Cl_4(C_2H_4)_2$ to displace both ethene ligands. Where possible, alkynes can be isomerized to π-allyl palladium complexes through addition–elimination of a palladium hydride.

5.2 Reactions of Coordinated Alkenes and Alkynes

Coordinated alkenes and alkynes undergo two kinds of reactions: substitution reactions and nucleophilic additions to the coordinated ligand.[49] While a relatively few examples of nucleophilic attack exist for stable Pd^{II}–alkene complexes, a far larger number of examples can be inferred from the palladium-catalyzed reactions of alkenes.

5.2.1 *Substitution Reactions of Coordinated Alkenes and Alkynes*

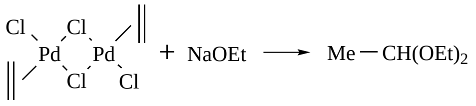
Most ligands will displace alkenes from $[Pd_2Cl_4(alkene)_2]$. However, the chelating alkene ligands derived from attack of nucleophiles on 1,5-cyclooctadiene complexes of Pd^{II} undergo bridge-splitting reactions with amine and phosphine ligands (equation 33).



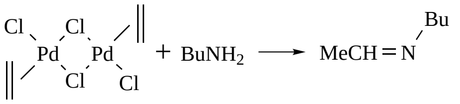
(33)

5.2.2 *Nucleophilic Attack on Coordinated Alkene Complexes*

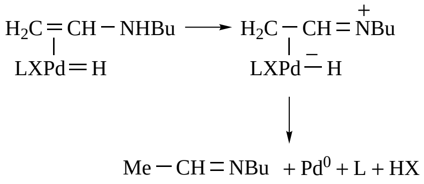
There is an extensive chemistry of nucleophilic attack on one of the double bonds of coordinated 1,5-cyclooctadiene; this is outlined in Section 6. In addition, the attack of water on ethene coordinated to Pd^{II} is the key step in the Wacker process for the oxidation of ethene to acetaldehyde, which is discussed in Section 9. However, there are some examples of nucleophilic attack on stable Pd^{II}–alkene complexes. The addition of NaOEt to $Pd_2Cl_4(C_2H_4)_2$ gives the diethyl acetal of acetaldehyde (equation 34) along with trace quantities of ethyl vinyl ether. A possible mechanism for this oxidation is outlined in Scheme 22. Addition of methoxide gives a $Pd–CH_2CH_2OMe$ intermediate, which undergoes β-elimination to form a coordinated vinyl ether. The resulting double bond can insert into the Pd–H bond, and cleavage of the resulting Pd–C bond by methoxide gives the acetal. With acetate as nucleophile in place of alkoxide, the product is vinyl acetate. With butylamine, $Pd_2Cl_4(C_2H_4)_2$ gives MeCH=NBu (equation 35). This reaction undoubtedly proceeds via nucleophilic attack on the coordinated alkene and β-elimination, as in the case of methoxide; however, the subsequent steps may differ, as outlined in equation (36).



(34)

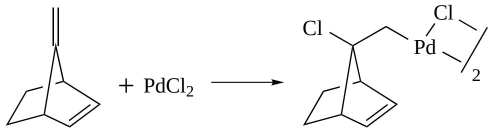


(35)



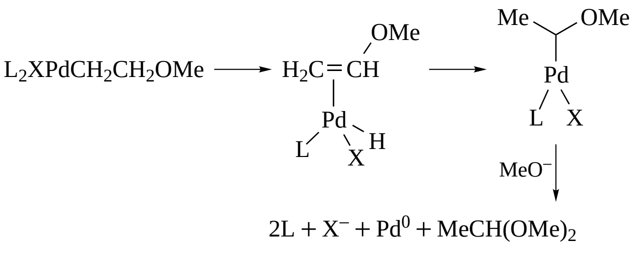
(36)

The geometry of alkene coordination appears to affect the reactivity toward nucleophiles. 7-Methylenenorbornene reacts with $PdCl_2$ to give the product from Pd–Cl addition across the *exo*-methylene double bond (equation 37). In the intermediate $PdCl_2$−diene complex, which could not be isolated, the 7-*exo* double bond would be coordinated so as to lie in the ring plane, while the other alkenic group would lie perpendicular to the palladium square plane, as is normal. From the structure of the product, trans addition of Pd and Cl occurs.



(37)

A general procedure for the addition of stabilized nucleophiles (such as diethyl malonate anion or the enolate of ethyl phenylacetate) to alkenes ($RCH{=}CH_2$) involves letting $PdCl_2(PhCN)_2$ react with an unhindered alkene at 25 °C to form $[PdCl_2(alkene)]_2$, followed by cooling to −78 °C and addition of two equivalents of Et_3N and the enolate (R′Li). Warming the reaction to room temperature leads to β-elimination, forming alkenes of the type $RR'C{=}CH_2$ from addition of the enolate anion to the more-substituted end of the alkene. If an H_2 atmosphere is added to the cold solution, no β-elimination takes place, and instead the newly formed Pd–C bond is hydrogenated, leading to $RR'CH–CH_3$. If HMPA is present in addition to Et_3N, less-stabilized carbanions can be used, such as phenyllithium. In this reaction, the nucleophile adds to the less-hindered carbon of the alkene. When the coordinated alkene has hydrogens α to the double bond that can be deprotonated to give a π-allyl complex, this deprotonation is facile as detailed in Section 7.



Scheme 22

5.2.3 Dimerization and Polymerization of Alkenes Catalyzed by Palladium (See **Oligomerization & Polymerization by Homogeneous Catalysis**)

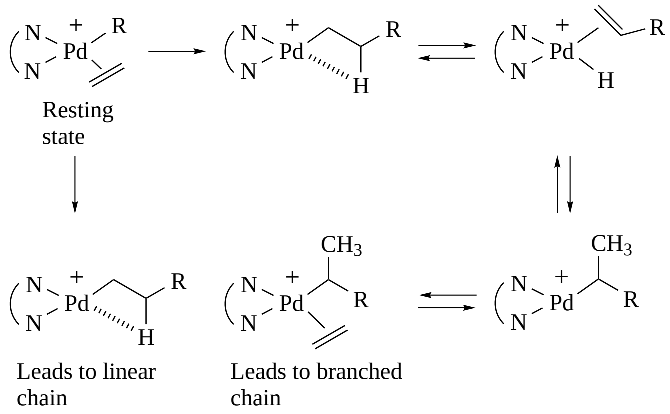
Palladium complexes have been found to dimerize ethene to butenes under a variety of conditions.**[50]** In ethanol, the reaction can take place at 20 to 70 °C and ethene pressures of 1 to 40 atm, using $PdCl_4^{2-}$. Propene is dimerized to high proportions (65−90%) of straight chain hexenes with $PdCl_2$ in solvents such as $CHCl_3$. With the catalyst mixture $PdCl_2$, $EtAlCl_2$, and PPh_3, propene gives 2-hexene as the predominant product.

New cationic Pd^{II} (as well as Ni^{II}) complexes have been discovered that polymerize ethene, α-olefins, and cyclic olefins as well as copolymerize alkenes with functionalized monomers, such as methyl acrylate.**[51]** These catalysts use α-diimines as ligands and have been trademarked by DuPont as the Versipol catalyst system. The polyethylene produced by the palladium catalysts is unlike the one produced by the related nickel systems. It is an amorphous, highly branched (with branched branches) polymer having a glass transition temperature below −30 °C. The exact structure depends on the extent of ‘chain walking’ engaged in by the catalyst, which refers to the series of β-hydride elimination and readditions that take place between each ethene insertion step (Scheme 23). The rotation of the $Pd–C_\alpha$ bond, that breaks an agostic interaction with the β-H, is the process that controls the overall rate of chain walking. The barrier to β-H elimination is approximately 33 kJ mol^{-1}, while the $Pd–C_\alpha$ rotation barrier is approximately 42 kJ mol^{-1}.

Unlike early metal ethene polymerization catalysts, these catalysts have a cationic alkyl/ethene complex as the resting state. The turnover-limiting step is alkene insertion, resulting in an alkyl group stabilized by an agostic interaction with the β-C−H bond. Chain growth kinetics are thus zero order in ethene. Insertion of ethene has a barrier of approximately 71 kJ mol^{-1} for palladium and 54 kJ mol^{-1} for nickel. The use of bulky α-diimine ligands retards chain transfer, leading to high molecular weight polymers.

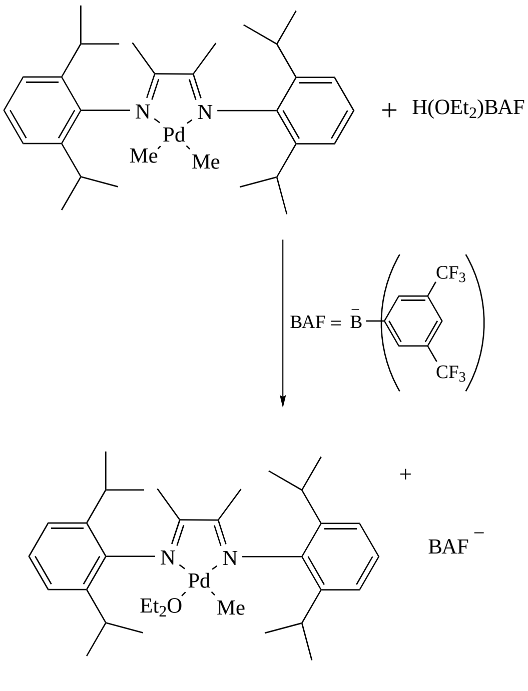
The specific catalysts that work the best are characterized by cationic palladium centers with bulky α-diimine ligands and noncoordinating counterions. Generation of a specific catalyst is shown in equation (38).

The palladium diimine catalysts can be used to prepare polymers of α-olefins as well as cyclic internal olefins. For α-olefins, the rate of polymerization is slower, compared to ethene, but high molecular weigh polymers are formed. Chain walking takes place with α-olefins, but the α-olefin does not insert into secondary methylene carbons. Copolymers of α-olefins and ethene give polymers with complex microstructures since ethene will insert into secondary

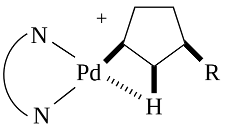


Scheme 23

Pd–alkyl bonds. Cyclic olefins are polymerized to high molecular weight polymers with useful processing properties. The resting state for the cyclopentene polymer has an agostic interaction with a ring β-H (**15**) as shown by ^{1}H NMR.



(38)



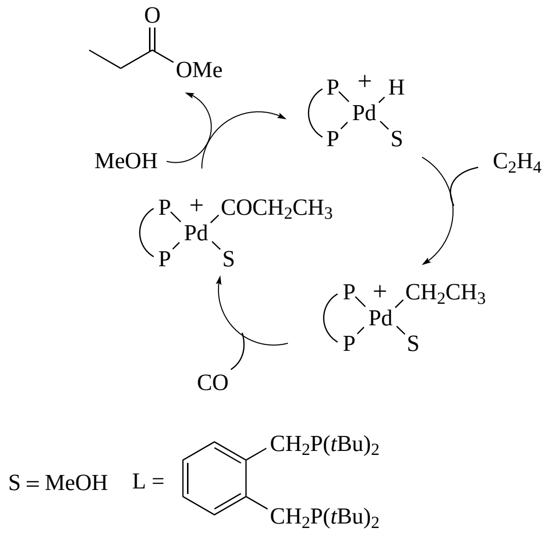
(**15**)

The cationic palladium α-diimine catalysts, much more so than their nickel analogs, are tolerant of polar functional groups. Emulsion polymerization in aqueous solvents can take place to give polymer microspheres useful as adhesives. Monomers such as acrylates, unsaturated ethers, and unsaturated alcohols can be added to ethene polymerization reactions to give random copolymers. Theoretical calculations suggest that oxygen-containing functional groups bind to the nickel catalysts in preference to ethene, while this binding is relatively weaker for palladium. The ethene/methyl acrylate copolymer has been extensively studied. The polymer possesses the highly branched polyethylene structure with ester groups distributed randomly through the branches, mostly at branch termini. The resting state for the ethene/methyl acrylate polymer is a six-membered C,O chelate ring with the palladium bound to the carbon chain and a carbonyl oxygen lone pair.

5.2.4 Coupling and Polymerization of Alkenes with Carbon Monoxide

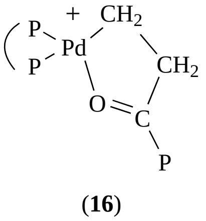
Methoxycarbonylation of ethene and CO in methanol to give methyl propanoate is carried out with a catalyst prepared by adding methanesulfonic acid to Pd(1,2-$(CH_2P\textit{t}Bu_2)_2C_6H_4$)dba. All the intermediates in the catalytic cycle for this reaction could be seen using low-temperature NMR and ^{13}C labeling.[52] The pathway was found to follow the hydride catalytic cycle, where ethene inserts into a Pd–H bond as part of the mechanism, as shown in Scheme 24. The alternative catalytic cycle, known as the methoxycarbonyl cycle, where CO inserts into a Pd–OMe bond to give PdCOOMe, followed by ethene insertion to give $PdCH_2CH_2CO_2Me$ and finally reaction with methanol to give the ester and regeneration of PdOMe did not occur.[53]

Slightly different ligands can lead to the polymerization of alkenes and CO to give alternating, 'polyketone' polymers with interesting and useful properties.[54,55] A diphosphine ligand such as 1,3-bis(diphenylphosphino)propane, dppp, added to $Pd(OAc)_2$ in methanol with an acid having a weakly coordinating conjugate base, such as tosylate or tetrafluoroborate gives ethene/CO copolymers with an average molecular weight of ~20 000 and total conversions of more



Scheme 24

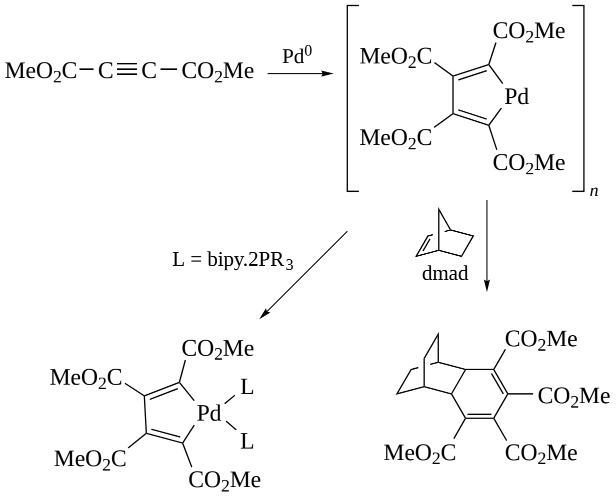
than 10^6 mol of ethene per mole of Pd. When PPh_3 or similar monodentate ligands are used, the phosphine ligands can adopt a trans-geometry, and the intermediate $L_2Pd–COCH_2CH_3$ will react with methanol to give an ester product. With cis-ligands, the growing chain and a vacant (or solvent-occupied) coordination site are always cis to one another. Since only cis-ligands can undergo insertion, bidentate ligands favor polymer production. The probable reason strict alternation of ethene and CO insertion occurs is that the chain adopts a chelate structure (**16**) that is more readily broken up by CO, since CO is a better ligand than ethene.



(**16**)

5.2.5 Coupling of Alkynes

Many zero-valent platinum group metals couple alkynes to metallacyclopentadienes or catalyze the trimerization to arenes. Normally, the alkynes are substituted with electron-withdrawing groups, such as dimethyacetylenedicarboxylate (dmad) or hexafluoro-2-buyne. When $Pd_2(dba)_3$ reacts with dmad, a 'base-free' palladacyclopentadiene polymer forms in addition to $C_6(CO_2Me)_6$ (Scheme 25). This complex reacts with ligands to generate discrete monomers. Addition of strained alkenes such as norbornene can give cyclohexadiene adducts.



Scheme 25

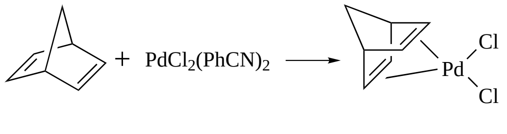
6 DIENE, CYCLOBUTADIENYL, AND CYCLOPENTADIENYL COMPLEXES

6.1 Diene Complexes of Pd^{II}

Both 1,4- and 1,5-dienes form stable complexes with Pd^{II}. For most 1,3-dienes, such as 1,3-butadiene, reaction with Pd^{II} compounds leads to π-allyl formation. These reactions are described in Section 7. The coordinated double bonds in palladium diene complexes are reactive toward attack by many nucleophiles, and the resulting chelating alkene palladium alkyls are easily isolated. Many useful reactions of dienes were discovered by Jiro Tsuji in the 1960s and 1970s. These have been recently reviewed in a historical memoir.[56]

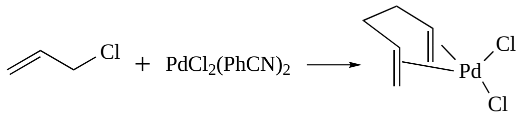
6.1.1 Synthesis of Palladium(diene) Complexes

A general route to Pd^{II}(diene) complexes is the reaction of the diene with $PdCl_2(PhCN)_2$. Norbornadiene, 1,5-cyclooctadiene, cyclooctatetraene, hexamethyl(Dewar benzene), and 1,6-cyclodecadiene all react to give $Pd(diene)Cl_2$ products (equation 39). For 1,5-dienes, the size of the organic ligand and the length of the palladium−alkene bond results in the two alkene groups subtending an angle of close to 90° at the metal, which is the favored angle for square-planar Pd^{II}. In the case of 1,4-dienes, the angle subtended is less, approximately 75°. However, the thermodynamic stabilities of $PdCl_2$(diene) complexes, measured via the enthalpy of the reaction of $PdCl_2(PhCN)_2$ with a diene, decrease in the order norbornadiene > 1,5-cyclooctadiene > 1,5-hexadiene > dipentene > cyclooctatetraene > dicyclopentadiene.



(39)

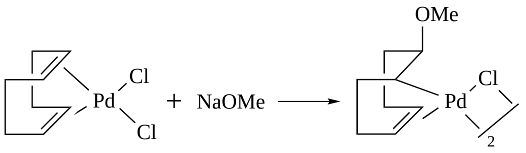
Cyclic dienes preorganize the geometry of the two double bonds, favoring chelation over π-allyl formation. Acyclic dienes tend to give π-allyl complexes. However, the reaction of allyl chloride with $PdCl_2(PhCN)_2$ at low temperatures in the absence of solvent gives the 1,5-hexadiene complex (equation 40).



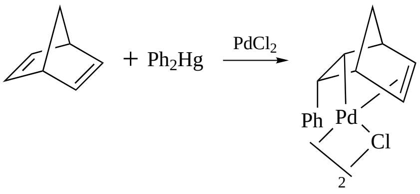
(40)

6.1.2 Reactions of Palladium(diene) Complexes

Many nucleophiles add to one of the double bonds of chelating palladium(diene) complexes to give a chelating Pd^{II}alkyl(alkene) derivative, as exemplified by the reaction of $PdCl_2$(1,5-cod) with methoxide (equation 41). In most cases, the direction of attack is exo. If the nucleophile is in a form that can undergo transmetalation with the Pd–Cl bond, such as Ph_2Hg, the nucleophilic group can be delivered endo. In this case, prior formation of a Pd–nucleophile bond accounts for the direction of attack (equation 42).

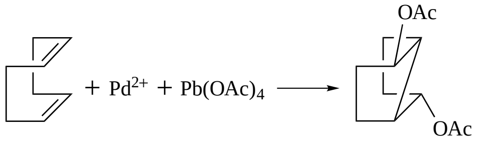


(41)



(42)

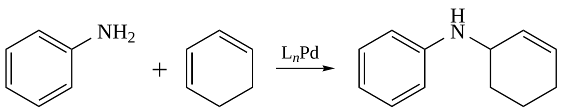
Among the nucleophiles that add exo to coordinated dienes are alkoxides, amines, azide, acetates, halides, and stabilized carbon enolates, such as malonates and β-diketones. The alkoxide addition is reversible if the product is treated with HCl. With a few nucleophiles, double addition reactions are observed. Acetate will react with 1,5-cod in the presence of $Pb(OAc)_4$ and palladium salts to give a bicyclic product from addition of two acetate groups, both exo (equation 43).



(43)

Reaction of 1,3-butadienes and Pd^{II} salts give numerous C_4 and C_8 products, depending on the exact reaction conditions. Either π-allyl C_4 complexes or bis-π-allyl C_8 dimers form, which can undergo further reactions with nucleophiles, CO, or solvent (Scheme 26).

The direct catalytic reaction of nucleophiles such as amines with 1,3-dienes to give allylic amines is difficult to achieve. A high-throughput assay was used to screen catalysts for the 1:1 hydroamination of aniline to 1,3-cyclohexadiene (equation 44).[57]

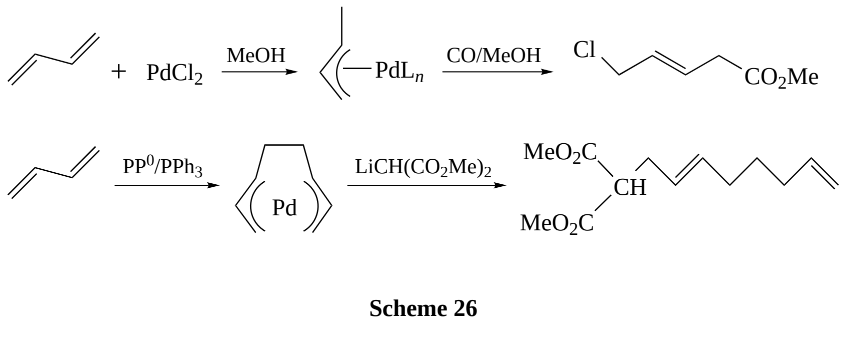


(44)

96-Well glass plates were loaded with different phosphines, metal complexes, aniline, and 1,3-cyclohexadiene. A colorometric assay for unreacted aniline (a red color arising from the acid catalyzed reaction of aniline with furfural) was used to screen successful catalysts, that is, those that did not turn red. Catalysts derived from $[Pd(\pi\text{-allyl})Cl]_2$ and PPh_3 were most active. Increasingly, such high-throughput methods are being used in catalyst discovery and optimization.

Nucleophiles that have a tendency to bind to soft metal centers will usually displace the diene ligand rather than add to the coordinated alkene bond. Among the nucleophiles that react in this way are phosphines, DMSO, and pyridine. The products from these reactions are $PdCl_2L_2$ and free diene. If a chelating phosphine or diamine, such as *o*-phenanthroline, is added to $PdCl_2$(1,5-cod) in the presence of the halide acceptor $AgPF_6$, the product is the cationic [Pd(1,5-cod)(*o*-phen)]$[PF_6]_2$. In addition to silver salts, $[Et_3O][BF_4]$ reacts with $PdCl_2$(1,5-cod) to remove Cl groups, leading to the formation of $[Pd_2Cl_2(1,5\text{-cod})_2]^{2+}$ $[BF_4]_2$.

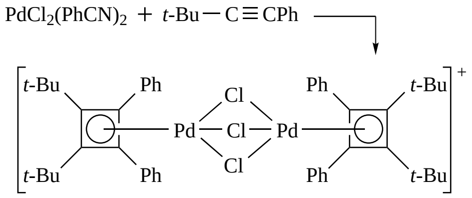
The zero-valent palladium complex Pd(nbd)(ma), nbd = norbornadiene, ma = maleic anhydride, is a useful precursor to novel Pd^0 complexes with nitrogen σ-donor ligands. In THF, pyridine, diethyl amine, aniline, and even NH_3 displaced the nbd ligand to form L_2Pd(ma) complexes.[58]



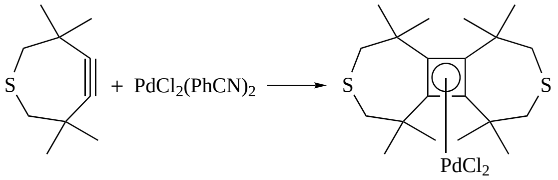
Scheme 26

6.2 Synthesis and Reaction of Cyclobutadiene Complexes

The reaction of alkynes substituted with bulky groups on both carbons with Pd^{II} complexes leads to complexes of substituted cyclobutadienes. Treatment of $PdCl_2(PhCN)_2$ with t-BuC_2Ph gives a cyclobutadiene complex (equation 45). A very interesting case of dimerization to a cyclobutadiene complex is provided by the strained seven-membered ring cyclic alkyne (equation 46).

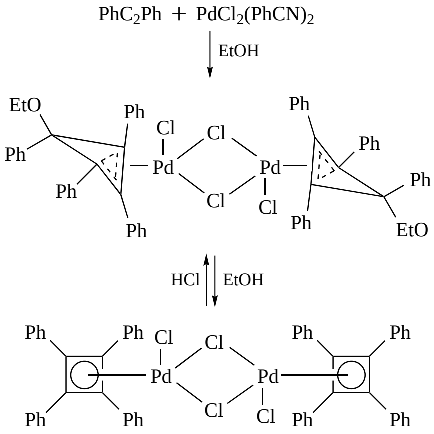


(45)



(46)

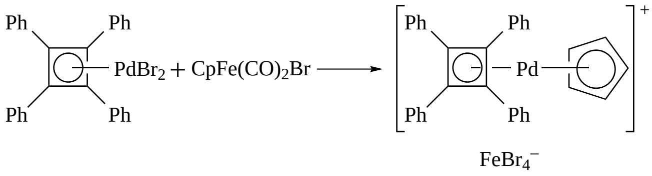
When alkynes such as diphenylacetylene are treated with $PdCl_2(PhCN)_2$ in ethanol, the product is a tetraphenylcyclobutadiene complex to which ethoxide has been added. Addition of HCl causes the alkoxycyclobutenyl ligand to eliminate alkoxide and reform the cyclobutadiene ligand (equation 47). Many of the palladium cyclobutadiene complexes isolated are 18-electron complexes rather than the 16-electron complexes that are common for square-planar Pd^{II}. It has been suggested that the small angle subtended at the metal by the cyclobutadiene ligand allows for three additional groups to bind to the Pd^{II} center.



(47)

6.3 Synthesis and Reactions of Cyclopentadienyl Complexes

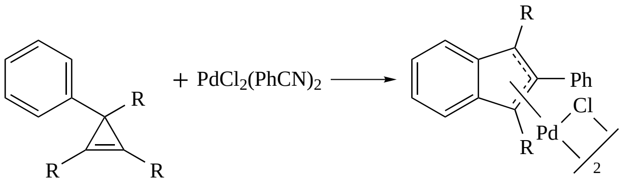
A number of cyclopentadienyl complexes of Pd^{II} are known. In most cases, the other groups are π-allyl, cyclobutadienyl, or a chelating dialkene. Reacting $[Pd(\eta^3$-$C_3H_5)Cl]_2$ with CpNa, for example, leads to the formation of $Pd(\eta^3$-$C_3H_5)(\eta^5$-$C_5H_5)$. Other sources of Cp^- that have been used are $CpFe(CO)_2Br$ and TlCp. This iron complex reacts with $Pd_2Br_4(C_4Ph_4)_2$ to produce a cationic cyclobutadiene cyclopentadienyl sandwich complex of palladium (equation 48). Unlike the case for Ni^{II}, there is no $PdCp_2$ sandwich complex known (*see Sandwich Compound*).



(48)

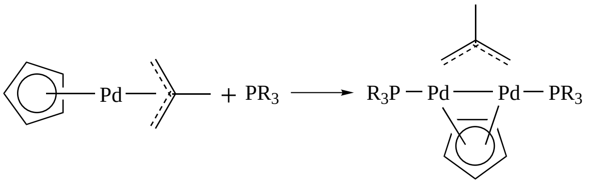
Notwithstanding the fact that $(\eta^5$-$C_5H_5)$ complexes of Pd^{II} are typically 18-electron complexes, they are often unstable toward substitution reactions, especially with phosphines. When $Pd(\eta^5$-$C_5H_5)Ph(PPh_3)$ is treated with excess PPh_3, decomposition takes place. It is probable that η^5 to η^3 to η^1 rearrangements are promoted by the addition of phosphines. The cyclopentadienyl ligand is also lost when $Pd(\eta^3$-$C_3H_5)(\eta^5$-$C_5H_5)$ is reacted with HCl, $HgCl_2$, or $FeCl_2$. In this case, the palladium-containing product is $[Pd(\eta^3$-$C_3H_5)Cl]_2$.

Indenyl complexes of Pd^{II} are prepared by the reaction of indenyl sodium with anhydrous $PdCl_2$. Alternatively, they are available by ring-opening reactions of aryl-substituted cyclopropenes with $PdCl_2(PhCN)_2$ (equation 49).



(49)

Finally, dinuclear Pd^{II} complexes can be prepared, which contain bridging cyclopentadienyl ligands (*see* ***Dinuclear Organometallic Cluster Complexes***). When $Pd(\eta^5$-$C_5H_5)(\eta^3$-2-$MeC_3H_5)$ is reacted with two equivalents of phosphines or phosphites, dinuclear species $Pd_2(\mu$-$C_5H_5)(\mu$-2-$MeC_3H_5)L_2$ are formed (equation 50).



(50)

7 π-ALLYL PALLADIUM COMPLEXES

Palladium forms a more extensive series of π-allyl complexes than any other transition metal. In many cases these molecules are thermally stable, air-stable crystalline solids. In addition to stoichiometric π-allyl compounds, many palladium π-allyls are prepared under catalytic conditions as intermediates in palladium-catalyzed organic synthetic reactions.

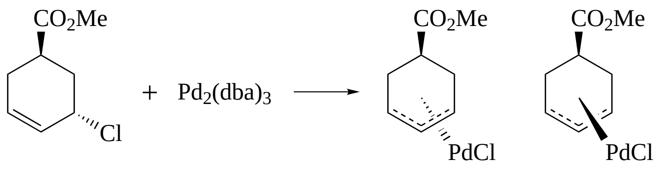
7.1 Preparation of η^3-Allylic Palladium Complexes

7.1.1 From Allylic Precursors

A number of allylic compounds, including allyl chloride and bromide, diallyl ether, allyl acetate, allylmagnesium chloride, and allyltrimethylsilane react with $PdCl_2$ to give $[(\eta^3\text{-}C_3H_5)Pd(\mu\text{-}Cl)]_2$. For these reactions, the Pd^{II} salt must be reduced to Pd^0, either by an added reagent, such as CO or methanol, or by the substrate itself, as in the conversion of diallyl ether to acrolein. It has been established, using allylic carboxylates, that cleavage of the allylic C–O bond by a Pd^0 species takes place with inversion at the C–O bond.[59] In other words, the Pd^0 acts as a nucleophile in an S_N2 reaction.

In the preparation of π-allyl complexes from cyclic allylic chlorides, the stereochemistry of chloride displacement has been found to depend on the reaction conditions (Scheme 27).[60] When the allylic chloride (**17**) is reacted with $Pd_2(dba)_3$, the product from syn oxidative addition, (**18**)-trans, predominates in nonpolar solvents, while polar solvents give the product from inversion, (**18**)-*cis*. When the $Pd(PPh_3)_4$ complex is used as the source of Pd^0, the isomer from anti addition is isolated in essentially quantitative yield. Apparently, more powerful donor solvents or ligands favor anti attack.

In some cases, the cleavage of allylic oxygen bonds by Pd^0 is reversible. When $CD_2{=}CHCH_2OAc$ is treated with $Pd(PPh_3)_4$, which is a common reagent for catalytic generation of allylic palladium complexes, no π-allyl product is observed. However, the isolated allyl acetate is isomerized to a mixture of $CD_2{=}CHCH_2OAc$ and $CH_2{=}CHCD_2OAc$. The reversibility of π-allyl formation in acetates may be the reason that addition of sodium halides frequently improves the yields of Pd^0-catalyzed allylic substitution reactions of allylic acetates.



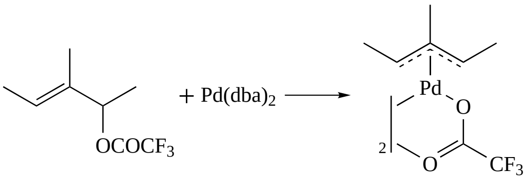
(**17**) (**18**)-*trans* (**18**)-*cis*

	(18)-trans	(18)-cis
Benzene	100	0
Acetone	75	25
DMF	29	71
Acetonitrile	5	95

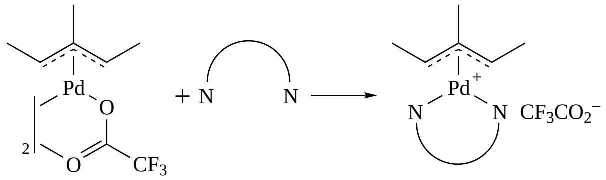
Scheme 27

Allylic carbonates undergo a useful conversion to π-allyl palladium complexes.[61] A Pd^0 reagent readily reacts with an allylic carbonate to form a cationic π-allyl palladium species. The alkyl carbonate anion loses CO_2 to generate a basic alkoxide anion, which is capable of deprotonating other species in the reaction medium.

Allylic trifluoroacetates are very reactive with Pd^0 reagents, generating η^3-allyl palladium trifluoroacetates (equation 51), which can react further to produce cationic π-allyl complexes when reacted with chelating amines (equation 52). The cationic complexes can also be synthesized from η^3-allyl palladium trifluoroacetates by treatment with HBF_4 and ligands, L, producing $PdL_2(\eta^3\text{-allyl})^+\ BF_4^-$ complexes.



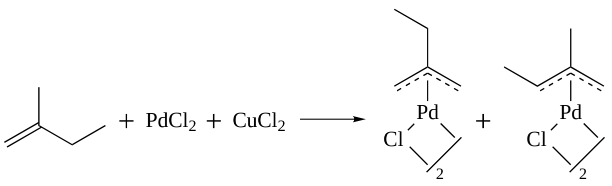
(51)



(52)

7.1.2 From Alkenes and $PdCl_2$

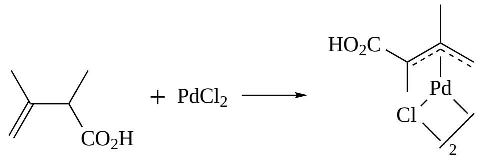
Many alkenes will react with $PdCl_2$, forming a π-allyl complex and one mole of HCl. A base is normally added to react with the HCl produced. Solvents that have proven useful include acetic acid, chloroform, methanol, and DMF. Where isomeric π-allyl palladium complexes can be formed, one often obtains a mixture of products. This is particularly true for reactions run in acetic acid. The addition of $CuCl_2$ causes an increase in regioselectivity, resulting in abstraction of the allylic C–H bond that leads to the more-substituted π-allyl complex (equation 53).



26% 74%

(53)

In general, 2-alkenes will form the more-substituted π-allylic complex, and 1-methylcycloalkanes react to give the π-allyl complex from abstraction of one of the $-CH_3$ hydrogens. If a given alkene is unreactive, use of the very electrophilic $Pd(O_2CCF_3)_2$ may result in reaction. When the alkene contains a particularly acidic C–H bond, such as one α to a carbonyl group, that C–H bond is normally the one abstracted to give the allylic complex (equation 54).

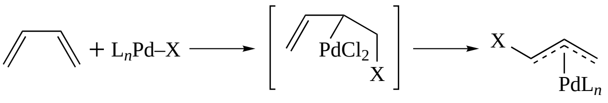


(54)

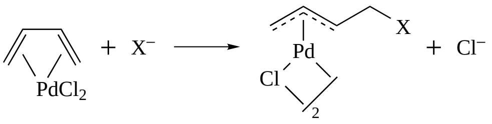
74%

7.1.3 *From Dienes*

The addition of Pd–X groups to 1,3-dienes is an excellent route to η^3-allyl complexes (equation 55). For example, a 1,3-diene and palladium salt in the presence of a nucleophile, such as Cl^-, RO^-, or $RCOO^-$, will produce a π-allyl complex through addition of the nucleophile to a palladium-coordinated double bond (equation 56). Allenes commonly react with addition of nucleophiles at the central sp-hybridized carbon, producing 2-substituted π-allyls. However, because of the orthogonality of the π-orbitals, an η^3-allyl cannot form directly. First an η^1-allyl is generated, then C–C rotation gives the π-allyl.



(55)

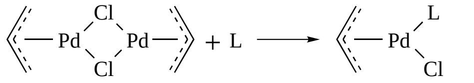


(56)

7.2 Reactions of π-Allyl Palladium Complexes

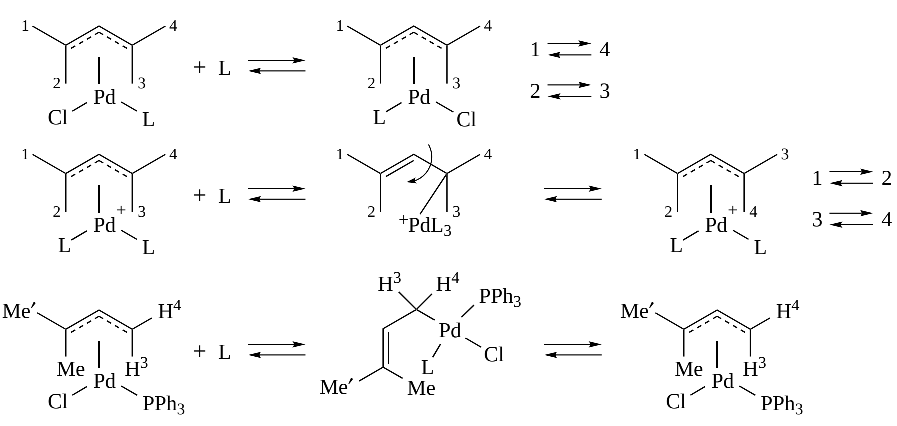
7.2.1 *Reactions at the Palladium Center*

Many ligands will cleave the chlorine-bridged dimer in $[Pd(\eta^3\text{-allyl})Cl]_2$ to give $PdL(\eta^3\text{-allyl})Cl$ (equation 57). Various types of exchange reactions can be followed in the NMR spectrum of π-allyl complexes, depending on the type of ligand added and the temperature of the exchange reaction (Scheme 28).

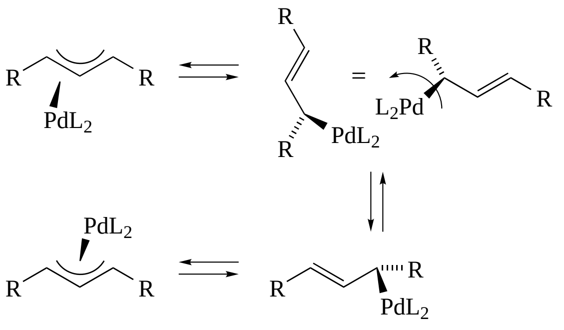


(57)

At lower temperatures, phosphine ligands will promote exchange of the syn protons (1 and 4) and the anti protons (2 and 3) through an associative mechanism. Subsequently, exchange can take place between the syn and anti protons (syn-4 and anti-3 as well as syn-1 and anti-2). Phosphines and other ligands promote this exchange through a complex, which is in equilibrium with an η^1-allyl intermediate. Rotation around the carbon–carbon single bond in the η^1-allyl intermediate exchanges protons 3 and 4, and analogously protons 1 and 2 exchange, leading to an NMR spectrum in which all four protons, 1, 2, 3, and 4, coalesce. A similar type of exchange changes the face of the allyl to which the palladium is bound (Scheme 29). A slightly different process can occur if the π-allyl complex is asymmetrically substituted (Scheme 28). With the 1,1-dimethallyl complex, addition of PPh_3 gives exchange of protons 3 and 4, as shown by coalescence of the NMR signals, but Me and Me′ do not exchange. This can be explained if a four-coordinate η^1-allyl intermediate forms, with the new phosphine ligand less tightly bound to palladium than the original phosphine, due to steric interactions with the methyl groups. Rotation around the carbon–carbon single bond exchanges 3 and 4, and loss of the less tightly bound phosphine returns the π-allyl complex. However, the other η^1-allyl isomer does not form to exchange Me and Me′. If two



Scheme 28



Scheme 29

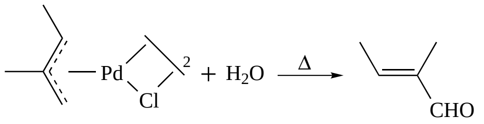
equivalents of PPh_3 are added to the 1,1-dimethallyl palladium complex, the NMR spectra are consistent with the formation of two η^1-allyl complexes, $PdCl(CH_2CH{=}CMe_2)(PPh_3)_2$ and $PdCl(CMe_2CH{=}CH_2)(PPh_3)_2$, in the ratio 5:1.

Further reactions can take place at the metal with the monomeric Pd(η^3-allyl)ClL, where L is a tertiary phosphine. Reaction of these complexes with MeLi at −78 °C produces the Pd(η^3-allyl)MeL species (L = $P(C_6H_{11})_3$, PPh_3, PPh_2Me). These yellow complexes are moderately stable in the air at room temperature for a few days. Thermolysis of these solids gives ethane as the major volatile product, rather than butenes from coupling of the allyl and methyl ligands. When an excess of phosphine ligands or maleic anhydride (which forms stable alkene complexes) is added to the thermolysis (50 °C) mixture, a mixture of butenes and ethane results. Only when allyl chloride is added, which presumably can undergo oxidative addition to give a Pd^{IV} intermediate, do butenes become the major product.

Cationic π-allyl palladium species of the type $[Pd(\eta^3\text{-allyl})L_2]^+$ are important reagents in palladium-promoted organic synthetic reactions.[62] While they can be generated in situ from an allylic acetate and $Pd(PPh_3)_4$, they are also available through the reaction of $[Pd(\eta^3\text{-allyl})(\mu\text{-Cl})]_2$ with silver salts of noncoordinating anions in the presence of ligands, including PPh_3, diphos, 2,2′-bipyridine, and $AsPh_3$.

7.2.2 *Oxidation and Reduction of Allylic Complexes*

At elevated temperatures of 60–100 °C, π-allyl complexes will react with water to give aldehydes or ketones (equation 58). The mechanism probably involves attack of OH^- on the coordinated π-allyl, and elimination of Pd–H to generate the aldehyde group. Molecular bromine cleaves π-allyl–palladium bonds to give allylic bromides. Peracids have been reported to convert π-allyl complexes into allylic alcohols. Photolysis of π-allyl complexes in the presence of oxygen results in the conversion of an allylic group into an α,β-unsaturated ketone.

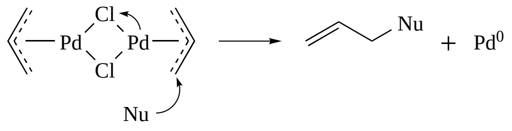


(58)

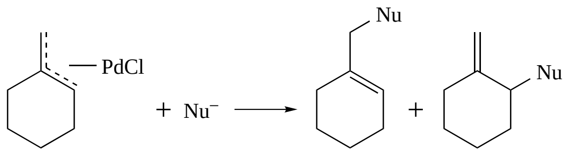
The reaction of π-allyl palladium complexes with hydrogen causes decomposition of the compounds, and produces either alkenes or alkanes, depending on the degree of substitution of the π-allyl complex and the reaction conditions. Hydride reagents, such as $NaBH_4$ and $LiAlH_4$, also reduce the allylic group to alkanes or alkenes.

7.2.3 *Reactions of Nucleophiles at the π-Allyl Ligand*

The addition of nucleophiles to the terminal carbons of the π-allyl group leads to allylation of the nucleophile (equation 59). The nucleophilic group normally bonds to the less-hindered terminal carbon. However, this preference depends on the other ligands coordinated to palladium. In the case of the π-allyl complex derived from methylenecyclohexane, the nucleophile $LiCH(SO_2Me)CO_2Me$ gives the product (**19**) from nucleophilic attack at the less-hindered carbon when the reaction is carried out in the presence of HMPA. Addition of the bulky phosphine tri-*o*-tolylphosphine gives the other regioisomer from bond formation at the more hindered site (**20**) (equation 60).



(59)



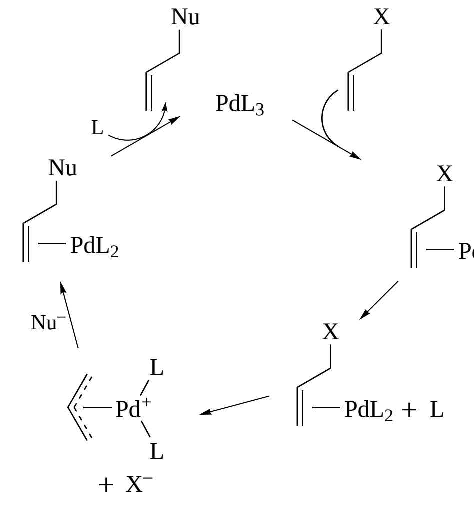
(60)

(**19**) (**20**)

Frequently, $Pd(PPh_3)_4$ (or another Pd^0 complex) is used as a catalyst for the displacement of allylic acetates or halides by nucleophiles. A general catalytic cycle is depicted in Scheme 30. If chloride ions are present, no $(\pi\text{-allyl})PdL_2^+$ forms. Instead, a $(\eta^1\text{-allyl})PdL_2Cl$ intermediate is formed. Thus, different precursors (such as allylic chlorides or allylic acetates) or different reaction conditions can lead to different reactivities, regioselectivities, and enantioselectivities.

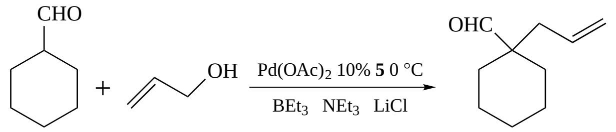
The range of carbon nucleophiles that can be used in the catalytic allylic substitution reaction is not unlimited. The use of more basic reagents, such as alkyllithiums or cuprates, usually results only in reduction of the allylic substrate. Malonate derivatives, enol stannanes, enamines, and stable enols, however, can give allylation products.

With suitable additives, $Pd(OAc)_2$ can catalyze the allylation of even aldehydes using allyl alcohol as the allyl



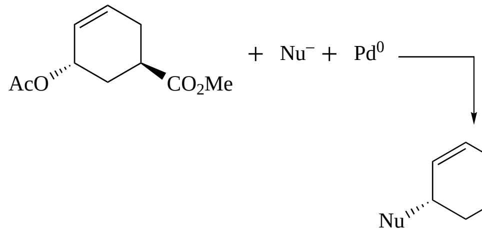
Scheme 30

source (equation 61).[63] Since aldehyde enolates undergo self-condensation and other reactions, this process is synthetically useful. No doubt procedures will be found to carry out allylation of other difficult substrates, such as ketone and ester enolates.



(61)

The stereochemistry of Pd^0-catalyzed allylic alkylation is net retention (equation 62). This arises from sequential inversion steps. Initially, the Pd^0 approaches from the face of the C3 unit opposite the leaving group, to form the π-allyl complex. Subsequently, the nucleophile adds to the face of the π-allyl opposite palladium. If a bulky or unreactive nucleophile is used with allylic acetates, the acetoxy group can add again to the complex. Ultimately, this results in the production of a mixture of stereoisomers upon nucleophilic addition. As an example of the range of allylic substrates that react, nitrogen nucleophiles, in particular primary and secondary amines, undergo palladium-catalyzed substitution with allylic alcohols, acetates, and ethers (equation 63).



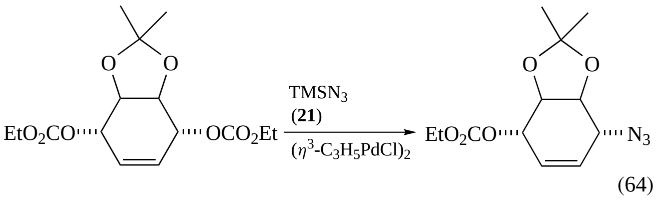
(62)

(63)

7.2.4 *Asymmetric Allylic Alkylation*

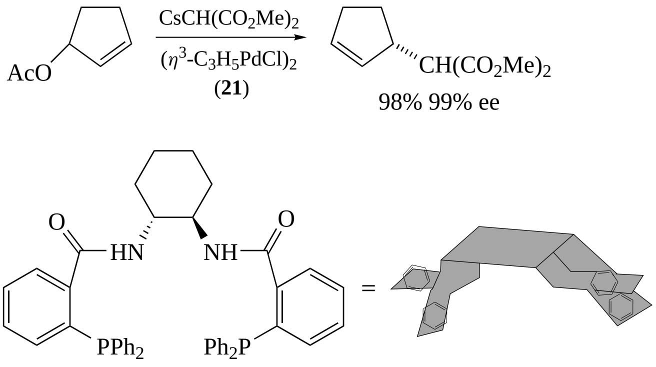
Essentially, any transition metal–catalyzed reaction that generates a product with a stereogenic center has been studied in an attempt to develop a version that is enantioselective. In general, chiral ligands are designed that favor one of two diastereomeric transition states, leading to new bond formation. The case of palladium-catalyzed allylic substitution is a particularly complex reaction to make enantioselective since any one of four steps, alkene complexation, leaving group ionization, nucleophilic attack at one of the allylic termini or exchange of the palladium group (via an η^1-allyl intermediate) between enantiotopic π-allyl cases can control enantioselectivity.[64] For *meso*-allyls, such as those derived from cycloalkyl acetates, it is the nucleophilic attack step that is enantioselective. Using *meso*-substrates, many ligands have been examined, with the bis-amide (**21**) (Scheme 31) being one of the most generally useful. The chirality of the backbone induces propeller twisting of the $P(Ph)_2$ groups, creating a chiral pocket for binding a palladium π-ally (Scheme 31).

The exact ee (enantiomeric excess) is very sensitive to reaction variables, such as solvent and additives (such as R_4NX salts), which influence the amount of ion pairing in the nucleophile. For substrates with enantiotopic leaving groups, the degree of asymmetric induction depends on the ionization step, and is relatively independent of the nucleophile (equation 64).



(64)

Proper choice of leaving group and nucleophile can produce deracemization of allylic carbonates.[65] When an allylic carbonate is treated with $Pd_2(dba)_3$ and (**21**), the loss



(**21**)

Scheme 31

of carbonate is reversible, but the anion can react with water to give bicarbonate. When bicarbonate adds to the π-allyl and CO_2 is then lost, the result is a chiral allylic alcohol (Scheme 32). For this process to work, loss of CO_2 from the allylic bicarbonate has to be faster than reformation of the π-allyl.

7.2.5 Reactions of π-Allyl Complexes Derived From 1,3-Dienes

Several palladium catalysts, including maleic anhydride bis(triphenylphosphine)Pd^0 and bis(π-allyl)Pd^{II}, will dimerize 1,3-butadiene to 1,3,7-octatriene. The mechanism of this reaction is believed to proceed by the formation of an octadienediylpalladium complex, which undergoes β-hydride elimination and transfer of the hydrogen atom to the other allyl group (Scheme 33).

Three-component additions, comprising two conjugated diene molecules and a nucleophile, can be catalyzed by palladium salts, such as palladium acetate. The major products are 1-substituted 2,7-octadienes, along with minor amounts of 3-substituted 1,7-octadienes (equation 65). Water, alcohols, phenols, carboxylic acids, and amines are some of the nucleophiles that have been used in this reaction.

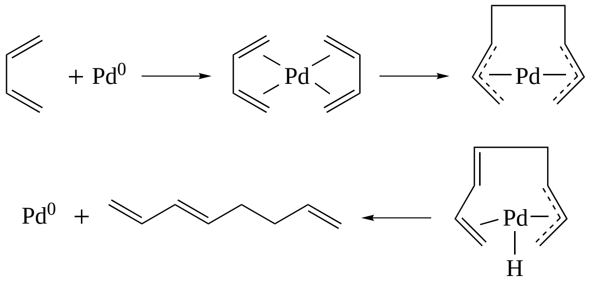
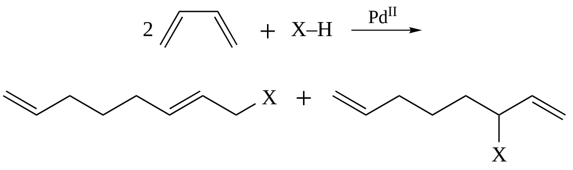


Scheme 33



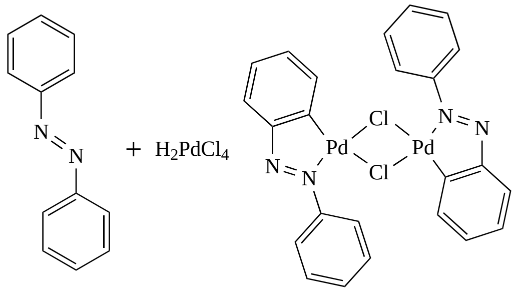
(65)

8 HETEROCYCLIC COMPOUNDS WITH PALLADIUM–CARBON BONDS

8.1 Cyclometalated Complexes: Introduction

Cyclometalation is one of the most reliable and versatile methods for the synthesis of stable Pd–C σ-bonds. In this reaction, a palladium (or other metal) complex is reacted with a ligand possessing a donor atom. The metal is directed by the donor atom to insert into a C–H bond, forming a chelate ring. This donor is usually the nitrogen of a tertiary amine, heterocyclic amine, or imine, or a phosphorus in a tertiary phosphine or phosphite. Other donor atoms, such as O and S, are occasionally encountered. The chelate ring size is normally five.[66]

The first report of cyclometalation in organopalladium chemistry was the reaction of azobenzene with potassium tetrachloropalladate to give the C,N-chelate (**22**) (equation 66). This reaction is characteristic of most cyclometalation reactions with palladium, in that it takes place with Pd^{II} in protic solvents with the loss of HCl, and the resulting chelate is stable to air and moisture.

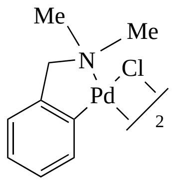


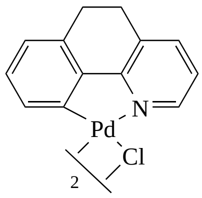
(66)

(**22**)

8.1.1 Scope of Cyclometalation

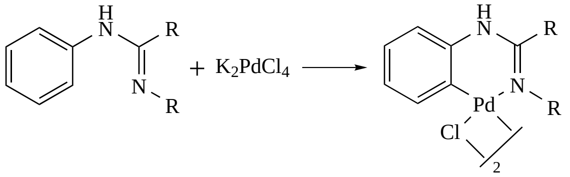
Many different palladium complexes have been used to form chelates via cyclometalation. Li_2PdCl_4 is preferred over $PdCl_2$ for solubility reasons. Also commonly used are $(PhCN)_2PdCl_2$, $Pd(OAc)_2$, $Pd(O_2CCF_3)_2$, and $Pd(acac)_2$. Where amines are the donor atom, dozens of different ligand types have reacted to form five-membered C,N-chelates. These include *N*,*N*-dimethylbenzylamines (**23**) and 3,2′-dimethylene-2-phenylpyridines (**24**).





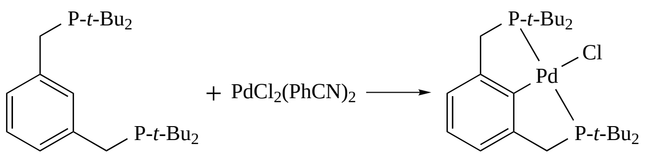
(**23**) (**24**)

Where halogen or acetate is the counterion, the cyclometalated products are halide- or acetate-bridged dimers. Particularly in the case of halides, these dimers are easily cleaved by various ligands, such as pyridine, phosphines, phosphites, and acetylacetone, to give more soluble, monomeric species. Cyclometalation, especially with nitrogen atom donors, inserts into C–H bonds to form five-membered rings. However, formation of six-membered rings can occur (equation 67).



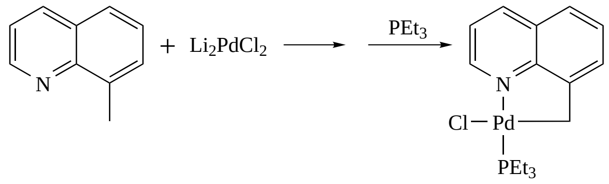
(67)

Cyclometalation directed by phosphorus is common. For example, in triaryl phosphite complexes of Pd^{II}, $PdX_2[P(OAr)_3]_2$ (X = Cl, Br, I; Ar = phenyl, *p*-chlorophenyl, *o*-, *m*-, or *p*-tolyl), react in decalin at reflux to give cyclometalated triaryl phosphite derivatives, $Pd[P(OC_6H_4)(OPh)_2][P(OPh)_3]X$, with loss of one molecule of HX. In these systems, the tendency to undergo cyclometalation is dependent upon the halide, and increases in the order Cl > Br > I. A feature of cyclometalation with phosphines is that bulky groups on the phosphine facilitate the reaction. The bulky diphosphine 1,3-bis[(di-*t*-butylphenylphosphino)methyl]benzene will cyclometalate with $(PhCN)_2PdCl$ in 2-methoxyethanol at reflux to give a tridentate P,C,P ligand (equation 68). These kind of tridentate complexes with one metal–carbon bond and trans donor ligands are known as pincer ligands.[67]



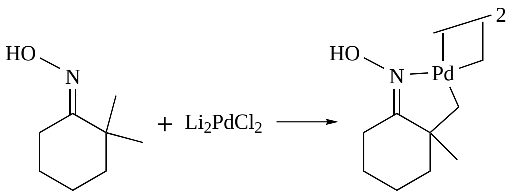
(68)

Cyclometalation occurs with other kinds of C–H bonds besides arene C–H bonds. The 8-methylquinoline ligand and its derivatives provide many such examples of metalation at sp^3-carbon atoms. Treatment of 8-methylquinoline with Li_2PdCl_4, followed by addition of PEt_3 to split the chlorine bridge, provides the cyclometalated complex (equation 69).



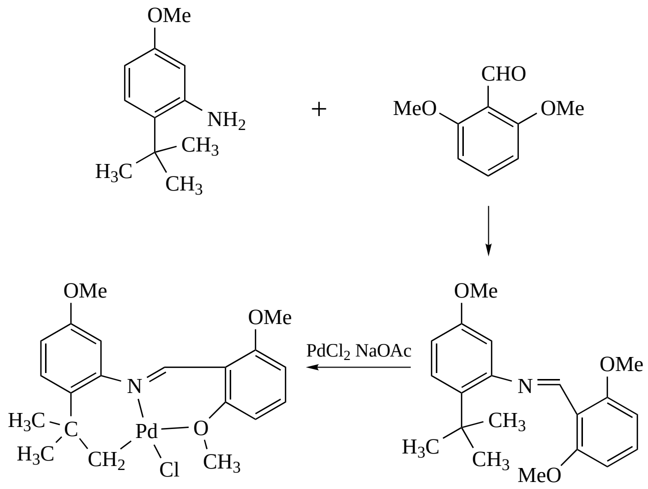
(69)

Other, less activated, sp^3 C–H bonds in addition to the benzylic C–H of 8-alkylquinolines will undergo cyclometalation. (*E*)-2,2-Dimethylcyclohexanone oxime will react with Na_2PdCl_4 to give metalation of the unactivated CH_3 group in 85% isolated yield (equation 70).



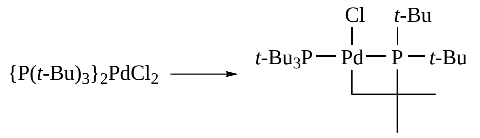
(70)

Unactivated C–H bonds can be functionalized if a suitable directing group can be incorporated into a substrate. For example, an *ortho*-*t*-butylaniline derivative will react with a substituted benzaldehyde to give an imine. This imine nitrogen then directs cyclometalation of the *t*–butyl methyl group (equation 71). The resulting Pd–C bond is then able to undergo further functionalization.



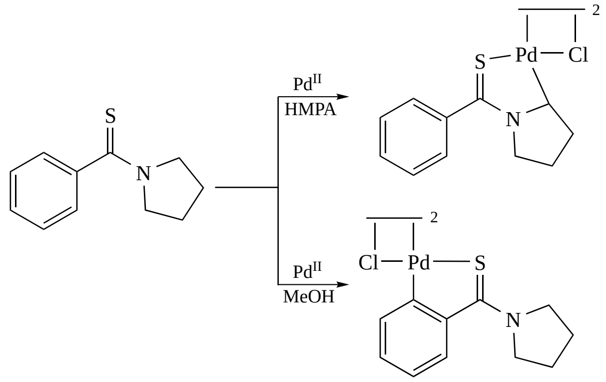
(71)

Phosphine ligands are also able to promote insertion of Pd^{II} into alkyl C–H bonds. For example, P-*t*-Bu_3 will react with $PdCl_2(cod)$ to generate, ultimately, a four-membered chelate ring (equation 72). The longer C–P and P–Pd bonds may be a factor in permitting a transition state, which leads to a four-membered ring. Bis-chelates can also be formed at sp^3 C–H bonds. The ligand P-*t*-$Bu_2(CH_2CH_2\underline{C}H_2CH_2CH_2)$P-*t*-$Bu_2$ undergoes cyclometalation at the underlined carbon, producing bicyclic chelates.



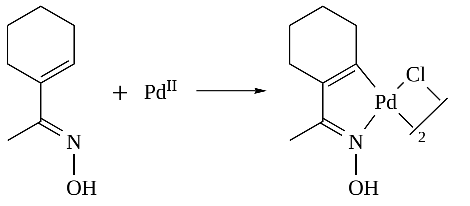
(72)

In some cases it is possible to control the site of palladation, choosing either an sp^3 or sp^2 C–H bond for insertion. When *N*-thiobenzoylpyrrolidine is treated with Pd^{II} in methanol, cyclometalation takes place at the aryl C–H, directed by one of the lone pairs on S (equation 73). When the same reaction is carried out in HMPA, an alkyl C–H bond reacts.[1] The reason for this change of reactivity with change of the solvent is not known. Certainly, different palladium complexes will be present in the two solvents.



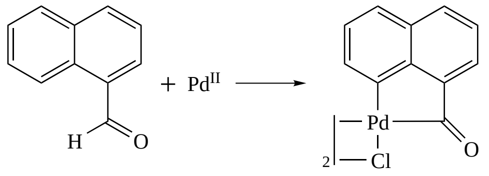
(73)

A limited number of cyclometalation reactions at alkene and related C–H bonds have been carried out. In part, this may have arisen because such ligands can form Pd–alkene π-complexes rather than give C–H insertion products. Nevertheless, examples can be found, as in the cyclometalation of vinylic oximes (equation 74).



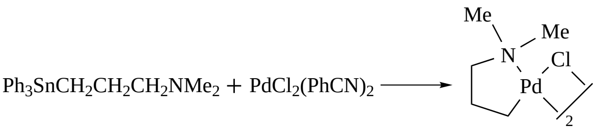
(74)

Aldehyde C–H bonds can also undergo cyclometalation with palladium salts. Reaction of 8-quinolinecarbaldehyde with $PdCl_4^{2-}$ gives a chloride-bridged dimer with a palladium–acyl bond (equation 75). No intermediates could be isolated in case of the palladium reaction, but when $[(PEt_3)PtCl_2]_2$ is reacted with 8-quinolinecarbaldehyde, a platinum complex is isolated with an intact aldehyde C–H bond. The nitrogen atom of the quinoline is coordinated to the platinum, and the aldehyde C–H bond occupies an axial site in the complex. Heating this material results in insertion into the aldehyde C–H bond and formation of a chelated platinum acyl.



(75)

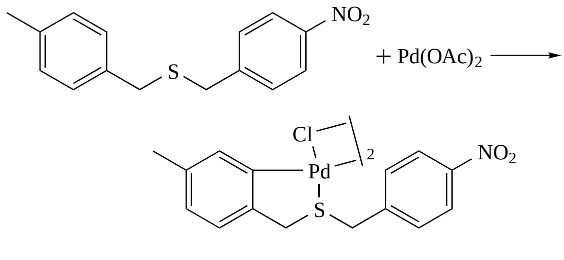
In addition to C–H bonds, cyclometalation can take place through the cleavage of other types of bonds. The ligands n-$Bu_3Sn(CH_2)_3NMe_2$ and $Ph_3Sn(CH_2)_3NMe_2$ react with $(PhCN)_2PdCl_2$ to give five-membered palladium chelates, in which the nitrogen atom is able to direct palladium insertion into a specific carbon–tin bond (equation 76). Normally, the Ph–Sn bond would be more reactive than the alkyl–tin bond, but the chelate formed from insertion into the $Sn–CH_2$ bond is isolated in 72% yield. Directing effects could not, however, lead to formation of four- or six-membered chelate rings via this strategy.



(76)

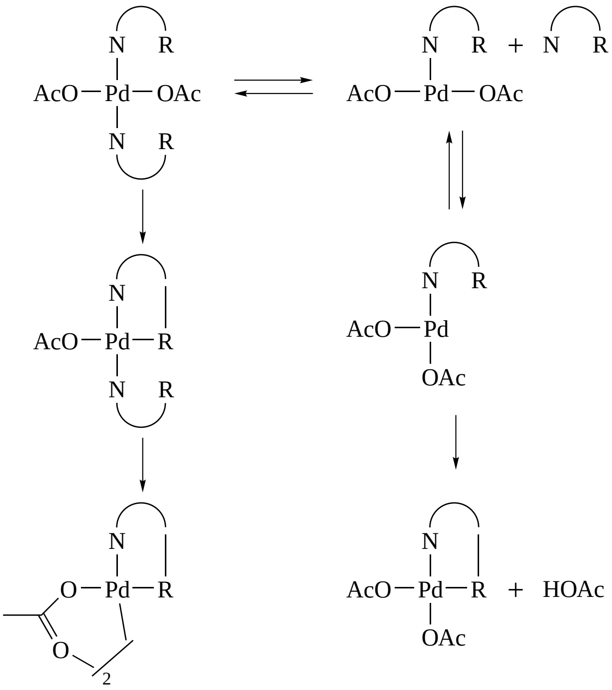
8.1.2 *Mechanism of Cyclometalation with Palladium*

Cyclometalation with Pd^{II} has the characteristics of an electrophilic substitution reaction.[68] With an unsymmetrically substituted azobenzene ligand, $(m\text{-}FC_6H_4)N{=}N(C_6H_5)$, Pd^{II} salts cyclometalate the more electron-rich ring preferentially. Similarly, in the unsymmetrically substituted benzyl sulfide $(p\text{-}MeC_6H_4)CH_2SCH_2(p\text{-}NO_2C_6H_4)$, palladium acetate reacts to give cyclometalation on the alkyl-substituted ring (equation 77).



(77)

Studies of the cyclometalation of *N*,*N*-dimethylbenzylamines in chloroform solution with palladium acetate support the mechanism shown in Scheme 34 (N–R represents the benzyl amine). Two parallel routes to the cyclometalated product exist. One proceeds through a 16-electron complex, while the second route goes via a 14-electron complex with cis acetate groups. The Pd–C bond-forming step is approximately 10^2 faster for the 14-electron complex. It exhibits a kinetic isotope effect, k_H/k_D, of 2.2. Electron-donating substituents on the aromatic ring increase the rate of the Pd–C bond-forming step, consistent with Pd^{II} acting as an electrophile. The $\Delta S^{\ddagger}$



Scheme 34

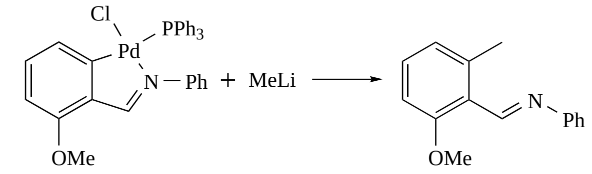
for the rate-limiting step is $-254\,\mathrm{J\,K^{-1}\,mol^{-1}}$, which suggests a highly ordered transition state, in which one acetate group acts as an internal base to remove the proton from the carbon undergoing cyclometalation. Metalation is proposed to take place in the palladium coordination plane.

This mechanism suggests why cyclometalation is common for aliphatic tertiary amines and rare for primary and secondary amines. In general, a tertiary amine is expected to dissociate from Pd^{II} bis(amine) complexes, leaving behind a 14-electron complex, more readily than a less-hindered primary or secondary amine. In order for cyclometalation to take place with primary or secondary amines, a coordination site should be opened up by loss of an anionic group. This can be achieved in halide complexes using Ag^{I} salts. Using (R)-8-(α-deuterioethyl)quinoline, cyclometalation was shown to take place with retention of configuration at carbon, as expected for an electrophilic mechanism.[69]

8.1.3 Reactions of Cyclometalated Complexes

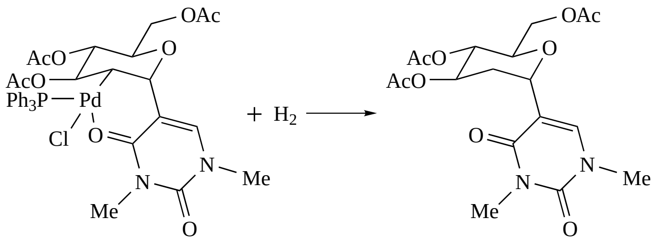
Many of the reactions outlined in Section 4 for Pd–C bonds occur in cyclometalated complexes. However, the existence of the Pd–C bond in a chelate ring imposes some kinetic stability on the bond. In general, mild acids and bases and oxygen are unreactive with cyclometalated palladium complexes. More vigorous reagents will lead to useful reactions, however.

Grignard and lithium reagents will alkylate or arylate the Pd–C bond in cyclometalated complexes. The mechanism involves Pd–halogen exchange with the anionic reagent and subsequent reductive elimination to produce the alkylated or arylated ligand (equation 78).



(78)

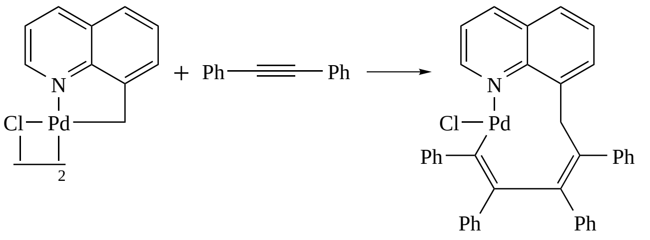
Hydride donors, such as $LiAlH_4$ or $NaBH_4$, will cleave Pd–C bonds, including those in cyclometalated complexes. If the molecule contains groups that will react with hydride reagents, the same transformation can be carried out using H_2 (equation 79). This reaction has been used with $LiAlD_4$ to establish the precise position of metalation.



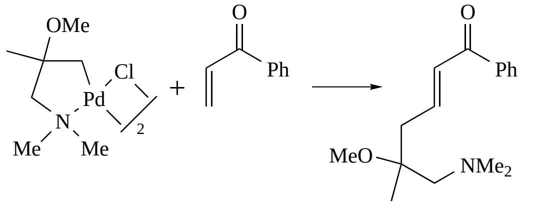
(79)

Electrophilic reagents, including Br_2, Cl_2, NCS–SCN, and I_2, will react rapidly and in high yield to add across the Pd–C bond. Mineral acids will cleave the bond in cyclometalated complexes as well. Since cyclometalation with palladium halide complexes generates HCl, frequently a weak base, such as sodium acetate, is added to prevent reversal of the cyclometalation reaction.

A characteristic reaction of the Pd–C bond in cyclometalated compounds is the insertion of alkynes and alkenes with electron-withdrawing groups. Hexafluoro-2-butyne is particularly reactive, but other alkynes, such as diphenylacetylene and dimethyl acetylenedicarboxylate will also insert into the cyclometalated Pd–C bond. When the chlorine-bridged dimer of cyclopalladated 8-methylquinoline is reacted with diphenylacetylene in refluxing chlorobenzene, two molecules of the alkyne insert to give a nine-membered chelate ring (equation 80). In contrast, hexafluoro-2-butyne produces the mono insertion product, in which the chlorine bridge is intact. Styrene and α,β-unsaturated carbonyl compounds will insert once into the chelate Pd–C bond, followed by β-hydride elimination to form HCl and regenerate the α,β-unsaturated carbonyl compound (equation 81).



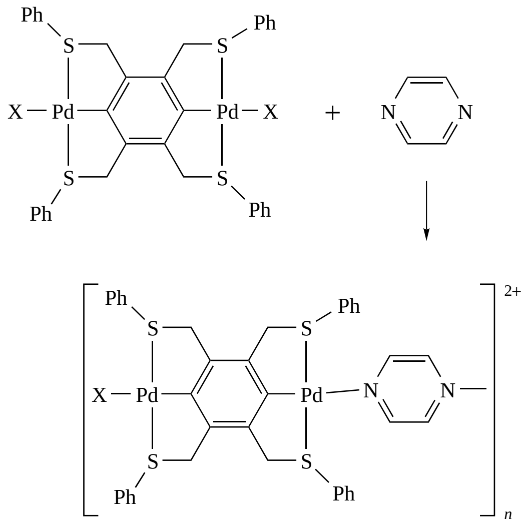
(80)



(81)

Cyclometalated complexes are effective catalysts for most of the common palladium-catalyzed reactions, including the Heck reaction, Suzuki and Stille couplings, the Buchwald–Hartwig amination reaction, and couplings of 1,3-butadienes with CO_2 and alcohols (Scheme 35). Some of these reactions have been suggested to take place through Pd^{IV} intermediates. However, involvement of anionic Pd^0 species, such as (**28**), is more likely. Advantages of palladacycles as catalysts include air and moisture stability, high turnover numbers and thermal stability (catalysts can be recovered and recycled).[70]

Because cyclometalated systems are rigid and stable, they can be used as building blocks for supramolecular assemblies. A 1,4-dipalladated aromatic ring can interact with pyrazine to give linear polymers (equation 82). With other nonlinear diamines, such as 4,7-phenanthroline, cyclic timers are formed.

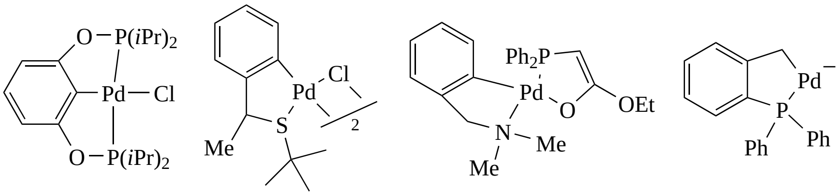


(82)

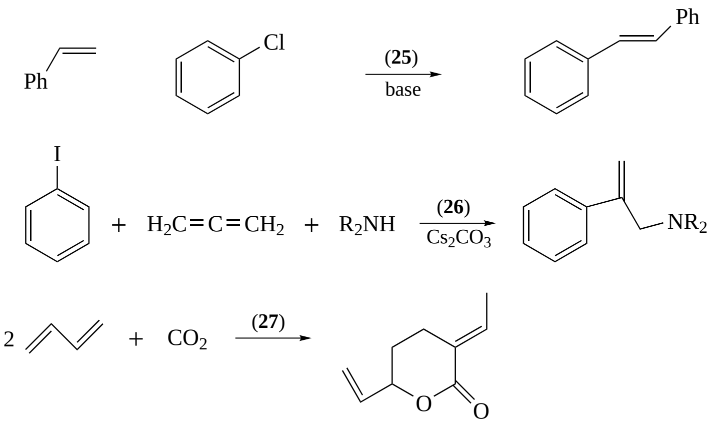
9 OXIDATION REACTIONS (*See Oxidation Catalysis by Transition Metal Complexes*)

9.1 Alkene Oxidations Related to the Wacker Process

The first important application of palladium compounds for industrial and laboratory syntheses was the oxidation of alkenes to carbonyl compounds, vinyl acetates, and related

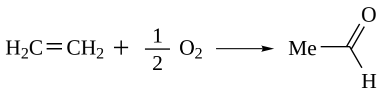


(**25**) (**26**) (**27**) (**28**)



Scheme 35

compounds. The classic example is the commercial process, the Wacker oxidation of ethene to acetaldehyde, which uses a Pd^{II} salt as catalyst, ethene, and water, with oxygen and Cu^{II} as oxidants (equation 83).[7] Under slightly different reaction conditions, ethene can be oxidized to $CH_2{=}CHOAc$, $CH_3CH(OR)_2$, $HOCH_2CH_2Cl$, and $ClCH_2CHO$, among other products. Terminal alkenes give excellent yields of methyl ketones.



(83)

The mechanism for these oxidations involves addition of a nucleophile to an alkene–palladium complex, followed by a step that cleaves the Pd–C bond. While Cu^{II} salts have been used commercially for reoxidation of the Pd^0, many other oxidants have been recommended, such as benzoquinone. Benzoquinone has an advantage for mechanistic studies over $CuCl_2$ in that it does not affect the $[Cl^-]$ concentration.

The kinetics of the reaction have been extensively studied. The rate expression

$$-\,d[C_2H_4]/dt = k^1 K_1[PdCl_4{}^{2-}][C_2H_4]/[H^+][Cl^-]^2$$

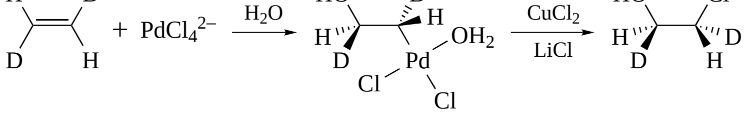
describes the overall kinetics of the reaction. With increasing amounts of $CuCl_2$, chlorine-containing by-products are formed, such as mono-, di-, and trichloroacetaldehyde, along with acetic acid. An interesting feature of the reaction is that when it is run in D_2O, the acetaldehyde product contains no deuterium. Thus, all four hydrogens of ethene are present in the final product. This implies that a vinyl alcohol π-complex of a Pd–H species is an intermediate in the reaction and that the Pd–H adds to the coordinated vinyl alcohol to give a species of the form $CH_3CH(PdL_n)OH$. This can eliminate Pd–H in the direction of the alcohol OH to produce acetaldehyde.

A long-standing controversy in the mechanism of the Wacker process has been the addition of water to the coordinated ethene. On the basis of kinetic arguments, a syn addition of coordinated hydroxide has been suggested. However, an anti attack of water from outside the coordination sphere can also fit the kinetic data. A stereochemical study used *trans*-1,2-dideuteroethylene. In the presence of $PdCl_2$, $CuCl_2$ (2.7 M), and LiCl (3.3 M) in water, β-chloroethanol is formed. The microwave spectrum of the product identified the product as the threo isomer, which would be the expected product if the attack of water on coordinated ethene were trans, and if cleavage of the Pd–C bond occurs with inversion of configuration (Scheme 36).[71]

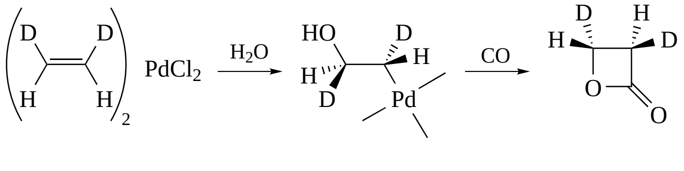
The point has been made that the conditions of β-chloroethanol formation are not the same as used for the Wacker oxidation. Cu^{II}–Pd^{II} chlorine-bridged dimers are likely reactants under higher $[Cl^-]$ reaction conditions, which may lead to a different reaction mechanism. However, a second stereochemical study also obtained results consistent with trans hydroxypalladation. When *cis*-1,2-dideuteroethene is oxidized in water with $PdCl_2$ under a CO atmosphere, the product is *trans*-2,3-dideutero-β-propiolactone (Scheme 37). The reaction conditions were, once again, not identical with standard Wacker process conditions, since the solvent was acetonitrile–water, the temperature was $-25\,°C$, the *bis*-ethene $PdCl_2$ complex was used, and there was no excess Cl^- present. Nevertheless, it is clear that, under many reaction conditions, a trans addition of water onto ethene coordinated to Pd^{II} is the favored reaction stereochemistry.

The rate of alkene oxidation depends on the substitution pattern of the alkene. For a series of alkenes oxidized in aqueous solution, with benzoquinone as oxidant for the $PdCl_2$, the relative rates are ethene (850) > propene(450) > 1-butene (380) > *trans*-2-pentene (90) > *cis*-2-pentene (80) > cyclohexene (8) > cycloheptene (1). Thus, selective oxidation of terminal alkenes to methyl ketones can occur in the presence of internal alkenes (equation 84).

When water is replaced by alcohols as the reaction solvent in Wacker oxidation, the primary products of ethene oxidation are acetals. If base is present, vinyl ethers and acetals

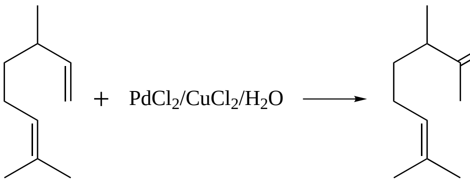


Scheme 36

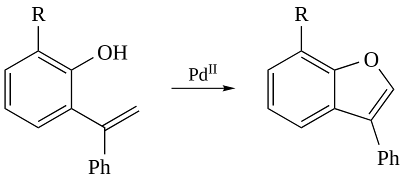


Scheme 37

are formed. For organic compounds with alkenes and OH groups in the same molecule, palladium salts can catalyze intramolecular cyclization (equation 85).

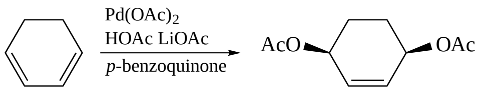


(84)



(85)

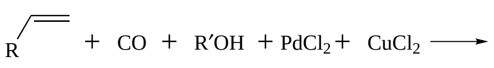
1,4-oxidation of 1,3-dienes is a useful reaction.[72] Nucleophiles such as carboxylic acids, halides, and amines add to the 1,4 positions and overall 1,4-*cis* stereospecificity is easy to achieve. The mechanism involves initial formation of a π-allyl complex that places a nucleophile at carbon 1. Delivery of the second nucleophile from the external direction gives the *cis*-1,4 products, while attack of a nucleophile coordinated to palladium gives the 1,4-*trans* isomer. The Pd^0 intermediates are reoxidized by added *p*-benzoquinone (equation 86).



(86)

9.2 Oxidative Carbonylation of Alkenes and Alcohol Oxidation

In the presence of CO, terminal alkenes are oxidized by $PdCl_2$ to $RCH(Cl)CH_2COCl$. When the reaction is made catalytic in palladium by the addition of $CuCl_2$ and oxygen, and carried out in alcohols, the products are α, β-unsaturated esters, β-alkoxy esters, and, under some conditions, succinate derivatives (equation 87). Two mechanisms are possible for this reaction. In the first, an oxypalladation can produce a $Pd–CH_2–CH_2–X$ species, which can undergo CO insertion into the Pd–C bond. Alternatively, an $XCOPd^{II}$ species can form and add across the double bond. Loss of Pd–H can generate the α, β-unsaturated ester, or a second carbonylation step can lead to succinate derivatives.

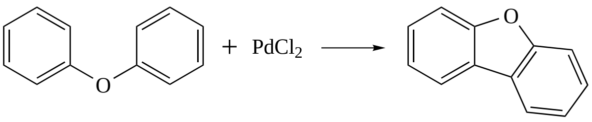


$$RCH{=}CHCO_2R' + R'CHRCH_2CO_2R + (CO_2R')RHCCH_2CO_2R \qquad (87)$$

The catalytic oxidation of alcohols to carbonyl compounds using the oxygen in air as an oxidant is an example of Green Chemistry, since no toxic by-products, such as reduced chromium salts are generated and the reaction could take place in aqueous solvents.[73] A specific catalyst system that works in water with primary and secondary alcohols to give aldehydes and ketones uses an 1,10-pehenanthroline derived ligand (substituted with sulfonic acids to produce water solubility) with palladium acetate and NaOAc. The alcohol is used as a second phase or a cosolvent can be added. The oxidation mechanism involves formation of a L_nPd^{II}-$OCHR_2$ species that undergoes β-hydride elimination to form the carbonyl group and an L_nPd^0 intermediate, which is reoxidized with molecular oxygen.

9.3 Arene–Arene Oxidative Couplings

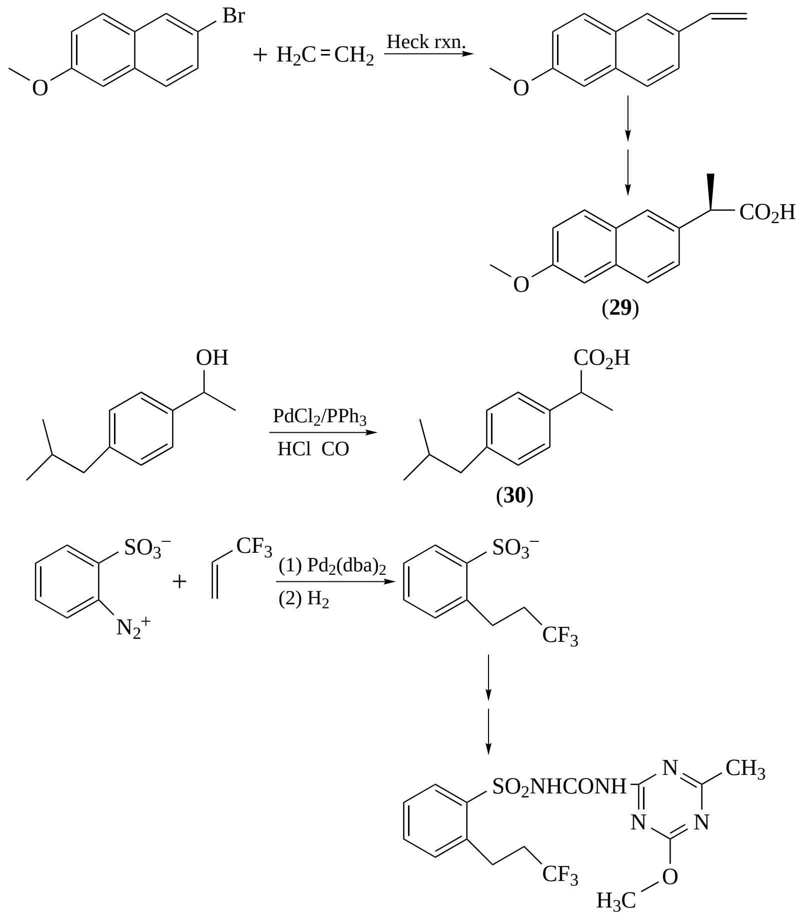
Benzene and related arenes will react with $PdCl_2$ to give good (40–80%) yields of biphenyl derivatives. If palladium acetate is the source of Pd^{II}, a second reaction is acetoxylation. The reaction has some of the characteristics of electrophilic aromatic substitution, in that electron-donating groups speed up the reaction and electron-withdrawing groups retard it. However, the isomer distribution is different from the standard electrophilic aromatic substitution reactions in that meta isomers are formed in substantial amounts from substituted benzene derivatives, and 4,4′-biphenyls are produced in much greater amounts than 2,2′-biphenyls. Intramolecular coupling to form fused heterocycles can take place in high yield (equation 88). Co-oxidants can be used to make the arene-coupling reaction catalytic in palladium. Mixed heteropolyacids of the composition $H_{3+n}PMo_{12-n}V_nO_{40}$ are interesting co-oxidants in that the possibility of chlorinated by-products is avoided.



(88)

10 ORGANIC SYNTHESIS WITH ORGANOPALLADIUM COMPOUNDS

With the variety of transformations that can be promoted by organopalladium reagents, it is unfortunate that palladium is such a rare metal. Biochemical processes might be much more exotic if palladium had been more abundant in the earth's crust at the origin of life (although selenium, which is an essential trace nutrient, is only approximately five times as concentrated as palladium in the earth's crust). The discovery of high turnover number catalysts has allowed several palladium-catalyzed reactions to be used in fine chemical and pharmaceutical synthesis.[74,75] Naproxen (**29**) can be made using a Heck reaction. Ibuprofen's (**30**) synthesis



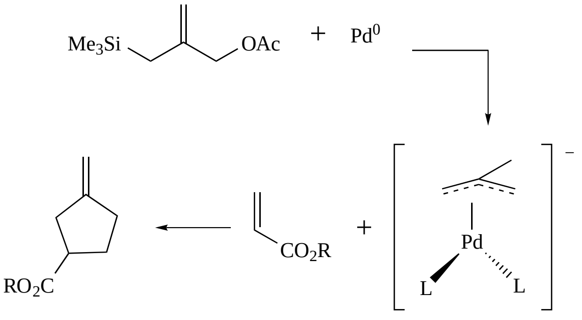
(29) (30) (31)

Scheme 38

involves a palladium-catalyzed carbonylation. The herbicide Prosulfuron (**31**) has been synthesized on a multiton scale using a Heck reaction with a diazonium ion–leaving group (Scheme 38).

10.1 Trimethylenemethane Reactions

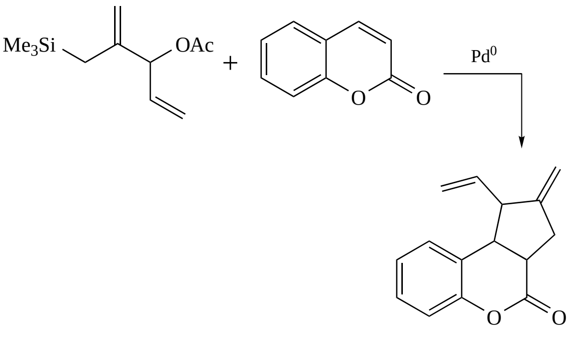
The reaction of $Pd(PPh_3)_4$ with 3-acetoxy-2-[(trimethyl silyl)methyl]-1-propene generates an organometallic *Ylide* complex (**32**), which adds to polarized alkenes (those attached to an electron-withdrawing group) to produce five-membered rings (equation 89).[76] The palladium complex is best described as a trimethylenemethane complex, which is bound in an η^3-fashion; however, this species has not been isolated in the case of palladium. The addition to conjugated alkenes is highly ordered, but stepwise, rather than concerted.



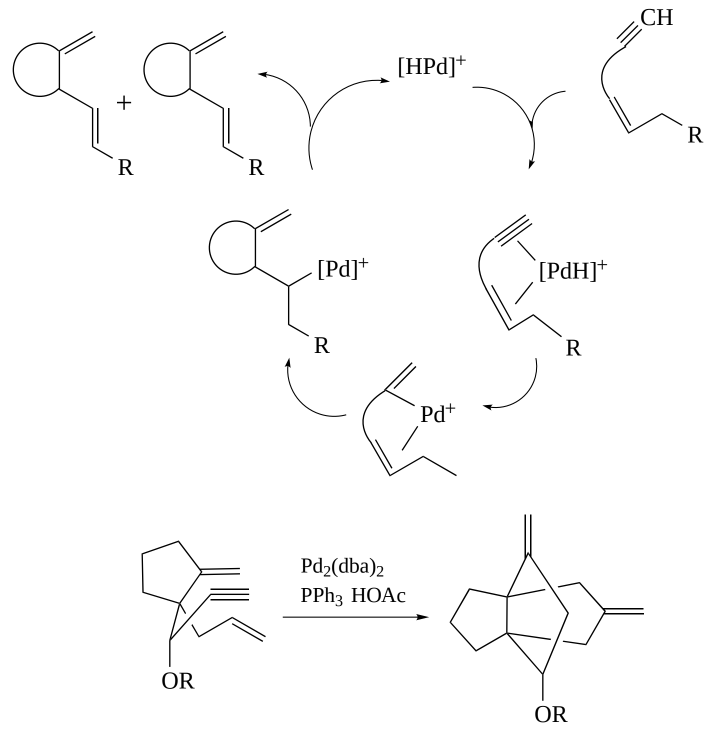
(32)

(89)

Substituted trimethylenemethane complexes can be prepared from the appropriate reagents. In general, any substituents on the trimethylenemethane group direct the attached carbon to the β-carbon of the acceptor alkene (equation 90). This directing effect is seen for both electron-donating and electron-withdrawing substituents.



(90)



Scheme 39

10.2 Cascade Reactions of Alkenes and Alkynes

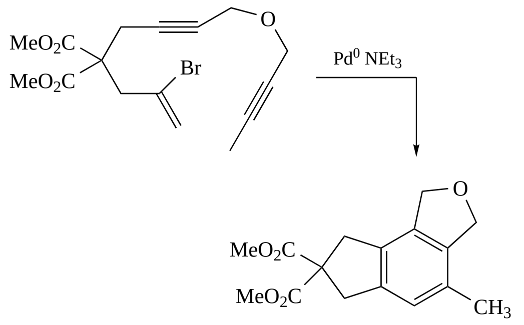
Depending on the organic framework, palladium complexes can initiate a series of additions and insertions with alkenes and alkynes, leading to polycyclic structures from linear or monocyclic starting materials.[77] A simple catalytic cycle for the cyclization of 1,6 and 1,7 enynes is given in Scheme 39.

A living oligomerization process can give linked spiro systems with the proper distance between alkene units (Scheme 40).

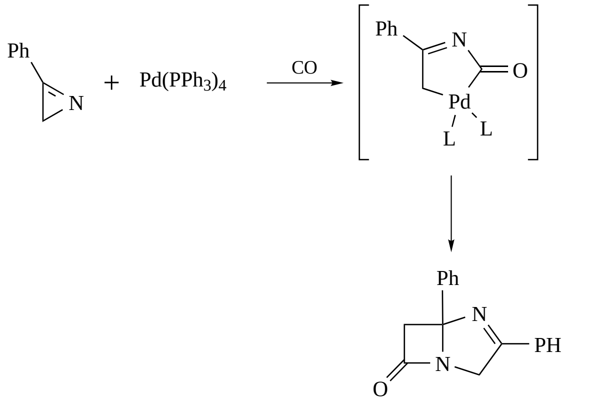
Generation of a σ-palladium species that can insert into alkene or alkyne bonds mimics [2.2.2] cyclization (equation 91).

10.3 Heterocyclic Synthesis via Organopalladium Intermediates

A number of different heterocyclic ring systems can be obtained through the use of palladium catalysts.[78] The facility with which CO, RNC, CO_2, and related unsaturated molecules insert into Pd–C bonds often leads to heterocyclic products. Many transition metal complexes can catalyze the formation of β-lactams. In the case of palladium, treatment of azirines with $Pd(PPh_3)_4$ under CO leads to a bicyclic β-lactam (equation 92).

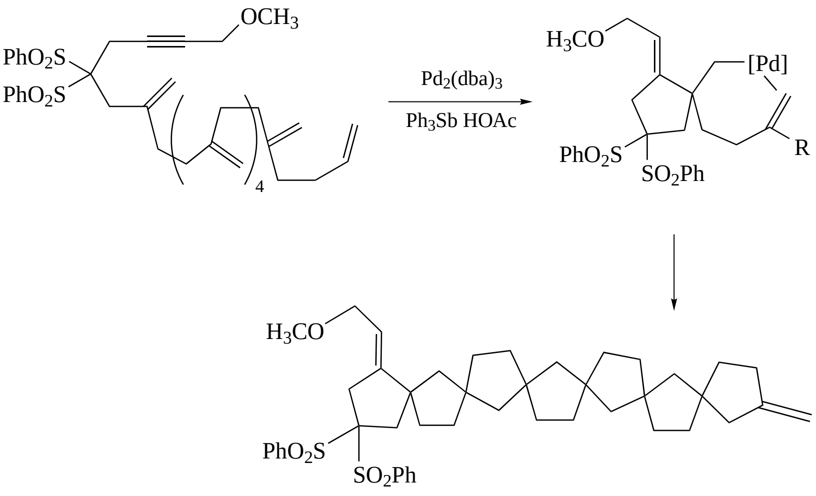


(91)



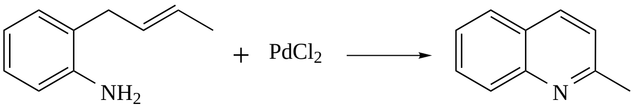
(92)

The palladium-catalyzed intramolecular addition of an amine to an alkene is an efficient route to nitrogen heterocycles. The products often undergo further dehydrogenation under the reaction conditions to form fully aromatic

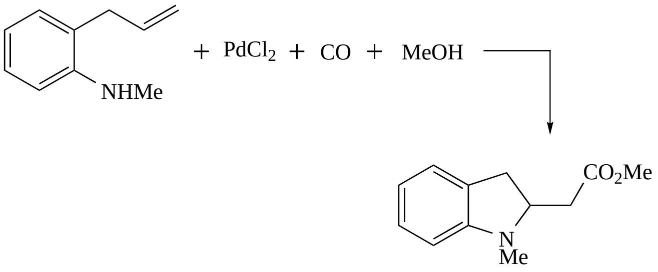


Scheme 40

products (equation 93). In many cases, running the reaction in the presence of CO can lead to insertion of CO into the transient Pd–C bond, and the resulting palladium acyl can react with an alcohol to give an ester (equation 94).



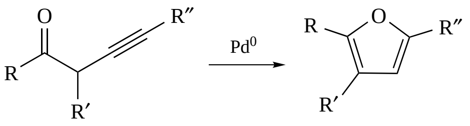
(93)



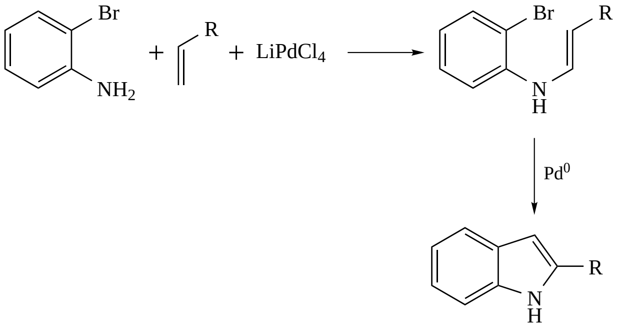
(94)

In these heterocyclization reactions, palladium can be used to introduce the alkene group as well as catalyze the cyclization. Reacting 2-bromoaniline with 1-alkenes and Li_2PdCl_4 at room temperature leads to the vinylamine. Upon heating this product with a Pd^0 reagent at 100 °C, an intramolecular Heck arylation follows to give the indole (equation 95).

Oxygen heterocycles can be prepared in several different ways via palladium catalysis, even though oxygen is a poorer nucleophile than nitrogen. For example, β, γ-alkynic ketones are cyclized to furans in the presence of $Pd(dba)_2$ and PPh_3 (equation 96).



(96)



(95)

Intramolecular cyclization of alcohols to 1,3-dienes can lead to fused tetrahydrofurans and tetrahydropyrans. In this reaction, using 5 mol% $Pd(OAc)_2$, the first step involves a trans oxypalladation to form the heterocyclic ring and a π-allyl palladium complex. In the presence of 0.2 equiv. of LiCl, AcO^- adds trans to the π-allyl, leading to a net *cis*-1,4 addition of oxygen nucleophiles to the diene. When LiCl is omitted, the AcO^- adds to the same face of the π-allyl as the palladium, giving net *trans*-1,4-addition of oxygen groups to the diene (Scheme 41).

acac = acetylacetonate; COT = cyclooctatetraene; Cp = cyclopentadienyl; Cp* = pentamethylcyclopentadienyl; dmit = 1,3-dithiole-2-thione-4,5-dithiolate; DFT = density functional theory; ESR = electron spin resonance; HOMO = highest occupied molecular orbital; LUMO = lowest unoccupied molecular orbital; Mes = mesityl; MO = molecular orbital; NMR = nuclear magnetic resonance; py = pyridine; R = alkyl or aryl moiety; S = spin quantum number; SQUID = superconducting quantum interference device; TCNE = tetracyanoethylene; THF = tetrahydrofuran; Tp = tris(pyrazolylborate); VSM = vibrating sample magnetometer; μ_{eff} = effective magnetic moment; μ_B = Bohr magneton.

1 INTRODUCTION

1.1 'Open-shell' Organometallic Systems

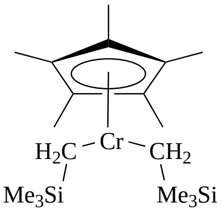
Since the beginning of transition metal organometallic chemistry, the field has been and is still dominated by compounds that follow the effective atomic number (EAN) rule (*see Effective Atomic Number Rule*), also commonly known as the 18-electron rule. However, odd-electron organometallic compounds, once considered to be unstable (with a few exceptions) are no longer rare. In particular, for the first-row transition metals (*see Transition Metals*), stable paramagnetic organometallic complexes have been the focus of numerous synthetic, structural, and reactivity studies.[1] The general notion that open-shell molecules (paramagnetic metal compounds or 'metalloradicals') may be more reactive and thus potentially important as catalytic intermediates has added impetus to the study of these systems.[2,3] As a result, a field completely dominated by the idea that only diamagnetic even-electron (16 or 18) species (*see Eighteen Electron Compounds*) could be involved in catalytic processes, has been increasingly enlightened by the potential of paramagnetic systems.[4,5] The presence of the unpaired electrons also allows for completely different reactivity patterns to be observed (e.g. one-electron redox processes) compared with the more familiar diamagnetic systems. Despite this, the chemistry of paramagnetic organometallic complexes is still relatively unexplored versus that of the diamagnetic, even-electron counterparts, and is thus an exciting, current field of active research.

1.2 Exceptions to the 18-electron Rule

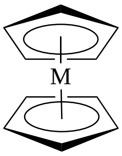
According to molecular orbital theory (*see* ***Molecular Orbital Theory***), maximum stability for a generic ML_n organometallic complex with n ligands results when all the valence shell orbitals are doubly occupied, giving rise to a closed-shell 18-electron configuration. Since the ligand field splitting (*see* ***Ligand Field Theory & Spectra***), Δ (or HOMO-LUMO gap *see HOMO–LUMO Gap*), is large for complexes with carbon-based, π-acidic ligands (*see π-Acid Ligand*) (e.g. CO, Cp, olefins etc.), such complexes readily adopt a diamagnetic (spin-paired) configuration. Still, paramagnetism (*see Paramagnetism*) can arise in 18-electron complexes if the ligand field splitting (*see Ligand Field Theory*) (Δ) is small. An example is the monomeric, paramagnetic, 18-electron, spin-equilibrium molecule Cp*Ni(acac), which is diamagnetic below 150 K but becomes paramagnetic with increasing temperature.[6] That said, paramagnetic organometallic complexes generally violate the 18-electron rule, with both odd- and even-electron stable compounds known. There are several reasons that can be invoked to justify this unexpected stability: (1) The complexes are stabilized with fewer ligands by use of π-donor ligands such as alkoxides, amides, and alkylthiolates that have lone pairs available for additional π donation to the paramagnetic metal center. (2) The complexes are kinetically stabilized with sterically demanding ligands. (3) In systems with fewer than 18 electrons, the incompletely filled molecular orbitals are nonbonding or only slightly bonding. (4) In systems with more than 18 electrons, the partially filled molecular orbitals are only slightly antibonding (*see* ***Molecular Orbital Theory*** and ***Electronic Structure of Organometallic Compounds***).

Open-shell organometallic compounds have electron counts spanning a range of 8–20 electrons. Low electron counts are less frequent, especially for the second and third-row transition metals. The 12-electron triamidoamine complex $MoR[N(CH_2CH_2NR)_3]$ (R = alkyl) is one such system, and is an example of the first factor above. Coordination numbers lower than four are also rare (*see* ***Coordination & Organometallic Chemistry: Principles***), although isolated

examples of two- and three-coordinate complexes such as $Mn[C(SiMe_3)_3]_2$ and $[Mn(Mes)_3]^-$ have been reported with extremely bulky ligands (factor 2). Similarly, the 13-electron complex $Cp^*Cr(CH_2SiMe_3)_2$ (**1**) uses sterically demanding trimethylsilylmethyl ligands to stabilize the mononuclear chromium complex and prevent dimerization.[7] Chromocene (*see Chromocene*) (Cp_2Cr; 16-electron complex) and cobaltocene (*see Cobaltocene*) (Cp_2Co; 19-electron complex) are examples of paramagnetic organometallic complexes that do not obey the 18-electron rule [Cp_2M; M = Cr or Co (**2**)], based on factors 3 and 4 respectively. The other neutral, first-row metallocenes (with the exception of 18-electron ferrocene) also illustrate these two factors at work.



(**1**)



(**2**)

In addition to the synthesis of stable paramagnetic organometallic complexes, studies of radical-based reaction mechanisms have generated investigations of organometallic radical reactivity. Organometallic radicals, especially those characterized with a 17-electron configuration, are receiving a great deal of attention in view of their involvement as intermediates in a variety of fundamental processes.[8]

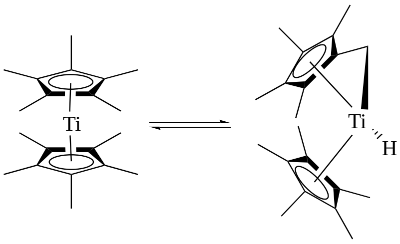
This article is divided into several parts, with long-lived organometallic complexes as the primary focus. Short-lived systems (*see* ***Short-lived Intermediates***), as well as techniques used to characterize paramagnetic systems, will also be discussed. In addition, potential applications of open-shell organometallic complexes, especially for catalysis and magnetic materials, will also be presented.

2 LONG-LIVED PARAMAGNETIC COMPLEXES

2.1 Paramagnetic Metallocene Derivatives

Modern transition metal organometallic chemistry can be said to have been invigorated by the discovery and subsequent bonding description of ferrocene (*see Ferrocene*) by Wilkinson and Fischer in 1951. As predicted by MO theory, all of the neutral first-row metallocenes (*see Metallocene Complexes*) (V–Ni) are paramagnetic, with the exception of ferrocene. Metallocenes probably represent the most studied of all paramagnetic organometallic complexes.

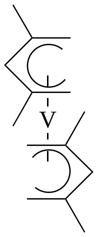
Paramagnetic 19-electron cobaltocene and 20-electron nickelocene (*see Nickelocene*) are stable despite their > 18-valence electron count. These 'extra' electrons occupy metal–ligand antibonding molecular orbitals and cause a lengthening of the M–C bonds (*see* ***Bonding Energetics of Organometallic Compounds***). Some paramagnetic metallocenes are not stable and instead adopt diamagnetic electron configurations, as demonstrated by titanocene (*see Titanocene*) (Cp_2Ti) and rhenocene (Cp_2Re). The latter complex dimerizes via metal–metal bond formation, whereas the former complex C–H activates a ring (*see* ***Alkane Carbon–Hydrogen Bond Activation***) and dimerizes with hydride bridges (*see* ***Hydride Complexes of the Transition Metals***) to give isomeric $Cp_2(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_5H_4C_5H_4)Ti_2(\mu\text{-}H)_2$. Niobocene and tantalocene also dimerize in a similar fashion. However, employing more sterically demanding moieties can stabilize the monomeric form of titanocene (and other paramagnetic metallocenes). The corresponding Cp* derivative of titanocene is thermally sensitive but is nevertheless an isolable compound, in which there is a tautomeric equilibrium (equation 1) between Cp^*_2Ti (**3**) and $Cp^*(\eta^6\text{-}C_5Me_4CH_2)TiH$ (**4**).[1]



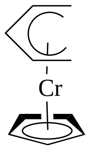
(1)

(**3**) (**4**)

Although analogous bis(pentadienyl) titanium complexes (also referred to as 'open titanocenes') are diamagnetic, paramagnetic 'open metallocenes', such as bis(pentadienyl) vanadocene (**5**) and 'half-open chromocene' (**6**), have also been reported (*see* ***Transition Metal Complexes with Bulky Allyl Ligands***).[1] Compared to Cp rings, the acyclic cyclopentadienyl system is a stronger electron acceptor for geometric and electronic reasons.[9]



(**5**)



(**6**)

A few paramagnetic metallocene cations such as chromocinium ($Cp^*_2Cr^+$) have been reported but are only stable when sterically protected.

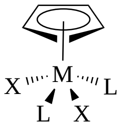
Recently, an effort has been made to develop 'maximum spin' transition metal Cp complexes of which high-spin

d^4 chromocenes and d^5 manganocenes, such as bis(1,3-dialkylindenyl)chromium and octaisopropylmanganocene would be examples. The effect of the eight isopropyl groups in the latter complex results in pure high-spin behavior ($\mu_{eff} = 5.87\,\mu_B$) even at 2 K. By altering the Cp-ligand, many such species are readily accessible, but are highly reactive and serve as versatile starting compounds for a broad range of products.[9] The high degree of reactivity is attributed to the large ionic contribution to metal–Cp bonding in high-spin systems compared to the corresponding low-spin metallocenes.

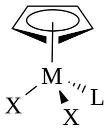
A related area of research involves the paramagnetic η^5-polyphospholyl complexes of the transition metals $[\eta^5\text{-}(C_nR_nP_{5-n})_2]M$ ($n = 0$–3), also referred to as 'phosphametallocenes.' Although the subject has been previously reviewed, several new trends have emerged, in particular, some promising applications in homogeneous catalysis.[10]

2.2 Cyclopentadienyl Ligands as Ancillary Ligands

As mentioned in Section 2.1, much of paramagnetic organometallic research is based on complexes containing Cp-type ligands (*see Cyclopentadienyl*). These ligands are often used as stabilizing ligands that are generally nonreactive (i.e. kinetically inert), and are thus referred to as spectator or ancillary ligands (*see Ancillary Ligand*). For example, so-called 'half-sandwich' compounds (*see Half-sandwich Complexes*), which contain one Cp-type ligand, are ubiquitous in organometallic chemistry. In particular, the group 5 metals (V, Nb, and Ta) form an extensive series of 17-electron, paramagnetic 'four-legged piano stool' complexes of the type $CpMX_2L_2$ (**7**); (X = halide, L = THF, py, PR_3 etc.).[1] The half-sandwich, 'three-legged piano stool' Cr(III) complexes also form a class of very well studied Cp-type systems, with general formulas of $[CpCrL_3]^{2+}$, $[CpCrXL_2]^+$, $CpMX_2L$ (**8**), and $[CpCrX_3]^-$.



(**7**)



(**8**)

The half-sandwich compounds of the trivalent group 6 metals (Cr, Mo, and W) demonstrate how the structure and the reactivity of paramagnetic organometallic compounds are related to their spin state. While molybdenum and tungsten form four-legged piano stool structures (**7**) with 17-electron counts ($S = 1/2$), the chromium system usually adopts the three-legged piano stool structure (**8**) consisting of a 15-electron count ($S = 3/2$).[11] The lower electronic configuration for Cr(III) is not solely attributed to the different metal size and M–L bond strengths, but also to the greater energetic advantage for unpaired electrons in this system (i.e. high spin-pairing energy vs. Δ). Many other paramagnetic half-sandwich compounds are also known and can be pursued in an excellent review.[1]

2.3 σ-Alkyl Complexes

In addition to the ubiquitous Cp-fragment, other donor functionalities can be used to stabilize paramagnetic organometallic compounds. For example, the triamidoamine ligand $[N(CH_2CH_2NR)_3]^{3-}$ has been effectively used to develop a class of paramagnetic Mo(IV) and W(IV) alkyls, aryls, and hydrides of the type $MR'[N(CH_2CH_2NR)_3]$ (**9**).[12] Highly steric β-diketiminate ligands have stabilized isolable three-coordinate σ-alkyl complexes (**10**) of iron, cobalt, and nickel.[13,14] The mixed-donor tridentate diphosphineamido ligand $[N(SiMe_2CH_2PPh_2)_2]^-$ has also been used[15] to stabilize low-coordinate metal compounds of the form $MR[N(SiMe_2CH_2PPh_2)_2]$ (**11**) (M = Co, Cr; R = Me, CH_2Ph, CH_2SiMe_3; M = Fe, R = CH_2SiMe_3, $CH(SiMe_3)_2$).[16–18] The chromium(II) σ-alkyl systems react with alkyl halides RX to give the unusual five-coordinate $Cr(R)X[N(SiMe_2CH_2PPh_2)_2]$ (R = Me, CH_2SiMe_3; X = Cl, Br, I).[18] This reaction also occurs with the simple $[Cr(H_2O)_6]^{2+}$ ion to give $[CrR(H_2O)_5]^{2+}$ cations that are used in organic synthesis (Scheme 1).[19] Such systems have relevance to radical-based organic transformations. This reaction route is also employed for the synthesis of vitamin B_{12} models.[20] The discovery that the active site of vitamin B_{12} contains a readily homolyzable Co(III)-carbon bond has fueled research into the preparation and reactivity of model species that can mimic the coenzyme's bioinorganic functions (*see* ***Cobalt: B_{12} Enzymes & Coenzymes***).

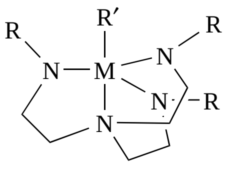
While hindered tris(pyrazolyl)borate (Tp) ligands (*see Tris(pyrazolyl)borates*) have been used extensively as ancillary ligands in bioinorganic and coordination chemistry,

$$Cr(H_2O)_6^{2+} + RX \longrightarrow CrX(H_2O)_5^{2+} + H_2O + R\bullet$$

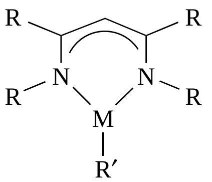
$$Cr(H_2O)_6^{2+} + R\bullet \longrightarrow CrR(H_2O)_5^{2+} + H_2O$$

$$2Cr(H_2O)_6^{2+} + RX \longrightarrow CrX(H_2O)_5^{2+} + CrR(H_2O)_5^{2+} + 2H_2O$$

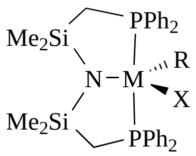
Scheme 1



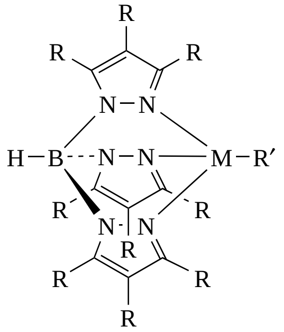
(**9**)



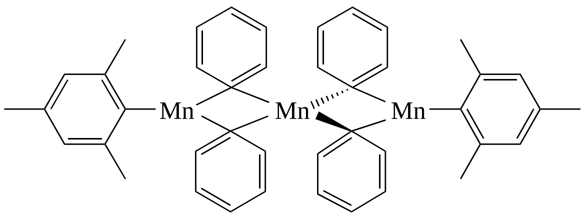
(**10**)



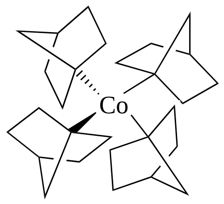
(**11**)



(**12**)



(**13**, central mesityl groups simplified)



(**14**)

their use in the preparation of paramagnetic organometallic compounds has been more limited. One of the most significant features of facial Tp ligands in first-row organometallic complexes is their ability to act as 'tetrahedral enforcers', giving rise to highly coordinately unsaturated (*see Coordinative Saturation & Unsaturation*) organometallic species of the type (Tp)MR′ (**12**) (M = Fe (14-electron species), Co (15 electron species); R′ = alkyl, aryl). The formation of these coordinately unsaturated complexes are important from the point of view that they are suggested to be key intermediates in catalytic C–C bond formation.[21]

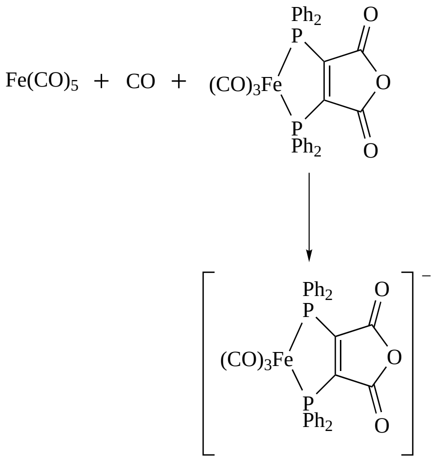
The use of very bulky alkyl groups has allowed for the isolation of highly coordinately and electronically unsaturated, homoleptic (*see Homoleptic Compound*) metal σ-alkyls, some of which are paramagnetic.[22,23] Examples include MR_3 (R = $CH(SiMe_3)_2$, M = Ti(III), d^1; V(III), d^2; Cr(III), d^3), $M(CH_2SiMe_3)_4$ (M = V(IV), d^1; Cr(IV), d^2), and $Mn(CH_2SiMe_3)_2$ (Mn(II), d^5). Homoleptic metal σ-aryls of the form $M(2,4,6\text{-}Me_3C_6H_2)_x$ (M(x) = V(III) and Cr(IV), d^2; Cr(III), d^3; Cr(II), d^4; Mn(II), d^5; Fe(II), d^6; Co(II), d^7) have also been reported; the manganese(II) complex is trimeric (**13**).[24] The 15-electron species $[NBu_4][Ni(C_6Cl_5)_4]$ is the first example of a homoleptic, organometallic Ni(III) compound.[25] The pentachlorophenyl group has also been used to develop a series of homoleptic organochromium derivatives of the type $[Cr(C_6Cl_5)_4]^{n-}$ (n = 0, 1, 2) in three adjacent oxidation states: Cr(IV), Cr(III), and Cr(II).[26] Finally, the series of $M(1\text{-norbornyl})_4$ (M = V, Cr, Mn, Fe, Co) complexes deserve special mention since they include rare examples of highly oxidized iron(IV) and cobalt(IV) (**14**) metal-alkyl complexes, which also have the unique distinction of being tetrahedral and low spin (*see **Ligand Field Theory & Spectra***).[27]

In general, high-oxidation state complexes have far fewer than 18 electrons because extreme steric crowding would result if enough ligands were bonded to the metal center to form either a 17- or 19-electron species. Similarly, dimerization to generate cluster-type complexes is often prevented for steric reasons (*see **Dinuclear Organometallic Cluster Complexes***).

2.4 Ligand Localized Nineteen-electron Complexes

Nineteen-electron organometallic complexes are important intermediates in many organometallic radical reactions.[28,29] However, the short lifetime of many 19-electron species has inhibited a thorough study of their reactivity and electronic structure. On the other hand, ligand localized, or radical-anion ligand complexes are stable systems in which the '19th' electron is localized on the π^* orbital of the ligand. Thus, one strategy for stabilizing such complexes is to introduce a ligand with a low-energy π^* orbital into the complex; such ligands include diazobutadienes, tetraazabutadienes, and quinones. In this case, the unpaired electron preferentially occupies the π^* orbital instead of a metal-centered orbital, which is higher in energy. Systems of this type are often referred to as $18 + \delta$ complexes as they can be described as 18-electron species with a partial electron density contribution to the metal (δ) via delocalization of the unpaired electron from the reduced ligand.[30] For example, the value of δ for compound (**15**) in CH_2Cl_2 (equation 2) is very low at only 0.01, whereas the analogous cobalt complex has a δ value of 0.25 in 2-MeTHF. Ranges of δ, as well as solvent, ligand, and metal effects on δ have also been discussed.[31] These $18 + \delta$ complexes are dissociatively labile, a feature that makes these molecules attractive candidates for catalysts in odd-electron processes. The ability of these systems to catalyze the

cyclooligomerization of acetylenes has been investigated.[32]



(15)

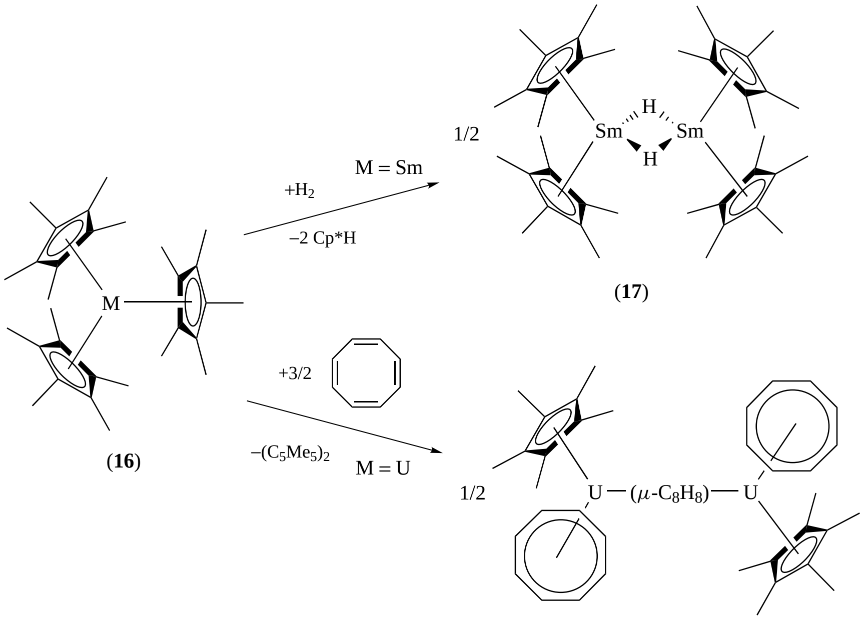
(2)

2.5 f Electron Organometallic Complexes

With the number of stable paramagnetic d element organometallic complexes increasing in the literature, the organometallic chemistry of the f elements is frequently overlooked. In fact, many paramagnetic organometallic lanthanide and actinide systems are also known (*see* ***Actinides: Organometallic Chemistry*** and ***Scandium, Yttrium & the Lanthanides: Organometallic Chemistry***). Organometallic complexes of the diamagnetic d^0f^0 actinides U(VI) and Th(IV),[33] and also the paramagnetic U(IV) and U(III) ions have been reported.[34]

As with their d element counterparts, many organometallic compounds of the f elements involve the use of Cp-type ligands, giving rise to many sandwich and half-sandwich complexes (*see Sandwich Compound* and *Half-sandwich Complexes*).[35,36] Thus, the monoanionic nature and steric flexibility of the Cp-type ligand has been widely exploited for the f elements, since Cp-ancillary groups provide electrostatic and steric stabilization while taking up only one valency of the metal (electrostatic charge balance is important for the f elements, since they have a tendency to form bonds with greater ionic character due to the limited extension of the 4f and 5f orbitals). Also, as the f-element metal centers are generally larger than their transition metal counterparts (*see* ***Actinides: Inorganic & Coordination Chemistry***), they can accommodate (or sometimes require) more sterically demanding ligand sets. For example, substituted cyclooctatetraenes are commonly used as ligands in f-element chemistry.[37] Another set of sterically demanding ligands that has been used to effectively stabilize f-element organometallic systems is the tris(pyrazolylborate)-based ligand framework.[38]

The interesting class of highly sterically congested, paramagnetic $(Cp^*)_3Ln$ complexes have contributed significantly to the advancement of lanthanide organometallic chemistry by introducing new types of reactions and complexes that are not typically observed in other f-element organometallic systems, and certainly not in the transition metal realm.[39] For example, $(Cp^*)_3Sm$ (**16**) has been found to (1) ring-open THF, (2) polymerize ethylene, and (3) react with hydrogen to form a hydride (**17**) with loss of Cp*H (equation 3). None of these processes are known to occur with $(Cp)_3Ln$ complexes.



(16) (17) (18)

(3)

The analogous uranium(III) compounds also show unusual reactivity patterns. For example, addition of COT to $(Cp^*)_3U$ yields a mixed metallocene dimer (**18**) bridged by a COT^{2-} ligand; in this reaction, the $(Cp^*)_3U$ complex has effectively acted as a formal three-electron reductant (equation 3).[40] A variety of substituted $(Cp')_3U$ complexes form adducts with CO and CNR (isocyanides) – these are rare examples of actinide metals with π-acidic ligands.[41] Paramagnetic uranium alkyl complexes are active in a range of catalytic processes.[42]

2.6 Paramagnetic Organometallic Carbene Complexes

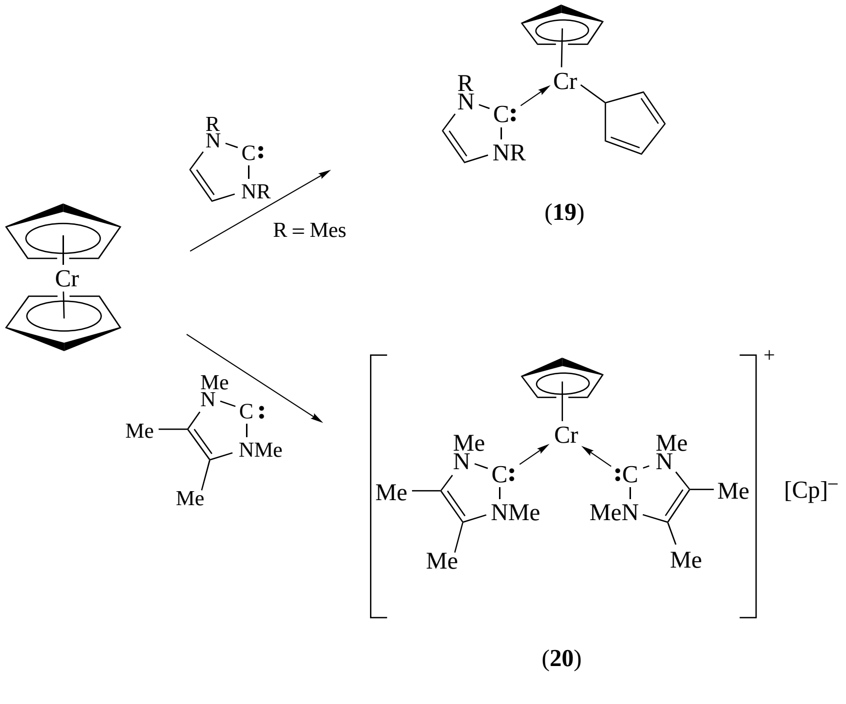
A relatively new area of organometallic research involves the use of carbene-type ligands (*see* ***Carbene Complexes***).[43] Carbenes are often viewed as alternatives to phosphine ligands as they are neutral, two-electron donor ligands, but they do not extensively π back-bond. An interesting example of an organometallic carbene system involves the reaction of carbenes with chromocene (Scheme 2) to generate the 14-electron species $(\eta^1\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)$Cr(carbene) (**19**) and/or a cationic Cr(II) system $[(\eta^5\text{-}C_5H_5)\text{Cr(carbene)}_2]^+$ (**20**).[44]

3 SHORT-LIVED PARAMAGNETIC COMPLEXES

Organometallic radicals are a topic of special interest due to their reactivity and potential activity in the catalytic realm. There are several methods used to generate short-lived organometallic radicals such as homolysis of metal–metal or metal–ligand bonds, electron transfer (*see* ***Electron Transfer in Coordination Compounds***), atom abstraction, or addition of organic radicals to closed-shell complexes.[2,29] In addition, chemical or electrochemical redox reactions can also be used (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). These methods will not be discussed here but can be pursued in the very thorough review conducted in the previous edition of this series.[45]

3.1 17- and 19-electron Radicals and 'Super Reducing Agents'

Transient species (17- or 19-electron) are generally formed from the starting diamagnetic 18-electron (or 16-electron) complexes by the addition or loss of one electron.[2,29] These radicals are usually much more reactive than their diamagnetic counterparts. For example, substitution of the 17-electron organometallic radical $[Fe(CO)_3(PPh_3)_2]^+$ by pyridine nucleophiles occurs 10^9 faster than in its 18-electron analogue $[Fe(CO)_3(PPh_3)_2]$.[46] The kinetics and reactivity of 17-electron radicals have been conducted both in organic solvents and also in aqueous solution.[47] In the presence of electron-pair donor ligands, 17-electron organometallic radicals readily convert to 19-electron adducts.[48] Experimental measurements of K_{eq} show that in many systems, the formation of a 19-electron adduct is thermodynamically stabilizing.[48] Stable 19-electron (or $18+\delta$) systems were discussed in Section 2.4; genuine 19-electron metalloradicals are those in which the extra electron is localized in a



Scheme 2

metal–ligand antibonding orbital. The inherent instability of such species gives rise to 'super reducing agents', which are, in principle, capable of single electron transfer to a wide variety of substrates. An example of a highly reducing 19-electron radical is the L-$W(CO)_5^{\bullet -}$ species, which is formed from the reaction of photogenerated $W(CO)_5^{\bullet -}$ radicals (*see* ***Luminescence Behavior & Photochemistry of Organotransition Metal Compounds***), with donor solvents or phosphine ligands (L = THF, MeCN, PEt_3; equation 4 and 5).[49] Electrochemical reduction has also been used to generate 19-electron radicals, such as the bis-phosphine nickel(I) species $CpNi(PR_3)^{\bullet +}$. It should be noted that $CpM(CO)_3L^{\bullet}$ radicals are often referred to as 19-electron radicals, however, these systems might adopt 17- or 18-electron configurations in solution via 'slippage' (η^5 to η^4 or η^5 to η^3) of Cp rings.

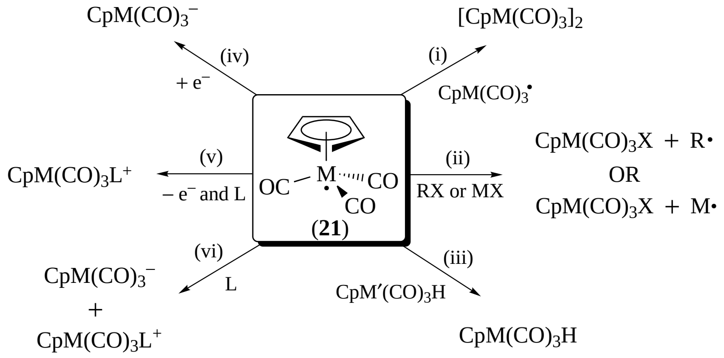
$$[W_2(CO)_{10}]^{2-} \underset{}{\overset{h\nu}{\rightleftharpoons}} 2\,W(CO)_5^{\bullet -} \quad (4)$$

$$W(CO)_5^{\bullet -} + PPh_3 \overset{k_f}{\rightleftharpoons} [W(CO)_5(PPh_3)]^{\bullet -} \quad (5)$$

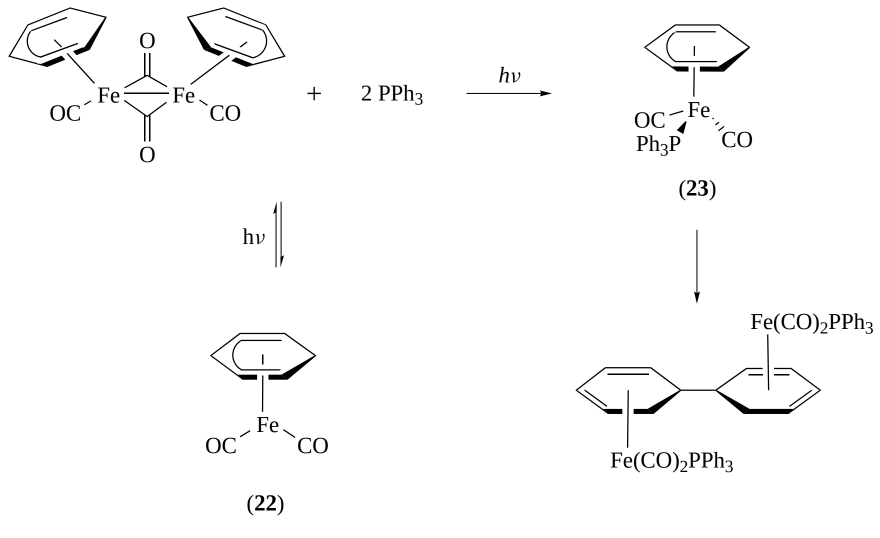
3.2 Reactions Involving Transient Organometallic Radicals

An organometallic radical may undergo several different types of reactions.[45] Scheme 3 illustrates some different reactions of $CpM(CO)_3^{\bullet}$ radicals (**21**)[50] including (i) dimerization; (ii) halide abstraction from an alkyl halide or metal halide; (iii) hydrogen atom abstraction from metal hydrides; (iv) electron-transfer reduction; (v) electron-transfer oxidation and ligand addition; (vi) electron-transfer induced disproportionation (*see* ***Electron Transfer in Coordination Compounds***).

Neutral 17-electron complexes tend to undergo metal-centered reactions, while reactivity of 19-electron complexes are typically ligand-centered. Scheme 4 displays an example of these reactivity differences within the same system.[51] Photolysis of the iron dimer results in homolysis of the metal–metal bond to form the neutral 17-electron species (**22**), whereas in the presence of PPh_3, the intermediate 19-electron radical (**23**) is produced, which then undergoes ligand oxidation to yield a 17-electron final product. Selected



Scheme 3



Scheme 4

aspects of metal radical reactivity have been previously reviewed.[52]

4 CHARACTERIZATION OF PARAMAGNETIC COMPLEXES

The study of paramagnetic organometallic complexes has been hampered by the difficulty of their characterization relative to diamagnetic systems. In particular, proton and multinuclear magnetic resonance spectroscopy are much less applicable to paramagnetic systems. Although ESR (or EPR) spectroscopy (*see Electron Paramagnetic Resonance*) is often considered a valuable tool in the study of paramagnetic systems, this technique can also be of limited use as many complexes are ESR-silent.

4.1 Paramagnetic NMR Spectroscopy

Paramagnetic complexes are characterized by the usual physical methods, however, the application of NMR spectroscopy usually yields resonances that are broadened and highly shifted from their diamagnetic values.[53] Furthermore, coupling information is usually lost. The unpaired electrons in a paramagnetic system can relax NMR-active nuclei via either dipole–dipole interactions or through-bond coupling resulting in broadened or even unobservable peaks. The shifting of resonances through either pseudo-contact shifting (through-space effects) or contact (Fermi) shifts (through-bond effects) can hinder resonance assignments. Despite these setbacks, assignments of a paramagnetic ^{1}H NMR spectrum can still be obtained using a combination of peak integration, broadness and shift patterns, and variable temperature studies.[54]

Generally, ^{1}H NMR peaks of paramagnetic molecules will sharpen and shift toward their diamagnetic values upon an increase in temperature. Consequently, plots of chemical shift (δ) versus 1/T are often useful as the y-intercept is the theoretical diamagnetic value of δ.

Unfortunately, nuclear relaxation effects in paramagnetic compounds are generally too strong to allow for the observation of spectra of other nuclei, such as ^{31}P or ^{13}C. However, ^{2}H NMR spectroscopy has been shown to be a useful procedure for obtaining sharper spectra as the deuterium nucleus relaxes at a substantially slower rate than the proton, allowing for sharper lines.[53,55] Solid-state NMR studies have also successfully been performed for paramagnetic organometallic complexes. The first 2D-correlation NMR experiment involving the detection of dilute spins (e.g. ^{13}C) in a nonlabeled paramagnetic solid Cu(II)(DL-alanine)$_2$·H_2O was recently observed.[56] Furthermore, solid-state NMR spectroscopy has also been applied toward the characterization of paramagnetic metallocenes and metallocenium ions.[57]

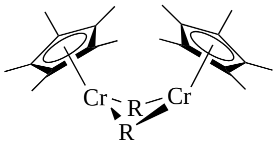
4.2 ESR Spectroscopy and DFT Calculations

ESR spectroscopy detects unpaired electrons and their coupling to nearby spin-active nuclei. However, due to fast relaxation of the unpaired electrons causing broadening of the resonances and zero-field splitting of integer spin states to yield a nonmagnetic $S = 0$ ground state, a large number of paramagnetic complexes are ESR-silent. Cooling the sample to liquid nitrogen or helium temperatures can sometimes reduce fast relaxation, and then in some cases, a signal can be observed. However, ESR spectroscopy is widely used in studying $18 + \delta$ complexes in order to identify the spin density and delocalization of the ligand-unpaired electron. When observable, ESR spectra are also used to study fluxional processes. The applications of ESR to organometallic chemistry have been reviewed.[2] The spin density distribution within organometallic compounds has also been examined via NMR spectroscopy.[58]

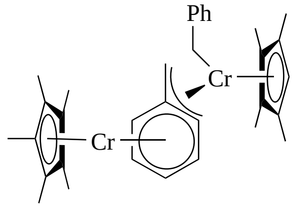
Density functional theory (DFT) has recently been employed in conjunction with ESR in order to determine where the ‘extra’ electron is in a 19-electron species (i.e. is it ligand localized, metal localized, or delocalized over the entire molecule). For example, this technique has been applied to determine that the 19th electron in both $[CpCo(CO)_2]^-$ and $[Mn(CO)_5Cl]^-$ is delocalized over the entire molecule.[59,60]

4.3 Magnetism

Paramagnetism typically results from magnetic effects due to the spin and orbital motion of unpaired electrons. A detailed theoretical explanation of magnetic behavior is well beyond the scope of this review (*see* ***Magnetism of Extended Arrays in Inorganic Solids*** and ***Magnetism of Transition Metal Ions***), and can be explored in various other treatises on the subject.[61,62] Solid-state magnetic susceptibilities (*see Magnetic Susceptibility*) of complexes may be obtained using VSM and SQUID magnetometers, while Evans' method[63] (*see Evans Method*) is an NMR technique for the measurement of magnetic susceptibilities in solution. The measurement of the magnetic susceptibility and calculation of the magnetic moment can provide important information as to the oxidation state and spin state of the compound. For mononuclear systems, this determination can be straightforward, but in cases where two or more paramagnetic metal ions are bridged by diamagnetic ligands, their spins may interact giving rise to antiferromagnetic (spins-opposed) or ferromagnetic (spins-aligned) coupling (*see Antiferromagnetism* and *Ferromagnetism*). For example, the dinuclear complex $[Cp^*Cr(\mu\text{-Me})]_2$ (**24**) has a magnetic moment smaller than that expected for a low-spin Cr(II) center ($S = 1$; $\mu_B = 2.87$), implying that the two chromium atoms of the dimer are strongly antiferromagnetically coupled.[64] However, ferromagnetic behavior is observed in (**25**), which is described as a mixed-valent Cr(I)/Cr(III) dimer. Thus, the spins of all the unpaired electrons are aligned with the magnetic



(**24**)



(**25**)

field (S = 3/2 for Cr(III) and S = 1/2 for Cr(I)), giving rise to a molecule with four unpaired electrons (S = 2) and a higher magnetic moment than expected.[65]

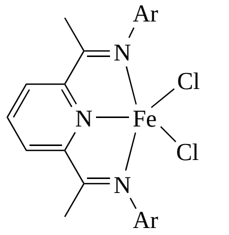
5 APPLICATIONS OF PARAMAGNETIC ORGANOMETALLIC COMPLEXES

The synthesis and reactivity of paramagnetic organometallic complexes (*see* ***Mechanisms of Reaction of Organometallic Complexes***), in particular reactions involving the metal–carbon bond, are of interest from both an industrial view (primarily catalysis) and from an academic view, in terms of the novelty of such compounds. The use of reactivity patterns (e.g. radical reactions) unique to the presence of unpaired electron density at the metal center is of interest to synthetic chemists. In addition to catalysis and organic synthesis, potential applications of paramagnetic organometallic complexes include their use as spin-labels,[66] as building blocks in supramolecular chemistry and crystal engineering,[67] and in the development of systems displaying optical limiting properties.[68]

5.1 Reactions and Catalytic Cycles Involving Paramagnetic Organometallic Species

One of the most useful applications of paramagnetic organometallic chemistry is in the area of catalysis. In addition to the development of diamagnetic zirconocene-based (Cp_2Zr) technology,[69] there has been intensive investigation into the study of the active site(s) of chromium-based catalysts, which produce approximately one-third of the world's polyethylene. A recent review examines several homogeneous, coordinatively unsaturated paramagnetic alkyl chromium complexes in intermediate oxidation states (II – IV) that have been studied with respect to their ability to act as catalysts for olefin polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).[70]

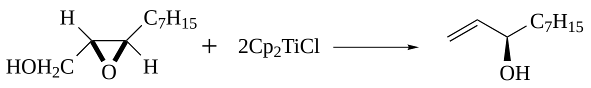
Diamagnetic group IV metallocene systems (and their related half-sandwich analogues) have typically dominated the field of olefin polymerization catalysis, but more recently focus has turned toward nonmetallocene paramagnetic species.[71] In particular, complexes of iron(II) and cobalt(II), featuring the bis(imino)pyridine ligand, have been shown to exhibit high activity rates (see complex (**26**) for the iron example), although the exact nature of the active site is still under investigation. In addition, vanadium(III) complexes, including substituted $V(acac)_3$ complexes, are widely employed in ethylene–propylene copolymerizations.[72] Paramagnetic organometallic species are also employed in other areas of catalysis – the 19-electron iron(I) complex $[FeCp(C_6Me_6)]$ has been effectively used as a catalyst to synthesize $Ru_3(CO)_{11}$-loaded dendrimers, which have potential applications as electron-transfer-chain catalysts.[73]



Ar = 2,6-$^iPr_2C_6H_3$, 2,4,6-$Me_3C_6H_2$

(**26**)

Paramagnetic metallocenes, such as the titanocene(III) species, have been shown to be effective reagents to reduce aryl and alkyl halides, ketones, and aldehydes (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***). $[Cp_2MCl]_2$ (M = Ti and Zr) are useful in carbohydrate chemistry for the conversion of glycosyl halides to glycals, and for the stereoselective preparation of glycosides.[74] The mechanisms of these reactions are proposed to involve the generation of free radicals.[75] Equation (6) shows the clean deoxygenation of the alcohol (*R*,*R*)-2,3-epoxy-1-decanol to (*R*)-1-decen-3-ol with no loss of stereochemistry.



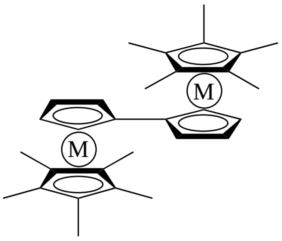
(6)

5.2 Magnetism and Metallocene-based Magnets

The synthesis of paramagnetic materials that have specifically tailored magnetic properties is gaining considerable interest (*see* ***Magnetism of Extended Arrays in Inorganic Solids*** and ***Magnetism of Transition Metal Ions***). For example, metallocenes and their derivatives are known to

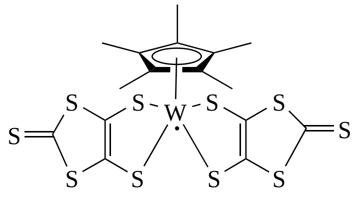
display molecular ferromagnetism, ferromagnetic, or antiferromagnetic exchange interactions and spin-crossover behavior. In addition, the 15-electron species vanadocene (*see Vanadocene*) has been used as a reducing agent in organic solution to generate a new method for the preparation of ultrafine iron powder and iron colloids. Such powders and colloids are of interest in areas such as catalysis, magnetic materials, and optics.[76] Recently, much effort has been made toward the synthesis of molecule-based magnetic materials. In these materials, the goal is to use open-shell molecules and arrange them in such a way that the magnetic exchange interactions between them give rise to spontaneous magnetization. Both organic radicals, open-shell molecules, and combinations of the two have been used as building blocks toward magnetic ordering.[77] Paramagnetic organometallic systems have also been employed in this field of research. Most notably, stacks of alternating radical anions such as TCNE (*see* ***Self-assembled Inorganic Architectures***) and metallocenium cations have been used to develop low-temperature magnets. An example is the electron-transfer salt $[(Cp^*)_2Fe]^{\bullet+}$ $[TCNE]^{\bullet-}$, which is a bulk ferromagnet below 4.8 K. Paramagnetic metallocenes have also been instrumental in developing higher temperature magnets.[77] The reaction of TCNE with the sandwich compound $V(C_6H_6)_2$ gives $V(TCNE)_z \cdot y$(solvent), which is a bulk ferrimagnet below its thermal decomposition temperature of 350 K. One potential application for this material is in magnetic shielding (i.e. the attenuation of magnetic fields found in many electronic applications such as high voltage lines or near cell phones).

Compared to organic or mixed organic/organometallic systems, as described above, attempts at developing ‘pure’ organometallic magnets have progressed less fruitfully. The fulvalene ligand has successfully been used as a link between two paramagnetic organometallic systems, giving rise to bimetallocenes (**27**).[78] While the magnetic properties that result invariably depend on the metal center, the cobalt system, for example, gives rise to ferromagnetic interactions between the organometallic fragments.



(**27**)

Antiferromagnets such as the organometallic dithiolene complexes $[Cp_2M(dmit)]^{\bullet+}$ $[X]^-$ (M = Mo, W; X = PF_6^-, AsF_6^-, SbF_6^-) offer a series of systems that have variable transition temperatures and magnetic anisotropy characteristics.[79] Interestingly, the $[Cp^*W(dmit)_2]^\bullet$ (**28**) system is a 15-electron neutral radical (d^1) with optical limiting properties in solution, and contains an antiferromagnetic ground state in the solid state.



(**28**)

Recently, the first example of unusual spin glass behavior in a mesoporous material has been described.[80] The study of mesoporous niobium oxide with a variety of organometallic sandwich-type compounds has resulted in the formation of a series of mesostructured composites with mixed oxidation state molecular phases within the pores. These systems have the potential to give rise to nanowire technology as well as conducting and insulating behavior. Examples of sandwich-type systems used include bis(benzene)chromium and vanadium as well as cobaltocene. While the niobium oxide-cobaltocene material shows superparamagnetic behavior, the niobium oxide-bis(cyclopentadienyl)nickel system exhibits spin glass behavior.

Glossary

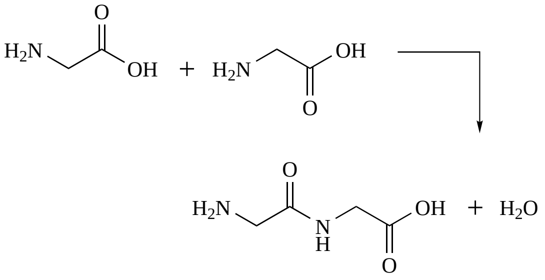
1N, 2N, 3N etc.: indicate the number of nitrogens coordinated to the metal ion

Abbreviations

Amino acid residues in peptides will be those recommended by IUPAC–IUB for the nomenclature of peptides.

1 INTRODUCTION

The condensation of two amino acids yields a dipeptide. The resulting amide bond is often referred to as a peptide bond or a peptide group (equation 1). Peptides can be effective ligands for a wide range of metal ions since they contain a variety of potential donor groups. In addition to the amino group of the N-terminus, and the carboxylate of the C-terminus, peptides can bind through the amide carbonyl, the deprotonated amide nitrogen, and through any functional groups on the side chains (*see* ***Ammonia & N-donor Ligands***). Metal–peptide complexes have aroused increasing interest in recent years. This attention is mainly because of the applications of such systems as models for the structures and reactions of metalloproteins, and the renewed interest in biologically active peptides such as peptide fragments of the prion protein. The reaction of copper(II) with proteins in strongly alkaline solutions to give a violet-red color, which was first noted by Wiedmann in the 1800s,[1] is one of the first examples of a metal ion reacting with a peptide. Schiff[2] also studied this reaction, which occurs with biuret and other compounds which contain two or more amide or peptide groups, and is now known as the biuret reaction. In the early 1900s, Kober and Sigiura studied the reactions of copper(II) with di-, tri-, and tetraglycine in basic solutions.[3] In later spectrophotometric investigations, Kober and Haw concluded that, in biuret reactions, the violet-red color was due to ring formation of the copper with the nitrogens of the peptide groups.[4] The isolation of the disodium salt of the copper–tetraglycine complex in 1934 by Rising *et al.* showed conclusively that the peptide hydrogens were replaced by copper.[5] Infrared studies by Chouteau later confirmed the existence of the metal–peptide linkage.[6] With the use of both potentiometric and spectrophotometric methods, the determination of the stability constants and pK_a values of several metal–oligopeptide complexes were made possible by the work of Dobbie and Kermack,[7] Martell *et al.*,[8] and Gurd and associates (*see* ***Stability Constants & their Determination***).[9]



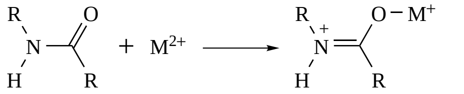
(1)

The hydrogen atom in the peptide linkage is not very acidic and, in the absence of metal ions, it is not ionized even in strongly alkaline solutions. This weak acidity makes quantitative equilibrium measurements difficult. The pK_a values for hydrogen loss of several peptides have been estimated to be 16.4 for *N*-methylacetamide, 14.1 for glycylglycinate, and 15.1 for triglycine with an estimated average value of 15.[10]

For H^+ addition, the amide group is a very weak base, and there once was considerable debate over whether the amide oxygen or the amide nitrogen was the most favorable protonation site. However, NMR experiments have decisively established that the oxygen atom serves as the main protonation site over the entire range of acidic solutions.[11,12] Several groups have estimated the ratio of the O- to N-protonated amide cations to be 10^7.[10]

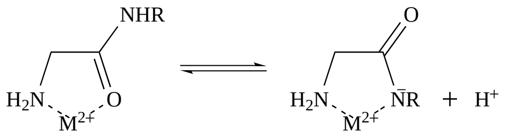
The replacement of a nitrogen-bonded hydrogen by a metal ion should form a strong bond. However, due to the weak acidity of the peptide hydrogen it is improbable that alkali or alkaline-earth metal ions would be able to remove this hydrogen. Transition metal ions, however, should be more effective in substitution for the nitrogen-bound hydrogen. The problem with transition metal ions is

that they are more susceptible to hydrolysis, and generally precipitation occurs in neutral and alkaline solutions. So simple amides in their neutral state form adducts with metal ions at the amide oxygen and not the amide nitrogen (equation 2). This has been confirmed by both experimental and theoretical results, which show an increase in double bond character in the C–N bond and a lengthening of the C=O bond.[13,14]



(2)

One possible way to prevent transition metal ions from precipitating, and thus allow them to coordinate to peptides, is to have a primary ligating site or anchor, which would allow the amide oxygen to chelate to the metal. This will allow for subsequent substitution of the amide hydrogen by the metal ion. This primary binding site reduces the importance of metal ion hydrolysis and permits attainment of pH values where substitution of a metal ion for an amide hydrogen may occur (equation 3).



(3)

There are two possible primary ligating groups available in peptides. The first is the carboxylate oxygen on the C-terminus. However, chelation involving the carboxylate oxygen and the amide oxygen would form an unfavorable seven-membered ring. It is possible to form a more stable five-membered chelate ring with the carboxylate oxygen and the deprotonated amide nitrogen of the peptide group; however, due to the weak basicity of the carboxylate these complexes are not very stable and the metal ion is eventually hydrolyzed. The other primary binding site is the amino group on the N-terminus. If the amino group acts as the primary binding site, this allows for the formation of five-membered chelate rings with either the amide oxygen or the deprotonated amide nitrogen of the peptide linkage (equation 3). As will be seen for simple peptides, it is the amino group that acts as the primary binding site in metal–peptide complexes.

Early studies on metal–peptide complexes were generally concerned with polyglycines, and there are several reviews on these complexes.[15] In the first part of this article, we will discuss various metal–peptide complexes that have coordinating side chains. Comparison of these metal–peptide complexes will be made with their glycine analogs, and the differences will be noted. The second part of the article will deal with metal-mediated peptide-bond cleavage.

2 COPPER–PEPTIDE COMPLEXES

Copper–peptide complexes have been the most extensively studied of all the metal–peptide complexes.[16] Copper(II) is the most important oxidation state in copper–peptide complexes, although copper(III) can be stabilized by coordination to peptides. The deprotonated peptide nitrogens help stabilize the higher oxidation state of copper; therefore the more deprotonated peptide nitrogens, the more stable the copper(III) complex. Copper(III) complexes are generally prepared by electrochemical oxidation of the copper(II) complex at pH 10 or higher.

The coordination geometry around copper(II) peptide complexes is generally tetragonally distorted octahedral, although there are some cases where square planar and square pyramidal geometries can also be found. X-ray crystal structure determinations have shown that copper(III)–peptide complexes have square-planar geometry[17] (*see* ***Copper: Inorganic & Coordination Chemistry***). In this section, we discuss copper(II)–peptide complexes; copper(III)–peptide complexes are reviewed elsewhere.[18]

The type of complex formed between copper(II) and amino acids depends largely upon which amino acid is present. Amino acids that contain a free amino terminus form 1N complexes with copper(II), in which the amino acid acts as a bidentate ligand, binding through the amino nitrogen and the carbonyl oxygen. The stability constants for these complexes are directly related to the basicity of the amine. For amino acids that are substituted at the amino nitrogen, such as *N*-acetylglycinate, copper(II) complexes show only unidentate coordination via the carboxylate oxygen.[19]

Simple peptides initially coordinate copper(II) via the terminal amino nitrogen and to the carbonyl oxygen of the amide group (1N). As the pH is raised to about 5, copper(II) displaces the proton on the amide nitrogen to form a $CuH_{-1}L$ complex (2N). This is followed sequentially at the nitrogens of the second and third peptide linkages to give $CuH_{-2}L$ (3N) and $CuH_{-3}L$ (4N) complexes (Figure 1). However, as amino acid residues with coordinating side chains are added to the peptide, the types of complexes are changed.

Stability constants of copper(II) complexes can be calculated most accurately from pH titrations. In addition, stability constants can be derived from *electron spin resonance spectroscopy* (*see Electron Paramagnetic Resonance*), although the precision of this method is usually significantly lower.[20] *UV-Visible Spectroscopy* provides a simple method for identifying the number of nitrogens coordinated to copper. Generally as the number of coordinated nitrogens increases, the λ_{max} for the d–d transition increases. 1N complexes are usually deep blue in color, while 4N complexes tend to be red in color (as seen with biuret). Another spectroscopic tool used to determine the structure of metal–peptide complexes is circular dichroism (*see Cotton Effect*), and there is a good review of this subject elsewhere.[21]

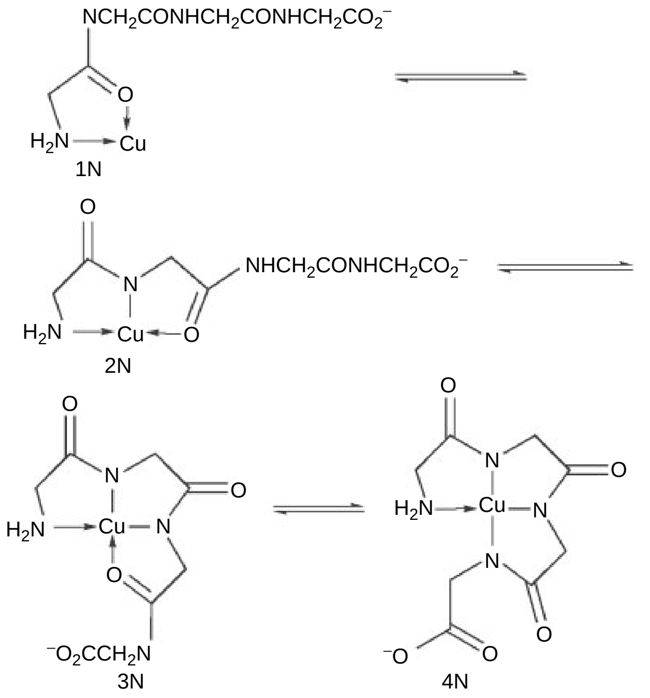


Figure 1 Stepwise complexation of copper(II) by tetraglycine

Copper(II) reacts with glycylglycine to form first a compound in which the copper is bound to the amino nitrogen and the carbonyl oxygen. As the pH is raised, the copper coordinates to the deprotonated amide nitrogen to form a complex that is bound through the amino nitrogen, the amide nitrogen and the carboxylate oxygen. The pK_a for this reaction is 3.99.[22] If the second glycine is modified at the amide nitrogen by methylation to form glycylsarcosine (glycyl-*N*-methylglycine), deprotonation of the peptide nitrogen cannot occur and a different complex is formed.[23]

2.1 Peptides with Noncoordinating Side Chains

Peptides that contain amino acid residues with noncoordinating side chains generally act like the polyglycine analogs. Those that contain aromatic rings such as phenylalanine are exceptional. The hydrophobic interactions or ring stacking of the phenylalanine residue can influence the structure as well as the stability of the copper(II) complexes that are formed. For example, a study was done with copper(II) and four optically pure dipeptides: L-Phe–L-Met, L-Met–L-Phe, L-Phe–L-Leu, and L-Leu–L-Phe.[24] The major complex formed in the pH range 5–8 was $CuH_{-1}L$. It was found that the formation constant for L-Leu–L-Phe was higher than that of L-Phe–L-Leu: there is an increase in stability when the aromatic ring is on the C-terminal residue. This enhanced stability is considered to be due to the interaction between the metal ion and the aromatic ring moiety. It is suggested that the weak carboxylate oxygen bond can be distorted by the metal ion–aromatic ring interaction when the phenyl ring is on the C-terminal residue. This interaction does not occur when the aromatic ring is on the N-terminal residue, because of the strong copper(II)–amine interaction. Such a difference is not seen for the dipeptides L-Phe–L-Met and L-Met–L-Phe. It is suggested that the copper(II)–sulfur and copper(II)–aromatic ring interactions have the same effect, so there is no significant difference resulting from switching the positions of the residues.

The proline residue is of interest for many reasons, even though it does not contain a coordinating side chain. Since the nitrogen of proline is secondary rather than primary, when it is incorporated into a peptide chain it does not have a dissociable hydrogen. So the proline residue acts as a break point for coordination. However, when proline is the N-terminus, it is able to coordinate through the nitrogen. A significant property of the proline residue is that it can induce β-turns within the peptide chain (*see Beta Turn*). This has importance since many biologically active peptides contain the proline residue. A study to determine the effect of a proline residue in a peptide chain was done with two sets of peptides.[25] The tetrapeptides Gly–Gly–Pro–Gly and Gly–Gly–Pro–Lys, and their octapeptide analogs $(Gly–Gly–Pro–Gly)_2$ and $(Gly–Gly–Pro–Lys)_2$, are models for dog tuftsinyltuftsin octapeptide. The copper(II) complexes of Gly–Gly–Pro–Gly and $(Gly–Gly–Pro–Gly)_2$ are very similar. At low pH, both peptides bond through the amino nitrogen and carbonyl oxygen of the first peptide linkage. As the pH is raised, the first peptide hydrogen is displaced to give a 2N complex. Since the next peptide linkage does not contain an ionizable hydrogen due to the proline residue, the next ionizable hydrogen is on the C-terminal glycine. This hydrogen is deprotonated at pH above 9.5 for both peptides. This indicates that the peptide is bent around the copper atom. The peptides Gly–Gly–Pro–Lys and $(Gly–Gly–Pro–Lys)_2$ initially form 1N complexes with copper(II). The most stable species in the pH range 6.5–10.0, however, is $CuH_{-1}L$ for the tetrapeptide and CuL for the octapeptide. These complexes have been determined to be coordinated by three nitrogens and are similar to those of the other two peptide complexes, except that the third nitrogen is from the ε-amino nitrogen of the lysine residue. It was determined from spectroscopic studies that it was the Lys^4 of the octapeptide that is coordinated to copper(II) rather than the Lys^8 residue.

2.2 Peptides Containing the Histidine Residue

Owing to the fact that imidazole (N^3-Im) forms very strong bonds with copper(II), peptides containing the histidine residue have been studied extensively. Histidine-containing peptides form a large range of complexes with copper(II), which include many polynuclear species. Whereas most peptides initially bind the metal through the amino nitrogen, it is possible for the imidazole nitrogen of a histidine residue to initiate coordination. When the C-terminal residue of

a dipeptide is a histidine, initial coordination through the imidazole nitrogen facilitates the deprotonation of the peptide group, which allows for the formation of a Cu–N bond at pH 4, which is one pH unit less than with simple dipeptides.[16]

There is interest in the interaction of copper(II) with luteinizing hormone-releasing hormone (LHRH).[26] LHRH is a decapeptide amide (*p*Glu–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2) which is the main mediator in the secretion of gonadotropins. The major copper(II) complex formed in the pH range of 5.5–9.5 is $CuH_{-1}L$, which means that it is the predominant species at physiological pH. The copper(II) is coordinated via the imidazole nitrogen and two deprotonated peptide nitrogens. This 3N complex is also seen with the copper(II) complex of the tripeptide *p*Glu–His–Pro–NH_2 (thyrotropin releasing factor) (TRF).[27]

A study done on three dipeptides containing the histidine residue, His–Gly, Gly–His, and Ala–His (carnosine), showed that various copper(II) complexes can be formed depending on the nitrogen atoms available and the metal-to-ligand ratio.[28] Coordination of carnosine and His–Gly was similar to that of Gly–Gly in which the dipeptides bond through the amino nitrogen, amide nitrogen, and carboxylate oxygen (2N). However, the main difference was that carnosine and His–Gly were able to form dimeric complexes of the form $Cu_2H_{-2}L$, in which the two copper atoms are bridged via the imidazole nitrogen donors. If an excess of His–Gly is present, the deprotonation of the peptide linkage is prevented owing to formation of the bis complex CuL_2 in which the ligands are bonded histamine-like. Carnosine was shown not to form any bis complex. The geometrical positions of the donor atoms in Gly–His make possible the coordination of the three nitrogen donors (amino, peptide, and imidazole). This results in a very stable monomeric complex $CuH_{-1}L$.

Initially, copper(II) coordinates to the octapeptide angiotensin II (Asp–Arg–Val–Tyr–Ile–His–Pro–Phe) at the imidazole nitrogen.[29] At neutral pH the main copper complex is CuL, which is a 3N complex (Figure 2). The copper(II) is bonded via the imidazole nitrogen of the histidine residue, and two deprotonated peptide nitrogens. As the pH is raised above 8.0, the coordination site changes to the N-terminus

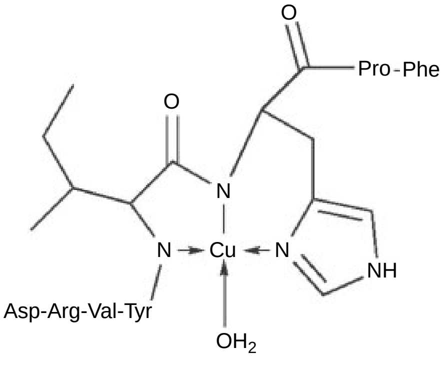

Figure 2 Copper(II)–angiotensin II 3N complex

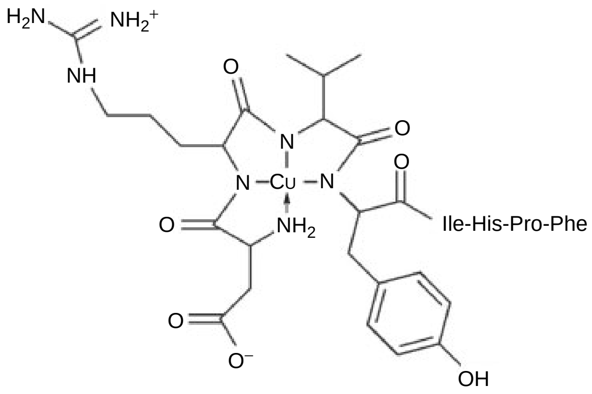

Figure 3 Copper(II)–angiotensin II 4N complex

of the peptide chain, where the copper(II) is bonded by the terminal amino, and three deprotonated peptide nitrogens in a 4N complex (Figure 3).

Analogs of the metal-chelating center of bleomycin, which is a glycopeptide antibiotic, have been synthesized and the structures of their copper(II) complexes have been determined. These complexes show similar bonding as bleomycin.[30] The copper is in a highly distorted environment approaching square pyramidal, with 3N coordination that includes coordination by an imidazole nitrogen.

2.3 Peptides with Side Chains Containing Other Donor Groups

The oxygen atoms in Gln ($(CH_2)_2CONH_2$) and Ser (CH_2OH) do not coordinate to copper(II) appreciably.[31] However, the β-carboxylate oxygen of the Asp residue is able to bind copper(II) very effectively. When Asp is the N-terminal residue of a peptide, initial coordination is made more facile due to coordination by the β-carboxylate of the Asp residue rather than the peptide carbonyl. When Asp is in the second or third position of a peptide chain, such as the tetrapeptide fragment of fibrinopeptide A (Ala–Asp–Ser–Gly), or Ala–Ala–Asp–Ala,[32] the most stable copper(II) complexes formed are $CuH_{-1}L$ (2N) and $CuH_{-2}L$ (3N), respectively. The increased stability of these complexes due to the Asp residue delays or even prevents coordination of a fourth nitrogen. As can be seen in the structure of $CuH_{-2}L$ (3N), the β-carboxylate oxygen of the Asp residue prevents coordination of the last peptide nitrogen (Figure 4).

In addition to the carbonyl oxygen on the side chain of Gln, there is also an amide nitrogen. This only deprotonates and coordinates at pH greater than 10, so it does not play a large role in the coordination of copper(II) complexes at physiological pH.[31]

When a Lys residue occurs toward the C-terminus of a peptide, as in Gly–His–Lys or Gly–Gly–Pro–Lys, the ε-amino nitrogen of Lys is too far from the other donor sites

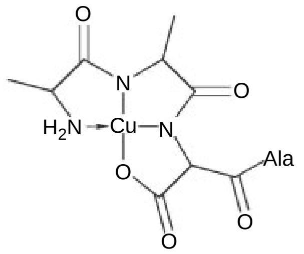

Figure 4 Copper(II)–(Ala–Ala–Asp–Ala) 3N complex

to allow it to coordinate effectively. However, if there is a proline residue in the peptide chain, then it is possible for the ε-amino nitrogen of Lys to coordinate due to the β-turn induced by the proline residue.[16]

When Tyr is the N-terminal residue, polynuclear copper(II) complexes can form, primarily because it is sterically impossible for the amino nitrogen and phenolic oxygen of the Tyr residue to bind the same copper(II) atom. A study done on β-casomorphin-5 (Tyr–Pro–Phe–Pro–Gly) and its fragments Tyr–Pro–Phe–Pro, Tyr–Pro–Phe, and Tyr–Pro,[33] showed that the dipeptide fragment Tyr–Pro (H_2L) acted as a simple amino acid, forming mono and bis complexes with copper(II). The dipeptide bonded copper(II) through the amino nitrogen and the peptide carbonyl. Since there was no ionizable hydrogen on the peptide nitrogen, there was no bonding by the peptide nitrogen. The major species of the other peptides at physiological pH were the dimeric species Cu_2L_2. In these complexes the copper(II) is bonded by the amino nitrogen and the peptide carbonyl of one ligand and the phenolic oxygen of a second ligand. If the pH is raised to above 8.0, then another species is formed, $Cu_2H_{-2}L_2$. In addition to being coordinated by the amino nitrogen and peptide carbonyl, as was seen with Cu_2L_2 species, the copper(II) atoms are also coordinated by the peptide nitrogens of the C-terminal residue of Tyr–Pro–Phe–Pro–Gly.

The coordination ability of several vasopressin-like peptides (AVP, D-VAVP, TMe-D-VAVP, AVT, and D-VAVT) (Figure 5) with copper(II) has been described.[34] With copper(II), AVT and AVP behave the same: the major species is $CuH_{-2}L$. Spectroscopic results have shown that the $CuH_{-2}L$ species is a 4N complex. The copper(II)–AVP complex is one of the most stable 4N copper–peptide complexes known. The high stability of both the AVP and AVT copper(II) complexes can be attributed to the disulfide bridge which makes the peptides resemble other macrocyclic ligands, and presents the nitrogen donor atoms in the correct conformation and at the right separations for coordination to copper(II). When the normal L-Gln residue is replaced with D-Val (a residue with the opposite chirality) there is a large difference in the stoichiometry of the complexes formed. The peptides D-VAVP and D-VAVT are the same as AVP and AVT except with a D-Val residue in place of Gln in position 4. The major complex formed with D-VAVT and D-VAVP is the $CuH_{-1}L$ species. Spectroscopic studies have shown this species to be a 3N complex.

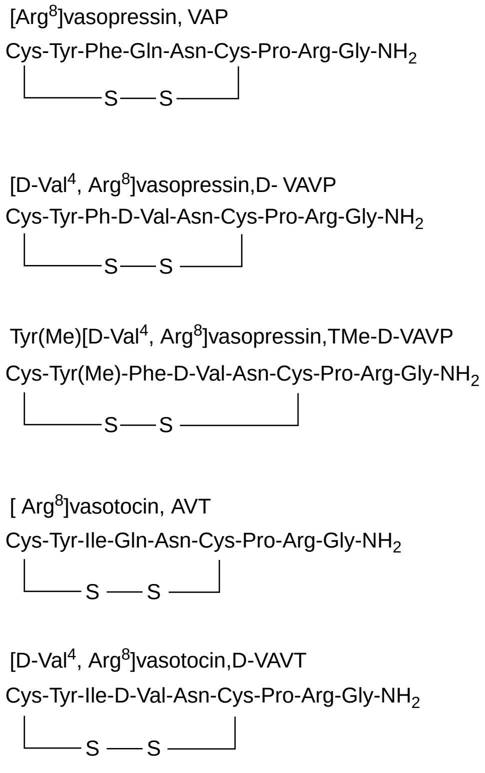

Figure 5 AVP, D-VAVP, TMe-D-VAVP, AVT, and D-VAVT

Copper(II) usually does not form very stable complexes with the sulfur side chains in amino acid residues such as Cys or Met, owing to the fact that the SH group tends to oxidize very rapidly (*see* ***S-donor Ligands***). However, when a thiocarbonyl group is incorporated into a peptide chain, the resulting metal complexes are usually more stable. The dipeptide amide Alat–Ala–OMe (Alat is the thiocarbonyl analog of Ala) initially forms the complexes CuL and CuL_2, in which the copper(II) ion is bonded via the amino nitrogen and the thiocarbonyl sulfur.[35] The stability constants for these complexes are slightly higher than their nonthio analogs. However, the thiocarbonyl group is not able to prevent peptide deprotonation, and at high pH the complexes $CuH_{-1}L_2$ and $CuH_{-2}L_2$, which have one or two ligands bound via the amino nitrogen and deprotonated peptide nitrogen, dominate. The peptide Asp–Phet–NH_2 (Phet is the thiocarbonyl analog of Phe), initially bonds copper(II) through the amino nitrogen and thiocarbonyl sulfur. In the pH region of 4.5–8.0 the major species is $CuH_{-1}L$ in which the copper(II) is bonded via the amino and deprotonated peptide nitrogens, and thiocarbonyl sulfur. When the pH is raised, the terminal peptide nitrogen is deprotonated, resulting in the $CuH_{-2}L$ complex, which has 3N coordination similar to the nonthiocarbonyl analog.

3 NICKEL–PEPTIDE COMPLEXES

Owing to their similarities, nickel(II)–peptide complexes are usually studied along with copper(II) complexes. As was seen with copper, the most common oxidation state of nickel in nickel–peptide complexes is +2. Like copper(III), nickel(III) is also stabilized by coordination to deprotonated peptide nitrogens, and this chemistry is reviewed elsewhere.[36] Nickel(II), which is d^8, can exist in two distinct coordination geometries depending on the ligand field (*see* ***Nickel: Inorganic & Coordination Chemistry***). In neutral to acidic solutions, simple nickel(II)–dipeptide complexes behave the same as nickel(II) tri- and larger peptide complexes. The nickel is coordinated through the amino nitrogen and the carbonyl oxygen (1N). When the pH is raised to 9.0, nickel(II) substitutes for a peptide hydrogen, and the coordination changes. The dipeptide complexes are coordinated through the amino and deprotonated peptide nitrogens and the carboxylate oxygen (2N), while larger peptides are bound via the amino and deprotonated peptide nitrogens and the carbonyl oxygen of the peptide group.

Since larger peptides have several peptide nitrogens that can be deprotonated, the nickel(II) complexes change from an octahedral geometry to a square-planar geometry in which the nickel(II) is bonded via the amino nitrogen, and three deprotonated peptide nitrogens (4N). This abrupt change in coordination geometry, which has been termed the *cooperative effect*, makes it very difficult to detect the $NiH_{-1}L$ (2N) and $NiH_{-2}L$ (3N) complexes. The change is caused by the enforced planarity of the peptide after the second peptide nitrogen is deprotonated. The change in geometry is accompanied by a change in color, from blue for the octahedral complexes to yellow for square-planar complexes.

Dipeptides do not have a second peptide nitrogen, so they do not force this change in geometry. Instead they form octahedral bis complexes with each dipeptide acting as a tridentate ligand. Coordination is through the amino and deprotonated peptide nitrogens and the carboxylate oxygen (Figure 6).

Dinuclear nickel(II) complexes are formed with the dipeptide Gly–L-Cys. The nickel atoms are coordinated by the amino and deprotonated peptide nitrogens and the sulfur groups, with the sulfur atoms bridging the two nickel atoms

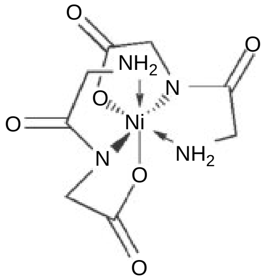

Figure 6 $Ni(Gly–Gly)_2$

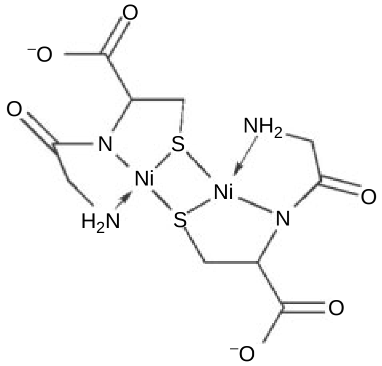

Figure 7 $Ni_2(Gly–L-Cys)_2$

(Figure 7).[37] This is in contrast to the dipeptide L-Cys–Gly where, due to the strong binding ability of the cysteine residue, nickel(II) is coordinated through the Cys residue only in a cysteine-like fashion, and no deprotonation of the peptide nitrogen is observed. Notably, copper(II) does not form stable complexes with sulfur-containing ligands. The NiL_2 species predominates at all metal-to-ligand ratios.[37] The dipeptides Ala–Cys and Phe–Cys form complexes similar to those of Gly–Cys.[38] The main difference is that the mono complex $NiH_{-1}L$, which is not seen with Gly–Cys, is seen with Ala–Cys and Phe–Cys owing to steric effects caused by the methyl and benzyl side chains. In the $NiH_{-1}L$ complexes the nickel is coordinated via the amino and deprotonated peptide nitrogens and the thiol group. This coordination is also seen in the dimer $Ni_2H_{-2}L_2$. At high pH and an excess of ligand, the dimer $Ni_2H_{-2}L_2$ is converted into the $NiH_{-1}L_2$ complex, which has one ligand coordinated through the amino, and deprotonated peptide nitrogens and thiol group, while the second ligand is coordinated through the thiol group only (Figure 8).

With the tripeptide Gly–Gly–L-Cys, two species were found to form with nickel(II). At low pH the NiLH species was found to dominate, but as the pH is raised there is a simultaneous release of three protons from NiLH to give the major species $NiH_{-2}L$. Only monomeric complexes are formed because there are no available binding sites in the planar species for sulfur to create polynuclear complexes. This is also seen with the tripeptide Ala–Ala–Cys, where the major species at pH 6.25 and above is $NiH_{-2}L$.[39]

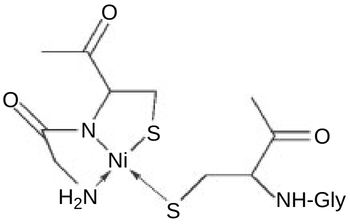

Figure 8 $Ni(Gly–Cys)_2$

The influence of the thiocarbonyl group on the coordination of nickel(II) by peptides was examined.[35] Initially Alat–Ala–OMe forms the bis octahedral NiL_2 complex which is coordinated via the amino nitrogen and thiocarbonyl sulfur. The thiocarbonyl group is not able to prevent deprotonation of the amide nitrogen, and the square-planar complex $NiH_{-2}L_2$, which is coordinated by the amino and deprotonated peptide nitrogens, forms at a lower pH than the corresponding non-thiocarbonyl analog. Similar nickel(II) complexes are formed with the dipeptide amide Asp–Phet–NH_2.

A study done with four optically pure dipeptides, L-Phe–L-Met, L-Met–L-Phe, L-Phe–L-Leu, and L-Leu–L-Phe, showed that the major species formed at physiological pH with nickel(II) is NiL. This is different from the complex with copper(II), in which the major product was $CuH_{-1}L$.[24] This difference is due to the fact that the first complexation with nickel(II) occurs at pH 4.5, while the copper(II) complexes begin to form between pH 2 and 3. It is this lesser ability of nickel(II) to deprotonate the peptide nitrogen that causes the difference. In the case of the $NiH_{-1}L$ complex the formation of L-Phe–L-Leu is more difficult than L-Leu–L-Phe. This suggests that the nickel(II)–aromatic ring interaction influences the stability, as was seen with the copper(II) complexes.

The dipeptide His–Gly coordinates to nickel(II) in the same manner as a substituted histidine would, that is through the amino and imidazole nitrogens (2N). This is another example of how the imidazole of the histidine residue effects the coordination of peptides when it is the N-terminal residue. However, the dipeptide Gly–His acts as a tridentate ligand, bonding through the amino, deprotonated peptide, and imidazole nitrogens (3N).[39] When the pH is increased to above 9.0, the imidazole pyrrole hydrogen is substituted by a nickel from another complex.[40] In the tripeptide Gly–Gly–His, coordination is through the amino nitrogen, two deprotonated peptide nitrogens, and the imidazole nitrogen (4N).[41] This complex is of interest because histidine is the third amino acid residue in both bovine and human serum albumins. Gly–Gly–L-His shows bonding similar to that of Asp–Ala–His–methylamide, which is the model for the N-terminus of human serum albumin.

With the biologically active peptide TRF (Gly–His–Pro–NH_2), two different types of complexes are formed.[27] At pH lower than 8.5 the major complex is the octahedral NiL, which is initially bonded through the imidazole nitrogen, not the amino nitrogen. At pH greater than 8.5 the major species is the planar $NiH_{-2}L$, which is bonded through the imidazole nitrogen and two deprotonated peptide nitrogens. A study done with angiotensin II (Asp–Arg–Val–Tyr–Ile–His–Pro–Phe) and two fragments, Asp–Arg–Val–Tyr (the N-terminal fragment) and MeCO–Tyr–Ile–His,[42] showed that, with nickel(II) at high pH, angiotensin II gave complexes closely similar to those formed with Asp–Arg–Val–Tyr (Figure 9). The imidazole nitrogen may play some role at lower pH, but comparison of the nickel(II) complexes of MeCO–Tyr–Ile–His with those of Asp–Arg–Val–Tyr indicate that the latter peptide forms complexes more readily.

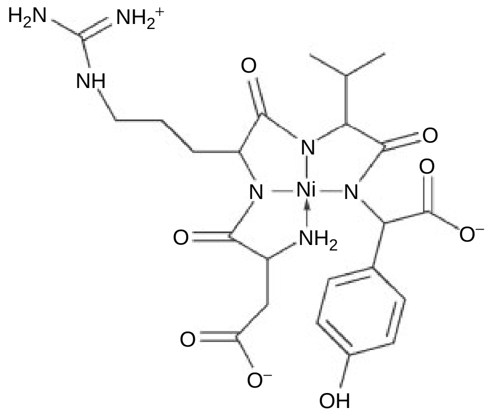

Figure 9 Ni(Asp–Arg–Val–Tyr) 4N complex

4 PALLADIUM–AND PLATINUM–PEPTIDE COMPLEXES

There is considerable interest in the cytotoxic activity of many platinum(II) complexes related to cisplatin $[Cl_2Pt(NH_3)_2]$ (*see* ***Platinum-based Anticancer Drugs***), and several analogs containing peptide ligands have been studied. Since platinum complexes are generally inert to substitution reactions, the palladium(II) analogs are generally used instead. Palladium(II) and platinum(II) complexes are similar to those of nickel(II) in that they all form square planar, four-coordinate complexes (*see* ***Palladium: Inorganic & Coordination Chemistry*** and ***Platinum: Inorganic & Coordination Chemistry***). Unlike copper(II), both palladium(II) and platinum(II) are soft acceptors and as such are expected to coordinate to soft donors like sulfur and aromatic nitrogen donors in residues such as Met and His, and deprotonated peptide nitrogens (*see* ***Hard & Soft Acids and Bases***). Palladium(II) has been found to promote the ionization of peptide hydrogens more easily than copper(II), nickel(II), and cobalt(II). Generally, the pK_a of deprotonation is 3.5,[43] although deprotonation has been observed at pH <2.0.[15] This value is 2, 5, and 7 pK units less than the values for copper, nickel, and cobalt respectively.

At low pH, dipeptides generally coordinate palladium(II) through the deprotonated peptide nitrogen in a monodentate manner. At high pH, the dipeptides act as bidentate ligands, coordinating through the amino nitrogen and the deprotonated peptide nitrogen. At intermediate pH values, dipeptides coordinate through the amino and deprotonated peptide nitrogens and the carboxylate oxygen.[44] Dipeptides in which the N-terminal residue is Met generally bond palladium(II) through the thioether sulfur and amino nitrogen at low

pH. At pH values greater than 7, a dinuclear complex is formed where the palladium(II) is bonded via the amino and deprotonated peptide nitrogen, while the sulfur atom coordinates to a neighboring palladium atom. This explains why the deprotonation of the peptide nitrogen occurs at such a high pH. Palladium(II) complexes of the type Pd(Met–X), where X is another amino acid, form bis complexes where at low pH the peptides are bonded through the sulfur and amino nitrogen, while at high pH the palladium is coordinated by four nitrogen atoms.

In the cysteine-containing dipeptides Cys–Gly and Gly–Cys, palladium(II) is bonded by the amino nitrogen and sulfur in the first dipeptide and by the amino nitrogen, deprotonated peptide nitrogen, and sulfur in the second dipeptide.[46] This is an example where strong coordination by the thiol group in cysteine can prevent the deprotonation of the peptide nitrogen, even though palladium(II) deprotonates the peptide nitrogens at a low pH. Palladium(II) coordinates to oxygen donors only very weakly; that is why the dipeptide Gly–His coordinates to palladium(II) in a 3N fashion through the amino, deprotonated peptide, and imidazole nitrogens, without coordination through the carboxylate oxygen.[47] A recent study on dipeptides which contain protected cysteine residues, Gly–S-Me–Cys, S-Me–Cys–Gly, and S-Me–Cys–S-Me–Cys, show that the S-Me–Cys residue binds through both the amino nitrogen and sulfur, as was seen with just the protected amino acid.[48] When the thioether is coordinated, this causes the sulfur to become chiral, and in solution two diastereomers are observed.

The dipeptides Gly–L-His, L-Ala–L-His, and L-Ala–D-His initially form 3N complexes with palladium(II), bonding through the amino, deprotonated peptide, and imidazole nitrogens. When the pH is raised above 9.5, the pyrrole proton is ionized, resulting in a 4N tetramer formation.[49]

The tripeptide Gly–L-His–Gly coordinates to palladium(II) via the nitrogen atoms of the amino group, deprotonated peptide, and the imidazole (Figure 10). The coordination of the imidazole nitrogen over the second peptide nitrogen is expected, due to the fact that palladium(II) favors soft donor atoms (like aromatic nitrogens) over harder donor atoms. This same coordination is also seen in the tripeptide Gly–L-His–Lys. The fourth coordination site of this complex is occupied by a chloride ion.[50] In the 1:2 palladium(II)–Gly–Gly–L-Cys complex, the palladium is bonded through the amino nitrogen, two deprotonated nitrogens, and the sulfur of the cysteine side chain.[45] As the pH is increased to 10.0 and above, the two peptides coordinate the palladium through the amino nitrogen and one deprotonated peptide nitrogen. For the 1:1 complex at pH above 10.0, the palladium–sulfur bond breaks and is replaced by a hydroxide ion.

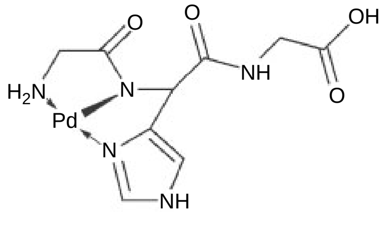

Figure 10 Pd(Gly–L-His–Gly) 3N complex

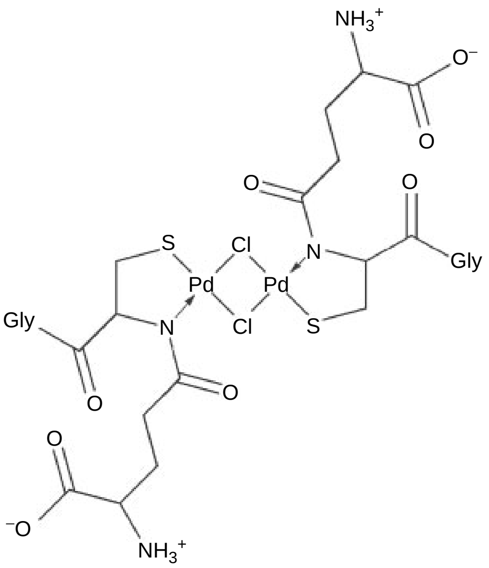

Figure 11 $[Pd(GluH_2)Cl]_2$

Glutathione (γ-Glu–L-Cys–Gly) has a large selection of possible donor atoms with which to complex palladium(II). A palladium–glutathione complex has been isolated with the formula $[Pd(GluH_2)Cl]\cdot 3H_2O$, where $GluH_3^+ = {}^+NH_3(CO_2^-)CHCH_2CH_2CONHCH(CH_2SH)CONHCH_2CO_2H$.[51] The IR spectrum showed a stretch for free CO_2H but no stretch for S–H, which implies coordination by the sulfur. In addition, there was a stretch in the region where a Pd–Cl–Pd bridge would appear. The suggested structure is a dimer with two bridging chlorines (Figure 11). Complexes with the formulae $[PdCl_2(GluH)]^{2+}$ and $[PdCl_2(GluH)_2]^+$ have also been isolated and their stabilities measured.

Palladium(II) and platinum(II) complexes as synthetic peptidases have been reviewed elsewhere.[52]

5 ZINC–PEPTIDE COMPLEXES

Zinc(II), unlike copper(II) and nickel(II), does not form very stable complexes with peptides. A study of 12 dipeptides containing the Gly, Ala, Leu, and Pro residues with zinc(II) showed that the only two species formed in detectable quantities were $[ZnLH]^+$ and ZnL_2H_2.[53] This is in contrast to copper(II) and nickel(II), in which the major species are $MH_{-1}L$ and $MH_{-3}L$. The main reason for the difference in

the type of complexes formed is that zinc(II) does not induce peptide-bond deprotonation as effectively as copper(II) and nickel(II). To allow for deprotonation of the peptide nitrogen, the pH has to be raised above pH 8.0, at which point zinc precipitates out as $Zn(OH)_2$ (*see* ***Zinc: Inorganic & Coordination Chemistry***).

With the dipeptides Ala–His and Gly–His at high pH, zinc(II) was shown to form complexes coordinated through the amino nitrogen, deprotonated peptide nitrogen, and the imidazole nitrogen. However, in dipeptides in which the N-terminus is the His residue, zinc(II) does not cause deprotonation of the peptide nitrogen.[54] The only complexes that are formed are the mono and bis complexes where the dipeptide is coordinated to zinc(II) in a histidine-like fashion (that is, coordination through the amino and imidazole nitrogens only).

The complexes formed when zinc(II) is coordinated to peptides which contain the cysteine residue, depend on the location of the cysteine.[55] The dipeptide Cys–Gly forms mono and bis complexes, with the bis complexes being the most stable. The zinc(II) is coordinated only through the cysteine residue of the dipeptide. The strong cysteine-like coordination via the amino nitrogens and the thiol groups precludes the possibility of amide deprotonation and coordination. When cysteine is the C-terminus in the dipeptide as in Gly–Cys, coordination through the sulfur and nitrogen is not possible due to the formation of an unfavorable eight-membered chelate ring. Coordination through the sulfur and oxygen is possible, with the formation of a more stable six-membered chelate ring. As with the dipeptide Cys–Gly, the bis complexes are the most favored with zinc(II) and Gly–Cys. One of the differences between the two dipeptides is that, with Gly–Cys, no mono complexes were detected. Also, since there is a free amine in the zinc(II)–Gly–Cys complexes, this allows for the formation of the protonated species $ZnLH^+$ at low pH values.

The complexes formed between zinc(II) and the tripeptide His–Gly–His are strongly dependent on pH.[56] At pH >7.5 the major species present is the bis complex in which the tripeptides are bonded via the amino and imidazole nitrogens. At lower pH, the zinc(II) ion coordinates via the amino nitrogen, imidazole nitrogen, and the carbonyl of the peptide linkage. At pH 7.0, zinc(II) forms a mono complex which is coordinated to the tripeptide Gly–His–Lys through the amino nitrogen, deprotonated peptide nitrogen, and the imidazole nitrogen. The amino group on the Lys side chain remains protonated.[57]

Unlike both copper(II) and nickel(II), zinc(II) does not form very strong complexes with LHRH. Studies have shown that, at pH 7.0, only 20% of LHRH is complexed with zinc(II).[58] In addition to binding to the imidazole of the histidine residue, the zinc(II) ion is also weakly coordinated by a carbonyl of a peptide group. NMR studies have indicated that it is the carbonyl oxygen of the His–Trp peptide bond that coordinates the metal ion.

In recent years, there has been a lot of interest in the binding of zinc(II) by the peptide sequence (Tyr, Phe)–X–Cys–$X_{2,4}$–Cys–X_3–Phe–X_5–Leu–His–$X_{3,4}$–His where X is a relatively variable amino acid.[59] This peptide sequence has been termed a *Zinc Finger*. The zinc ion is coordinated tetrahedrally by the two cysteine and histidine residues. Proteins that contain these sequences have been shown to bind to specific sites on nucleic acids (*see* ***Zinc: DNA-binding Proteins***).[59]

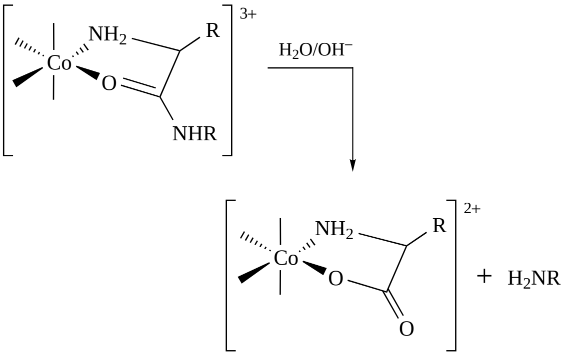
6 METAL-MEDIATED HYDROLYSIS OF AMINO ACID ESTERS AND PEPTIDES

Hydrolysis of proteins and peptides is an important reaction in many biological processes. Amide bonds are extremely unreactive, with an estimated half-life for hydrolysis in neutral solution of about 9 years.[60] Hydrolytic procedures in biochemical work usually call for prolonged heating and high concentrations of strong acids or bases, and usually these esters have to first be activated. In the body, however, proteolytic enzymes hydrolyze even unactivated amide bonds rapidly and under mild conditions.[61] Studies have shown that certain proteolytic enzymes require metal ions for activity.[62] This fact has brought the inorganic chemist into the area of peptide-bond cleavage.

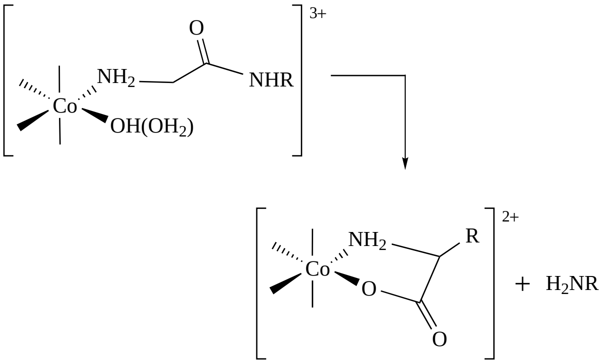
Early investigations of metals showed that divalent metals such as copper(II), cobalt(II), and nickel(II) could catalyze the hydrolysis of amino acid esters.[63] It was the work of Buckingham and Collman in the early 1960s that led to the investigation of using cobalt(III) to hydrolyze amino acid residues (*see* ***Cobalt: Inorganic & Coordination Chemistry***).[64] Cobalt(III) was selected because it was believed that if cobalt(III) could chelate the N-terminus of a peptide, it might enhance hydrolysis via direct polarization of the carbonyl oxygen of the peptide linkage, as was seen with the divalent metals. Cobalt(III) should strongly coordinate to the amino nitrogen, and form a favorable five-member chelate ring with the carbonyl oxygen. Unlike copper(II) and nickel(II), cobalt(III) does not induce deprotonation of peptide nitrogens until relatively high pH. This is important since coordination through the peptide nitrogen results in a complex that is more stable toward hydrolysis. Like the divalent metals which were studied early on, cobalt(III) is able to polarize and thus facilitate the reactions of coordinated ligands. The ligands are less labile, so it should be possible to identify reaction intermediates, helping to clearly differentiate various mechanisms.

There has been a lot of research done on cobalt(III)-mediated peptide-bond cleavage.[64] This section will discuss some of the basic features of the reactions and mechanisms. Also, the idea of metal-mediated peptide-bond cleavage will be extended to the relatively new area of metal–chelate mediated peptide-bond cleavage.

Two mechanisms of cobalt(III)-mediated peptide-bond cleavage have been investigated. The first one involves hydrolysis of a directly activated amino acid ester, or peptide (equation 4). The other mechanism involves the intramolecular attack of an amino acid ester or peptide by a *cis* coordinated hydroxide or water molecule (equation 5). In both cases, the cobalt(III) complex must have two open coordination sites *cis* to each other. For the directly activated mechanism, these sites are needed to bind the amino acid ester or peptide. The intramolecular reaction requires one site for coordination of the ester or peptide, and one site for the coordination of the hydroxy or water molecule. One of the initial cobalt(III) complexes to be investigated was $[Co(en)_2(OH_2)(OH)]^{2+}$.[65,66]



(4)



(5)

6.1 Directly Activated Amino Acid Esters

The rate of hydrolysis of esters is dependent upon whether the ester is activated (bound to the metal) or unactivated. For esters that are coordinated to cobalt(III) in a monodentate fashion (Figure 12), the rate of hydrolysis is only accelerated by about 100 times over that of an uncoordinated ester.[67] However, when the ester is coordinated in a bidentate fashion through the amino nitrogen and carbonyl oxygen (Figure 13), the rate of hydrolysis is accelerated by 10^6 times.[64] Compared to hydroxide, water does not cause a large increase in the rate of hydrolysis, and it is 10^{11} times slower.[68]

$[L_5Co\text{-}NH_2CHRCO_2R]^{3+}$

Figure 12 Monodentate coordination

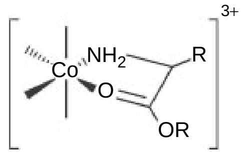


Figure 13 Bidentate coordination

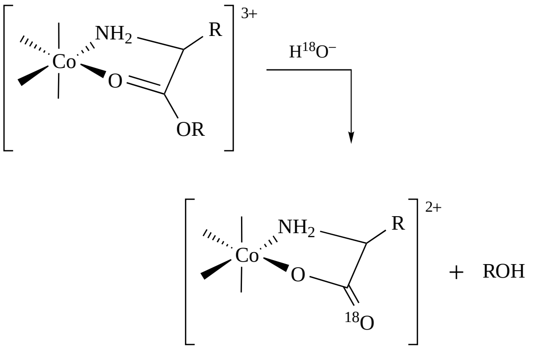
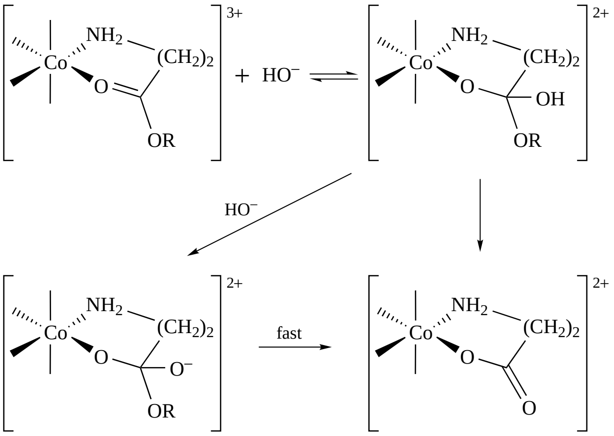
The hydrolysis reaction has been studied by using ^{18}O-labeled hydroxide. There was no evidence of any ring-opened species. This indicates that the chelate ring remains intact throughout the hydrolysis (equation 6).[69]



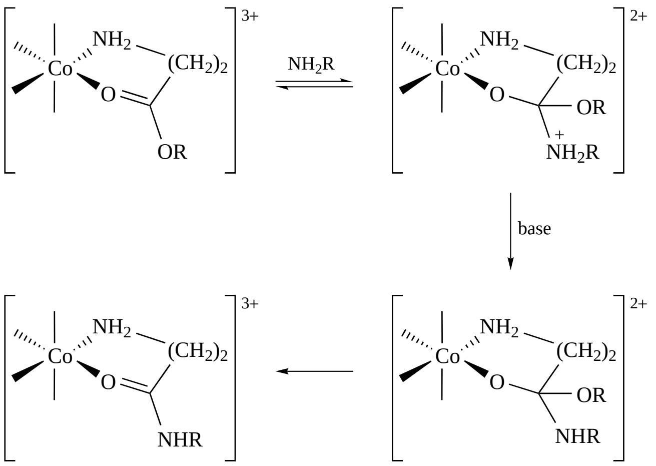
(6)

One of the main questions in the cobalt(III)-promoted hydrolysis of activated amino acid esters is whether the rate-determining step is addition of hydroxide to the carbonyl carbon, or loss of the alkoxide from the intermediate. Work with β-alanine ester showed that below pH 8.5 the rate-determining step was the elimination of alkoxide.[68] At pH 10 and above, the rate-determining step changes and the addition of hydroxide to the activated ester becomes the rate-controlling step. This is due to the fact that above pH 10 the hydroxyl group of the intermediate becomes deprotonated (equation 7). The deprotonation of the hydroxyl group accelerates the loss of alkoxide by 10^5 times.[68]



(7)

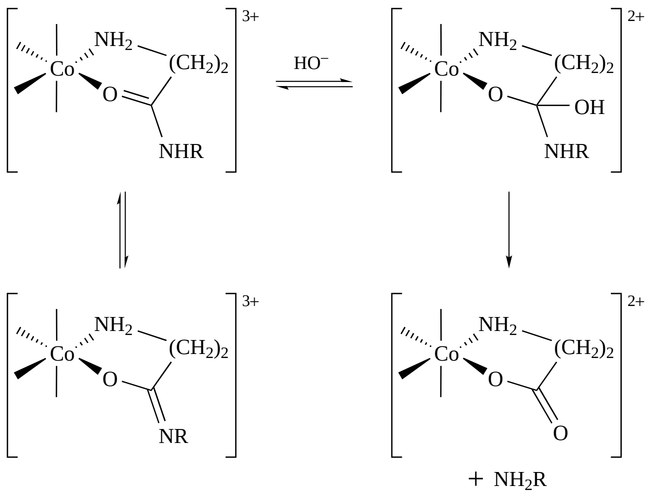
When amines are substituted for hydroxide as the base, there is no change in the rate of hydrolysis. This is because amines do not catalyze the hydrolysis of amino acid esters; instead they prefer to add directly to the carbonyl carbon to form the corresponding amides. In this reaction the rate-limiting step is not the addition of amine, but rather the deprotonation of the coordinated amine by another base (equation 8). The pK_a of the tetrahedral intermediate is approximately 7 since almost any nonsterically hindered base with a pK_a above 7 can deprotonate it.[64]



(8)

6.2 Directly Activated Peptides

Owing to the success of cobalt(III)-mediated hydrolysis of amino acid esters, the next step was to examine how these complexes reacted with peptides. If similar hydrolytic results could be obtained with peptides, then one of the potential uses of cobalt(III) complexes would be in the N-terminal determination and sequential analysis of polypeptides. This area has been investigated by several groups.[70] Peptides



(9)

coordinate to cobalt(III) through the amino nitrogen of the N-terminal amino acid, and carbonyl oxygen of the first peptide linkage. The hydrolysis of peptides goes through a tetrahedral intermediate similar to the hydrolysis of amino acid esters (equation 9). The main difference is that the rate-limiting step in the hydrolysis of peptides is the attack on the peptide carbonyl carbon by hydroxide. This is true at all pH values except for 7.0–8.0, where the loss of hydroxide is comparable to the loss of amine. Above pH 11 the peptide nitrogen is deprotonated, forming a stable imidate which causes the reaction to no longer be first order in hydroxide.[71]

The rate of hydrolysis of peptides by cobalt(III) complexes is 10^4 times faster than hydrolysis with no metal present.[64] Unlike the hydrolysis of amino acid esters, where the rate of hydrolysis is dependent on how the ester is bonded to the cobalt(III) complex, peptides are hydrolyzed equally if they are bound to the cobalt(III) complex in a monodentate fashion (through the carbonyl oxygen) or in a bidentate fashion (through the amino nitrogen and carbonyl oxygen).

6.3 Intramolecular Hydrolysis of Amino Acid Esters

The second route for hydrolysis of amino acid esters involves water or hydroxide bonded directly to the cobalt(III) complex. Through the use of isotopically labeled oxygen it has been determined that the mechanism of hydrolysis involves an intramolecular attack of the carbonyl oxygen by a *cis* coordinated hydroxy or water molecule (cf. equation 10 for peptide hydrolysis).[72] The most important feature in this mechanism is that the carbonyl carbon must be held in close proximity to the metal center to allow the attack. This importance can be seen in the difference in rate of hydrolysis between glycine and β-alanine. Glycine is a shorter amino acid than β-alanine, and holds the carbonyl carbon in a more favorable position for attack by the hydroxy or water molecule. This results in a 10^3 increase in the rate of hydrolysis over that of β-alanine. In addition, glycine forms a five-membered chelate ring intermediate. The conformation of this ring compared to that of the six-membered chelate ring formed with β-alanine also adds to the increase in hydrolysis rate.

The importance of the ring size in the intramolecular reaction is the opposite from what was seen in the directly activated reaction, where the ring size has almost no effect on the rate of hydrolysis. In addition to the difference ring size plays in the intramolecular reaction, another major difference between the directly activated reaction and the intramolecular reaction is the importance of the buffer. For the directly activated ester reaction the buffer has no effect on the rate of hydrolysis, and in some cases causes a decrease in hydrolysis due to nucleophilic attack of the carbonyl carbon by the buffer. The intramolecular reaction, however, can be greatly affected by the buffer present, with CO_2^{2-} and PO_4^{3-} having the greatest influence.[68]

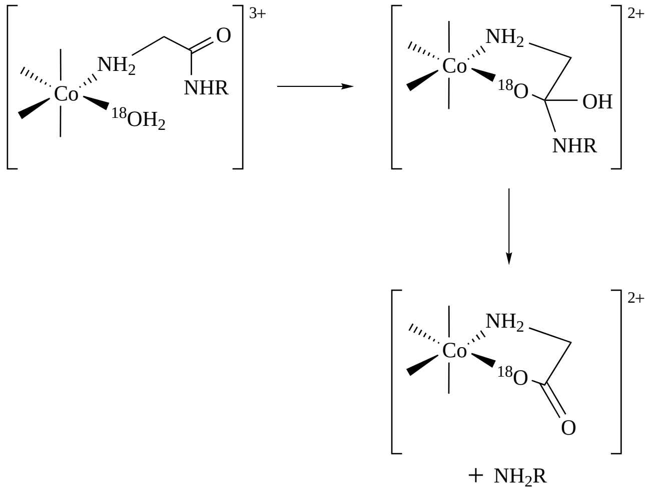
The hydrolysis of amino acid esters by directly coordinated hydroxy or water molecules is slower than the corresponding

reactions involving the directly activated esters. The rate of hydrolysis for coordinated water is 30 times slower, while the rate for coordinated hydroxide is 10^5 times slower.[64]

6.4 Intramolecular Hydrolysis of Peptides

The hydrolysis of peptides by coordinated water or hydroxide follows a path similar to that of amino acid esters (equation 10). The rate of hydrolysis is 10^2 times faster for coordinated water compared to coordinated hydroxide.[73] As with the hydrolysis of amino acid esters, the attack of the coordinated water or hydroxy group is the rate-limiting step in the hydrolysis of peptides. However, it has been shown that the elimination of the amine group is an important feature in the mechanism.

At acidic to neutral pH, the hydrolysis of a peptide is faster via the attack of a coordinated water or hydroxide relative to that of the directly activated peptide. However, as the pH is raised to 9.0 and above, the hydrolysis of the directly activated peptide becomes the favored route. Also, if the metal binds strongly to the carbonyl oxygen, then the hydrolysis will follow the directly activated mechanism, not the intramolecular mechanism.



(10)

6.5 Metal–Chelate Mediated Peptide Hydrolysis

Because cobalt(III) complexes bind to the N-terminal amino acid residue of peptides, only the N-terminal peptide bond is hydrolyzed. It would be advantageous if the metal complex could coordinate to various parts of a peptide chain, thus allowing for cleavage of other areas of the peptide chain. Recently this has become an active area of research, and there have been several publications on the cleavage of the polypeptide backbone of proteins promoted by metal complexes.[74–78] The advantage that these complexes have over the cobalt(III) complexes is that they can be selectively introduced on to various amino acid side chains, allowing for cleavage of peptide bonds at locations other than the N-terminus. This is of interest because, by selectively incorporating the metal chelate on to the polypeptide backbone of a protein, it may be possible to learn structural features of the protein by analysis of the cleavage products.

One such experiment involved the introduction of an iron chelate on to a unique residue on the protein human carbonic anhydrase I (HCAI).[77] By labeling the free SH group of Cys-212 of HCAI with (*p*-bromoacetamidobenzyl)EDTA, in which the EDTA was loaded with iron(II), the HCAI peptide backbone was cleaved in one place. The cleavage takes place in the presence of ascorbate and hydrogen peroxide. It is believed that the mechanism for cleavage is by nucleophilic attack of an iron-coordinated peroxo group at the carbonyl carbon. This is similar to the hydrolysis of peptides by coordinated water or hydroxide.

The peptide bond that is cleaved is the bond between Leu-189 and Asp-190. There are two peptide bonds in close proximity to the iron chelate on Cys-212. The other peptide bond is between Ile-144 and Gly-145. The Cys-212 sulfur is 5.1 Å from the carbonyl carbon of Gly-145, and 5.3 Å from the carbonyl carbon of Leu-189. However, the main difference is that the peptide bond of Leu-189–Asp-190 is oriented parallel to Cys-212, while the peptide bond of Ile-144–Gly-145 is oriented away for Cys-212. As was seen with cobalt(III) hydrolysis of peptide bonds, the proximity and orientation of the carbonyl carbon is important for hydrolysis. This approach has been extended to the cleavage of multisubunit proteins.[79] Palladium(II) and platinum(II) complexes as synthetic peptidases have been reviewed elsewhere.[52]

Glossary

Maximum total coordination number: the highest value of the total coordination number of the central atom likely to be encountered in a given period: for example, four in the second period

Penultimate total coordination number: the next-to-highest value of the total coordination number of the central atom likely to be encountered in a given period: for example, three in the second period

See also definitions of terms italicized in Tables 1 and 7

Total coordination number: the total number of atoms (and unshared electron pairs, if in the p-block) around a central atom

Abbreviations

HSAB = hard–soft acid–base (principle); HA = hard acid; HB = hard base; SA = soft acid; SB = soft base; χ_P = Pauling electronegativity; χ_{AR} = Allred–Rochow electronegativity; ΔH_{hyd} = hydration energy; ΔH_{atom} = atomization energy; $\Delta H(A–A)$ = bond dissociation energy of the bond between two atoms of element A; IE = ionization energy; pK_a = negative of the logarithm of the acid dissociation constant; pK_b = negative of the logarithm of the base dissociation constant.

1 INTRODUCTION

Inorganic chemistry is a field taught by inorganic chemists, largely for inorganic chemists, even though its content is also of serious interest to scientists in many allied fields of chemistry and science in general (e.g. analytical chemistry, biochemistry and medicinal chemistry, environmental science, agricultural and geochemistry, industrial chemistry and safety, metallurgy, materials science, surface chemistry). Students and research workers in these allied fields, who have limited time to take chemistry courses, find too little material they can profitably use in the typical one-semester Advanced Inorganic Chemistry course. A recent survey[1] shows that such courses in the United States place special emphasis on topics of relatively little use to such nonspecialists: symmetry and group theory, molecular orbital theory, and organometallic chemistry. Little time is spent on some areas that would meet their needs: redox chemistry and aqueous descriptive chemistry (and this limited coverage is diminishing with time). Some areas that are potentially useful to them are allocated little time, but are receiving increasing emphasis: bioinorganic and materials chemistry. Earlier we wrote a textbook which had, as one of its objectives, to capture the interest of, and serve students in, those allied sciences;[2] later we expanded it to cover these interests as well as the topics traditionally covered in an Advanced Inorganic Chemistry course for chemistry majors.[3] (When the French edition of the latter text appeared,[4] it was marketed specifically for an applied group, engineering students.)

It is, of course, challenging to present a generally useful survey of inorganic chemistry that is concise enough to serve chemistry majors and also fit into the curricula of nonspecialists: one must make potentially arguable choices on what to cover, how to cover it, and to what depth. We chose to look at a selection of inorganic reaction categories and property types that are broadly useful for diverse students. Great advances were made in the teaching of organic chemistry when it first began to focus on one type of chemical reactivity in one class of compounds (e.g. addition reactions of alkenes) at a time. The approach described here similarly looks at a given type of physical property or chemical reaction of a given class of inorganic species (e.g. trends in the acid–base reactivity of cations of all elements) across the entire periodic table at once.

The article then explains the periodic trends using the most accessible and generally applicable types of inorganic concepts. The most broadly applicable of all inorganic concepts is that of the periodic table and of chemical periodicity. The periodic table can be compared to a forest: it is a beautiful whole, which when examined more closely, consists of various zones (blocks of the periodic table), then further consists of a number of trees (18 or 32 groups), which each have components (elements). Unfortunately its complete study takes too much time for nonspecialists. Many presentations of the useful descriptive material are organized

by groups of the periodic table (looking at the trees). But, considering that nonspecialists might then not be able to see the forest for the trees, we have attempted to see how much could be learned looking at the periodic table as a whole (a forest). This article attempts a brief summary of this way of looking at useful inorganic chemistry through the periodic table as a whole.

The physical and chemical property types considered can be grouped broadly into five categories familiar to the student from the General Chemistry course: acid–base reactivity, coordination chemistry, precipitation reactivity, redox reactivity, and physical properties. The inorganic species studied begins with the most important class of all for many applied fields: the ions of the elements (monatomic at first, then polyatomic ions such as oxo anions (*see Oxoanion*), and then complex ions). We begin with the acid–base reactivity of ions: trends in the reactivity of all monatomic cations with water to form hydrated cations, followed by their hydrolysis to give acidic solutions. This trend is examined for all of the approximately 150 known simple cationic forms of the elements, regardless of the block, period, or group in which they are found, since many important properties such as these do vary smoothly and predictably across the periods, groups, and blocks of the periodic table.

One of the goals of our first textbook[2] was to apply Occam's Razor to the proliferation of theories and rationalizations taught in the early study of inorganic chemistry: we strove to make do with the minimum number of theories and periodic trends in atomic properties necessary to explain and organize adequately the numerous physical properties and reactivity types covered. Many periodic trends can be simply related to just three atomic properties: the ionic radius (r) (*see Crystallographic Radius*), the charge (Z), and the Pauling electronegativity (χ_P, *see Electronegativity*) of the element in the ion. Other more sophisticated theories and properties become necessary from time to time, such as electron configurations, relativistic effects (*see Relativistic Effects*), ligand field (*see* ***Ligand Field Theory & Spectra***) and molecular orbital (*see* ***Molecular Orbital Theory***) theories, symmetry, and so on; these are included as needed in the text, but will not be described here.

2 PERIODIC TRENDS IN FUNDAMENTAL ATOMIC PROPERTIES

Since so much can be predicted or at least rationalized on the basis of the periodicity of a few simple atomic properties, especially Pauling electronegativity, size, and charge (or oxidation number) (*see Oxidation Number*) of the atoms or ions involved, we begin by looking at these trends in some detail (beyond that done in General Chemistry courses) and then look into the physical reasons for the periodic trends in these properties.

In probing the broad and finer trends of periodicity in these properties, we have found it advantageous to use the calculations of the effective nuclear charges of atoms, Z^*, as predicted by Slater's rules. Even though much more accurate calculations have since been done, Slater's rules have the advantage of having been verbalized as rules; hence they can be explained in terms of the shielding and penetration of atomic orbitals, which can in turn be understood in terms of the radial extension and nodal properties of atomic orbitals. Periodic trends in radii, for example, can be rationalized using the old Bohr equation for the radius of the orbit of an electron (even though the absolute values of radii obtained from this equation are poor):

$$r = \frac{a_0(n^*)^2}{Z^*} \quad (1)$$

Appropriate calculations using this equation (in which n^* is the effective principal quantum number of the orbital, also given by Slater's rules) reproduce the main horizontal and vertical periodic trends in ionic or covalent radii (*see Covalent Radii*), and illustrate the scandide contraction that follows the filling of the first set of d orbitals. The calculations do not catch the effects of the lanthanide contraction (*see Lanthanide Contraction*, but this is due to the fact that Slater, in pursuit of simplicity, did not write any rules to catch the poor shielding effects of inner f orbitals. A modification of Slater's rule 4 to give $(n-2)$f orbitals poorer shielding effects of 69% rather than the previous 100% has been proposed recently.[5] Slater's rules are based on nonrelativistic calculations, and so do not capture relativistic effects;[6–8] for example, the relativistic contraction of s orbitals with many inner lobes in very heavy atoms, in which the electrons are accelerated to near the speed of light, become more massive, and hence contract in radius. They also cannot include crystal or ligand field effects on d orbitals, which influence a number of properties in substances not traditionally thought of as complexes.

Slater's rules have these limitations, but are easily used to predict trends in electronegativities using the equation that gives Allred – Rochow electronegativities:

$$\chi_{AR} = \frac{3590(Z^* - 0.35)}{r_{cov}^2} + 0.74 \quad (2)$$

In most parts of the periodic table, Allred – Rochow electronegativities match Pauling electronegativities well; hence, trends in effective nuclear charges and shielding can be used to explain the main periodic trends in Pauling electronegativities, as well as the effect of the scandide contraction. Since Allred – Rochow electronegativities do not capture the effect of the lanthanide contraction, relativistic effects, or crystal-field effects, they are low in parts of the d-block and, in particular, in much of the sixth period, but modifications recently proposed[5] give substantially higher

values for post-lanthanide elements such as Tl. Gold has the largest discrepancies between its Allred – Rochow and Pauling electronegativities ($\chi_{AR} = 1.44$; $\chi_P = 2.54$) since relativistic effects reach a maximum at the element.

Pauling electronegativities are based on experimental properties: bond energies and heats of formation, which are affected by the lanthanide contraction, crystal-field effects, and relativistic effects. Many other electronegativity scales are based on nonrelativistic calculations or properties that cannot be accurately determined for heavy atoms. Since we desire to correlate electronegativity with experimental properties of elements across all of the periodic table, including the heavy elements near gold, we have chosen to emphasize correlations with the Pauling scale of electronegativities; many other electronegativity scales give much poorer correlations with important periodic chemical trends. This is because many electronegativity scales do not correlate well with each other beyond the s and lighter p elements. Since each electronegativity scale is based on a different physical property with different problems of measurement or interpretation, and uses a different interpretation of Pauling's original definition of electronegativity, we suggest that 'electronegativity' is not one concept but is a family of related, but distinct concepts.

Besides charge, size, and Pauling electronegativity, other parameters such as valence electron configurations of atoms and ions are also important in predicting the periodicity of chemical properties. Since ions are more important than isolated gaseous atoms for nearly all atoms, and important ions have no anomalous electron configurations, there is little reason to worry students with anomalous electron configurations of atoms: we prefer to teach 'characteristic' electron configurations without anomalies in the occupancies of d and s orbitals in the transition elements or d, s, and f orbitals in the inner transition elements. Such characteristic electron configurations are most easily arrived at by considering the f-block of elements to begin with La and Ac and end with Yb and No, allowing Lu and Lr to be members of group 3 of the d-block, an adjustment of the periodic table that has been advocated on several chemical and physical grounds.[9–13]

3 ACID–BASE REACTIVITY OF IONS OF THE ELEMENTS

The first and most fundamental reaction of cations in the most common solvent, water, is the formation of hydrated ions; Latimer[14] gave an equation relating ΔH_{hyd} for this reaction to the charge and size of the cation, which we have updated to be compatible with the Shannon – Prewitt ionic radii in pm:

$$\Delta H_{hyd} = \frac{-60\,900 Z^2}{(r + 50)\ \mathrm{kJ\,mol^{-1}}} \quad (3)$$

It is clear that the electronegativity of the cation also has an influence, but this has not been quantified.

Subsequently hydrated ions react as Lewis acids with solvent water molecules:

$$[\mathrm{M(H_2O)_6}]^{z+} + \mathrm{H_2O} \rightleftharpoons [\mathrm{M(H_2O)_5(OH)}]^{(z-1)+} + \mathrm{H_3O^+} \quad (4)$$

This reaction and the corresponding one for anions turn out to be useful prototypes for a number of Lewis acid properties of fundamental importance in aquatic chemistry, bioinorganic chemistry, and inorganic chemistry itself. Six broadly applicable categories of the acid–base reactivity of cations and anions have been defined (Table 1):

Adding a soluble salt of a strongly or very strongly acidic cation to water can produce dramatic effects, as illustrated in a recently produced discovery video.[15] One of the most elementary applications of these categories and pK (*see Acidity Constants*) ranges is in predicting the pH conditions under which the cation or anion actually exist (and is the predominant form) in aqueous solutions (such as natural waters). To a rough approximation (neglecting effects such as those due to variations in concentrations), a cation will predominantly exist as the hydrated ion at pH values up to the pK_a of the cation; above a pH roughly equal to the pK_a of the cation, the hydroxide or oxide of the cation will predominate (and normally will precipitate). Correspondingly, an anion will predominate in hydrated forms at pOH values up to the pK_b of the anion; above that pOH (below the corresponding pH) the anion will mainly be protonated. Thus, nonacidic cations such as K^+ predominate at all pHs up to about 14, that is, at all practical pHs. Nonbasic anions such as Cl^- predominate at all pHs down to 0. The protonated form of Cl^-, HCl, is not the predominant form at any practical pH. In contrast, very strongly acidic cations such as 'P^{3+}' predominate only at pHs somewhere below −4, and very strongly basic anions such as O^{2-} predominate only somewhere above a pH of 18: these 'ions' are too reactive to exist in water.

These categories are useful for understanding the kinetics of exchange reactions (less acidic cations tend to exchange water or other ligands more rapidly), environmental persistence, and nutritional availability (*see* ***Nutritional Aspects of Metals & Trace Elements***). Thus, natural waters polluted by acid rain may have pHs as low as 2 or 3; in such waters and only in such waters do moderately acidic cations such as Fe^{3+} and

Table 1 Categories of acid–base reactivity

An ion is *nonacidic* or *nonbasic* if its pK_a or pK_b exceeds 14.
An ion is *feebly acidic* or *feebly basic* if its pK_a or pK_b lies between 11.5 and 14.
An ion is *weakly acidic* or *weakly basic* if its pK_a or pK_b lies between 6 and 11.5.
An ion is *moderately acidic* or *moderately basic* if its pK_a or pK_b lies between 1 and 6.
An ion is *strongly acidic* or *strongly basic* if its pK_a or pK_b lies between −4 and +1.
An ion is *very strongly acidic* or *very strongly basic* if its pK_a or pK_b is below −4.

Al^{3+} become predominant (through dissolution of $Fe(OH)_3$, etc.); the toxic effects of acid rain involve the leaching of such metal ions into the water. Correspondingly, the widespread nature of iron deficiency is related to the precipitation of the moderately acidic Fe^{3+} ion at the pHs found in the intestine.

The categories and pK values in Table 1 are related to the charge, size, and electronegativity (if it exceeds 1.50) of the cation:

$$\mathrm{p}K_\mathrm{a} = 15.14 - 88.16\left[\frac{Z^2}{r + 0.096(\chi_\mathrm{P} - 1.50)}\right] \quad (5)$$

In this relationship, the acidity is determined primarily by the charge-to-size ratio, Z^2/r, which is a useful way of characterizing the approximately 150 monatomic cations from across the periodic table (Table 2, Figure 1).

The basicity categories of Table 1 can not only be applied to simple monatomic anions (of which there are relatively few) but also to the far more abundant and practically important oxo anions (*see Oxoanion*) $MO_x{}^{y-}$; for the latter, the categories can be predicted from the number of oxo groups present, x, and the number of units of negative charge, y:

$$\mathrm{p}K_\mathrm{b} \text{ of } MO_x{}^{y-} = 10.0 + 5.7x - 10.2y \pm 1 \quad (6)$$

Increasing the negative charge of an anion increases its basicity, while increasing the number of oxo groups decreases its basicity (since this increases the size and the number of electronegative atoms in the anion). Monatomic and oxo anions can thus be classified as in Table 3.

It is straightforward, using the concepts of conjugate acids and bases, to derive the familiar principles for the relative strengths of the oxo acids (*see Acids & Acidity*). Since these have no charge, their acidity depends only on the number of oxo groups (x in the formula $(HO)_yMO_x$): oxo acids with three oxo groups are very strong acids; those with two oxo groups are strong acids, those with one oxo group are moderately acidic, and those without oxo groups are (at best) weakly acidic.

Table 2 Acidity categories of metal ions[a]

Nonacidic cations have Z^2/r ratios *below 0.01*; examples include Na^+ through Cs^+, R_4N^+, and most complex cations.
Feebly acidic cations have Z^2/r ratios *between 0.01 and 0.04*, and include most +2 ions of the s and f-blocks.
Weakly acidic cations have Z^2/r ratios *between 0.04 and 0.10*, and include most +2 ions of the d-block and +3 ions of the f-block.
Moderately acidic cations have Z^2/r ratios *between 0.10 and 0.16*, and include most +3 ions of the d-block and +4 ions of the f-block.
Strongly acidic cations have Z^2/r ratios *between 0.16 and 0.22*, and include most +4 ions of the d-block.
Very strongly acidic cations have Z^2/r ratios *above 0.22*, and include the 'cations' of the nonmetals.

[a]Radius in pm; if the electronegativity of the metal exceeds 1.8, it is moved up one category in acidic strength.

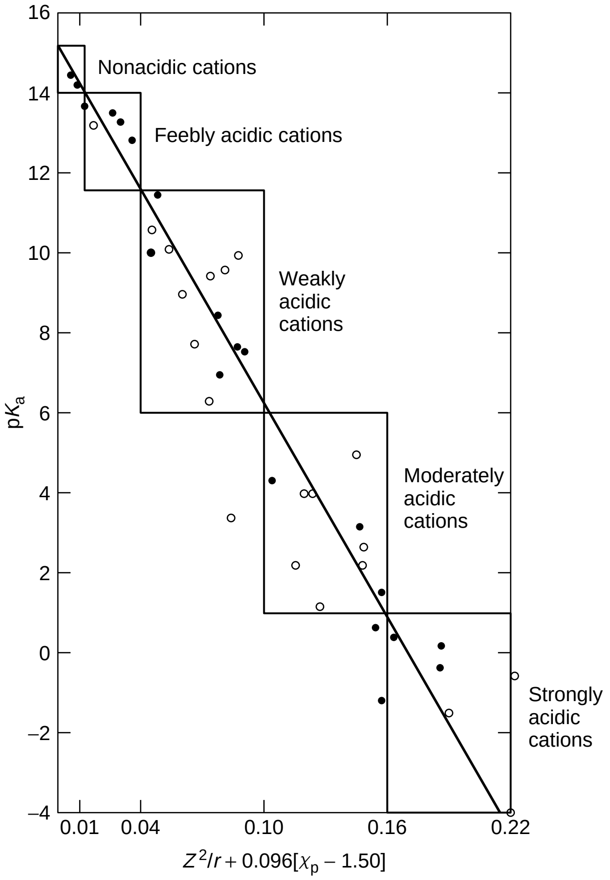

Figure 1 pK_a values of cations as a function of charge, size, and electronegativity. Closed circles equal metals of electronegativity (χ_P) less than 1.5, plotted as a function of Z^2/r. Open circles equal metals of electronegativity greater than 1.5, plotted as a function of $Z^2/r + 0.096(\chi_\mathrm{P} - 1.50)$. (Ref. 3. Reproduced by permission of University Science Books)

Table 3 Basicity categories of anions

Nonbasic anions include Cl^-, Br^-, I^-, and oxo anions for which p$K_\mathrm{b} > 14$ (e.g. $ClO_4{}^-$, $NO_3{}^-$), and most other complex anions.
Feebly basic anions include F^- and oxo anions for which $11{-}11.5 <$ p$K_\mathrm{b} < 14$ (e.g. $SO_4{}^{2-}$, $NO_2{}^-$).
(Weakly basic anions are few; they fall at the margins of this category and have no clear special properties, so we do not usually invoke this category, transferring F^- and $MO_2{}^-$ to the feebly basic category, which they almost fit, and $MO_3{}^{2-}$ to the moderately basic category, which it almost fits.)
Moderately basic anions include Te^{2-} and oxo anions for which $1 <$ p$K_\mathrm{b} < 6$ (e.g. $PO_4{}^{3-}$, $CO_3{}^{2-}$).
(Strongly basic anions are few, marginal, and have no clear special properties, so we do not usually invoke this category.)
Very strongly basic anions cannot exist as such in water, but must be (at least partially) protonated; this category includes O^{2-}, N^{3-}, and oxo anions for which p$K_\mathrm{b} < -4$ (e.g. $SiO_4{}^{4-}$).

The formulas of oxo anions are seemingly aperiodical (e.g. $CO_3{}^{2-}$, $SiO_4{}^{4-}$, $SnO_6{}^{8-}$) but have profound effects: carbonate minerals bear no structural relationship to silicate minerals.

Fortunately the chemical formulas can be rationalized on the basis of the size of the central atoms involved; it is not necessary to memorize their formulas! In general, second-period atoms are limited to a maximum total coordination number (the total coordination number counts unshared electron pairs in the p-block) of four; third and fourth-period atoms can have maximum total coordination numbers of six; fifth and sixth-period atoms can exceed a total coordination number of six. These observations explain the hydrolytic inertness (and persistence in the atmosphere) of compounds such as CF_4 and SF_6, which contain very strongly acidic 'cations'; they also explain why the formulas of fluoro anions vary (e.g. BF_4^- in period 2; AlF_6^{3-} in period 3; WF_8^{2-} in period 6). Evidently, because of the influence of π bonding to oxygen, central atoms in oxo anions fail to exhibit these coordination numbers, but instead settle for lower penultimate total coordination numbers: 3 in the second period, for example, CO_3^{2-}; 4 in the third and fourth periods, for example, SiO_4^{4-} and $GeO4^{4-}$; 6 in the fifth and sixth periods.

Some of these categories of ions show distinctive structural and thermodynamic properties. The nonacidic metal cations and nonbasic anions are distinct from all of the other categories, in that there is a positive entropy change accompanying their hydration as they dissolve from the solid state (Figure 2); they are known to physical chemists as electrostatic structure breakers because these large ions break up the structure of liquid water (which is sometimes described in terms of 'icebergs'). The feebly acidic cations and feebly basic anions have small negative entropy changes ($T\Delta S$ between 0 and $-35\,\mathrm{kJ\,mol^{-1}}$ at room temperature) accompanying their hydration; these entropy changes are too small to govern their solution properties. All stronger categories of acidic and basic ions have larger, chemically significant negative entropy changes accompanying their hydration, and are among the electrostatic structure makers; these ions hydrate very strongly and extensively, forming multiple hydration spheres involving dozens or even hundreds of water molecules. Collectively we may call this group of cations, with strengths ranging from weakly acidic to very strongly acidic, the acidic cations; the corresponding group of anions we may call the basic anions.

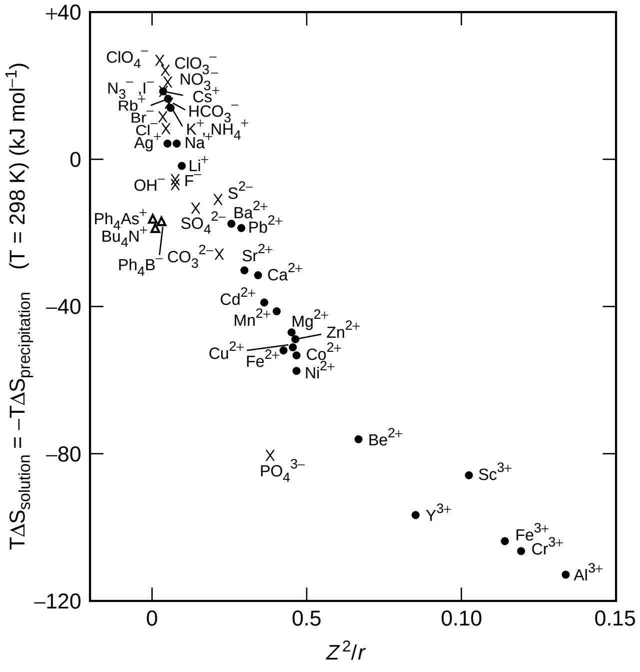

Figure 2 298 K entropy terms ($T\Delta S_{\mathrm{solution}} = -T\Delta S_{\mathrm{precipitation}}$) for cations and anions as a function of Z^2/r. Crosses equal anions; dots equal metal cations; triangles equal organic ions. (Ref. 3. Reproduced by permission of University Science Books)

4 SOLUBILITY AND COMPLEX-ION FORMATION TENDENCIES OF METAL IONS

The solubilities of salts in water (clearly of importance in aquatic, analytical, and geochemistry) can be fairly well predicted and explained using two principles; later we shall return to the more familiar of these, the hard–soft acid–base (HSAB) principle (*see* ***Hard & Soft Acids and Bases***). To control this principle, we must first consider only salts of anions that are hard bases, that is, salts of oxo and fluoro anions, and oxides, hydroxides, and fluorides. The solubilities of salts of these anions can be fairly well predicted and explained on the basis of the acidity classification of the cation and the basicity classification of the anion, that is, on a principle of acid–base strength. The numerous 'solubility rules' taught in General Chemistry could be replaced with four solubility principles (Table 4), two of which are quite reliable and two of which are less reliable, for known reasons.

The precipitation of salts according to Rule I is accompanied by a large favorable entropy change, as the strongly hydrated cations and anions release numerous waters of hydration. In contrast, the dissolution of salts according to Rule II is accompanied by very little entropy change, since one ion is a structure breaker, while the other is a structure maker; the dissolution occurs because the ions are mismatched

Table 4 Solubility principles for salts of hard-base anions

Rule I. Acidic cations and basic anions give insoluble salts (e.g. TiO_2, Mg_2SiO_4).

Rule II. Acidic cations and nonbasic anions, or nonacidic cations and basic anions ('cross-combinations'), give soluble salts (e.g. $Fe(NO_3)_3$, Na_3PO_4, NaOH).

Tendency III. Large nonacidic cations plus large nonbasic anions tend to give relatively insoluble salts (e.g. $KClO_4$, $[(CH_3)_4N][PF_6]$, $[Cr(NH_3)_6][Ni(CN)_5]$).

Tendency IV. Large feebly acidic cations and large feebly basic anions tend to give relatively insoluble salts (e.g. $BaSO_4$).

in size, and therefore give lattice energies that are smaller in magnitude than the combined hydration energies.

Tendencies III and IV are tendencies rather than rules because the effects of ΔH and $T\Delta S$ work in opposition to each other, giving varying, somewhat unpredictable results and moderate driving forces for precipitation; the smaller nonacidic cations (Na^+) and the smaller nonbasic anions (NO_3^-) tend not to show the predicted behavior. The mild insolubility that results when Tendency III holds favors good crystal growth, so Tendency III is often used by synthetic inorganic and organic chemists to isolate newly synthesized ions (which tend to be large, therefore nonacidic or nonbasic) in crystalline solids.[16] The prevailing driving force when Tendencies III and IV work is the formation of good crystal lattices because both the cation and anion are matched in size and charge; this force also favors thermal stability of the solid. It should be noted that unusual types of lattices and hydration are to be expected for grossly nonspherical complex cations and anions so that these rules and tendencies may not be reliable for these types of ions.[17] It is often important to dissolve metal salts in organic solvents (e.g. as catalysts); principles covering solubility of salts in organic solvents are given in our textbooks.[2,3] Room-temperature ionic liquids are a new class of organic solvents that should show distinctive properties as solvents for inorganic salts.[18]

The other principle that governs solubility across groups, periods, and blocks of the periodic table is the well-known Hard–Soft Acid–Base Principle (*see* ***Hard & Soft Acids and Bases***), which states that 'Hard(er) (Lewis) acids tend to combine with hard(er) bases, while soft(er) acids prefer soft(er) bases.[19] Table 5 shows the classifications of the most common ions of the elements. Whereas the strength of cations and anions is primarily determined by their Z^2/r ratios and only secondarily by their electronegativities, the softness of cations and anions is primarily a function of the electronegativities of the donor or acceptor atoms and only secondarily of their charges (oxidation states) and sizes. Hard acids and hard bases characteristically have very disparate Pauling electronegativities (0.7–1.6 for hard acids, 3.4–4.0 for hard bases), so combinations of them benefit from strong ionic bonding; softer acids and softer bases characteristically have similar, more moderate electronegativities (1.9–2.54 for soft acids, 2.1–3.0 for soft bases), so combinations of them are good for covalent bonding. The softest acids are those closest to the metal with the highest Pauling electronegativity, Au ($\chi_P = 2.54$); the softest bases are those near the metal–nonmetal boundary, where electronegativities are in the vicinity of 2.1. Of recent interest are new classes of weak soft Lewis bases, the chlorocarbons, bromocarbons, and iodocarbons,[20] (*see Halocarbons & Halocarbon Complexes*)

and xenon atoms in complexes such as $[AuXe_4]^{2+}$ and $[Re(C_5H_5)(CO)_2(Xe)]$.[21]

Solubility rules for salts of the heavier halide and chalcogenide ions are primarily based on the HSAB principle, but also involve strength to some degree. The chloride, bromide, iodide, and many pseudohalide ions (*see Pseudohalide*) involve borderline-to-soft donor atoms and characteristically combine with (give insoluble salts with) soft-acid cations. The sulfide, selenide, telluride, and arsenide ions are also soft bases, but have greater basic strength than chloride, bromide, and iodide, and so give insoluble salts not only with the soft acids near gold but also with the borderline acids further from gold, which characteristically are either smaller or more highly charged than the soft acids, and hence have more acidic strength.

In geochemistry, these two principles resulted in the differentiation of the metallic elements as lithophiles (hard acids; *see Lithophiles*) and chalcophiles (borderline and soft acids; *see Chalcophiles*) during the formation of the earth, and continue to affect the chemistry that occurs in the black smokers at the midoceanic ridges; these are also the organizing principles behind the familiar qualitative analysis scheme of the cations.[22]

The two principles of acid/base strength and hardness/softness apply not only to the prediction of the results of solubility equilibria but also to the prediction of complex ion equilibria (*see* ***Coordination & Organometallic Chemistry: Principles***). In such equilibria, we also take into account the additional principles of the chelate (*see Chelate Effect*) and macrocyclic (*see* ***Macrocyclic Ligands***) effects: chelate (*see Chelating Ligands*) ligands tend to form more stable complexes than analogous monodentate ligands, and macrocyclic ligands tend to form more stable complexes than analogous chelate ligands.

Among many possible applications, we may mention the prediction of the toxicities of simple ionic species (*see* ***Metal Ion Toxicity*** and ***Metal-related Diseases of Genetic Origin***). Soft-acid metal ions (except Ag^+) are uniformly very toxic because they bind preferentially to sulfur donor atoms in the body, frequently rupturing the disulfide linkages in the cystine in enzymes and consequently disrupting the tertiary and quaternary structure of the enzyme. Soft bases are also often very toxic since they bond strongly to (borderline acid) metal ions such as Fe^{2+} in the body, displacing less soft but more essential ligands such as O_2 (in oxygen transport by heme); however, the very toxic soft donor atom, selenium, also has beneficial effects in that it is softer than sulfur, and hence can apparently successfully remove soft-acid metal ions such as Hg^{2+} from the sulfur atoms in enzymes. Medicinal chemistry often employs the proper degree of softness in the design of pharmaceuticals so as to remove toxic metal ions; to ensure selectivity and good formation constants, ligands generally chosen are also chelate (or macrocyclic) ligands (*see* ***Metal-based Drugs***).

Since the HSAB classifications seem to depend principally on the Pauling electronegativity of a donor or acceptor atom, and Pauling electronegativities are based on bond energies (*see Bond Dissociation Energy*); the HSAB principle is best explained by analyzing the strengths of the bonds broken and formed during a typical HSAB reaction, in which HA = hard acid, SB = soft base, and so forth:

$$\text{HA:SB(g)} + \text{SA:HB(g)} \rightleftharpoons \text{HA:HB(g)} + \text{SA:SB(g)} \qquad (7)$$

We evaluate the donor–acceptor bond energies of each of the reactants and products using the equation that defines the Pauling electronegativities, χ_P, of the acceptor and donor atoms A and B:

$$\Delta H(\text{A–B}) = \frac{1}{2}[\Delta H(\text{A–A}) + \Delta H(\text{B–B})] + 96.5[\chi_P(\text{A}) - \chi_P(\text{B})]^2 \qquad (8)$$

This equation has recently been found to be much more accurate in predicting bond energies ($\pm 6\,\text{kJ mol}^{-1}$) than was commonly thought, provided the equation is applied as originally intended.[23] When we take the sum of the bond dissociation energies of the reactants minus the sum of the bond dissociation energies of the products, all the terms involving element–element bond energies (ΔH(A-HA), etc.) drop out, leaving four terms:

$$\Delta H = 96.5\{[\chi_P(\text{HA}) - \chi_P(\text{SB})]^2 + [\chi_P(\text{SA}) - \chi_P(\text{HB})]^2 - [\chi_P(\text{HA}) - \chi_P(\text{HB})]^2 - [\chi_P(\text{SA}) - \chi_P(\text{SB})]^2\} \qquad (9)$$

Let us now take some typical electronegativity values for the donor and acceptor atoms of hard and soft acids and bases: $\chi_P(\text{HA}) = 1.6$; $\chi_P(\text{HB}) = 3.4$; $\chi_P(\text{SA}) = \chi_P(\text{SB}) = 2.5$. Substituting these values in equation (9) gives us

$$\Delta H = 96.5[0.81 + 0.81 - 3.24 - 0] = -156\,\text{kJ mol}^{-1} \qquad (10)$$

This calculation indicates that the reaction to give the products HA-HB and SA-SB is accompanied by a favorable ΔH, which is supported by experimental data for a typical HSAB reaction (in which water, aq, is the hard acid and the hard base):

$$\text{Hg}^{2+}(\text{aq}) + \text{I}^-(\text{aq}) \rightleftharpoons \text{HgI}^+(\text{aq}) + \text{aq.aq}; \quad \Delta\text{H} = -315\,\text{kJ mol}^{-1}; \quad -T\Delta\text{S} = +10\,\text{kJ mol}^{-1} \qquad (11)$$

The calculation of equation (10) also indicates why the HSAB principle works so often: the driving force of the HSAB reaction lies in the formation of the very stable ionic hard acid–hard base product.

The chemical periodicity exhibited in the crystal or ligand field splitting of d-block metal-ion complexes, as a function of their d-electron configuration, is familiar and needs no elaboration here (*see* ***Ligand Field Theory & Spectra***;

Coordination & Organometallic Chemistry: Principles). Often cited are the effects of this periodicity on the hydration energies of metal ions, the lattice energies of simple salts, the enthalpies of formation of simple salts, complex-ion formation constants, and radii of d-block metal ions: all of these show double-humped curves when measured across a period for like-charged ions in high-spin octahedral complexes. Less well known is the fact that the Pauling electronegativities of the fourth-period d-block metal ions also show such a double-humped curve; this is because the Pauling electronegativities of the fourth-period d-block metals are obtained from the enthalpies of the formation of simple salts of these metals, which show high-spin octahedral coordination. And in fact, since appropriate ionic radii and Pauling electronegativities already incorporate crystal-field effects, the hydration energies of d-block metal ions, for example, do not show deviations from the Latimer-type equation (1).

For the benefit of nonspecialists with orientations toward biochemistry, the effects of crystal-field splitting are nicely illustrated using the Perutz model of the cooperative binding of O_2 as a ligand by the Fe^{2+} of hemoglobin, which undergoes a transition from high to low-spin upon binding O_2, which in turn triggers dramatic conformational changes in the protein of heme (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***). The coordination of the strong-field ligand nitric oxide, NO, is very important biochemically (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***) in triggering smooth-muscle relaxations such as are involved in penile erections, as well as in numerous other processes in the brain.[24]

5 REDOX REACTIVITY OF ELEMENTS AND THEIR IONS

The standard reduction potentials (*see Redox Potential*) of the elements and their compounds have many important applied implications for chemists, not the least of which is being aware when a compound or mixture of compounds they are handling has the potential for exploding. This should be considered as a possibility when the appropriate potentials differ by more than about one volt and appropriate kinetics considerations apply. A simply predictable case is the sometimes-violent reaction of metals with acids, as illustrated in a recently produced discovery video.[15] Redox activities of elements are most commonly (and most precisely) analyzed via thermochemical cycles such as the familiar Born–Haber cycle for the production of NaCl from Na and Cl_2. A similar analysis of the activities of different metals in their reactions with acids shows that the standard reduction potential for the metal (the quantitative measure of the activity of the metal) can be expressed in terms of the appropriate ionization energies of the metal, the atomization energies of the metal (*see Atomization Enthalpy of Metals*), and the hydration energies of the metal ion:

$$96.5E^{\circ} = \frac{\Delta H_{\text{atom}}}{z} + \frac{\Sigma \text{IE}(z)}{z} + \frac{\Delta H_{\text{hyd}}}{z} - 439\,\text{kJ}\,\text{mol}^{-1} \qquad (12)$$

where z is the charge on the metal ion produced (this equation neglects the small contribution of $-T\Delta S$). By the time this equation is solved, however, the explosion may have occurred, so a more useful empirically based prediction of the metal's activity is based on the good correlation of metal standard reduction potentials and low Pauling electronegativities (Figure 3; Table 6).

Since Pauling electronegativities are stated in terms of bond energies, the theoretical derivation of the relationship of the activity of a metal to its Pauling electronegativity[25] requires analysis of the electronegativity differences in the bonds being broken and formed during the reaction of a metal (containing metal–metal bonds of variable bond order) with hydronium ions to form hydrogen and hydrated metal ions (containing variable numbers of coordinate-covalent metal-oxygen bonds). Applying the Pauling equation rigorously requires that the reaction conserve the total number of bonds (including consideration of their bond orders). This condition cannot be met generally for the dissolution of solid metals to give hydrated ions. Thus, the empirical relationship of Figure 3 cannot be derived exactly, but its form can be explained: if the metal is less electronegative than hydrogen, there is a greater electronegativity difference and ionic character in the M^+–OH_2 bond than in the H^+–OH_2 bond; hence, the total bond energies are maximized for the products rather than for the reactants.

Standard reduction potentials also relate to the commercial methods of production of the elements, to the methods of production and use of oxo anions as oxidizing agents, and to the oxidation states in which the elements will be found in natural waters and soils. Many of these tendencies depend both on the reduction potential and the pH of the system in which the elements are found, and can be shown graphically in Pourbaix

Table 6 Redox categories of elements

Very electropositive metals have low Pauling electronegativities ($\chi_P < 1.4$) and standard reduction potentials ($E^{\circ} < -1.6$V), and include the very active metals such as Na whose cations are hard acids.
Electropositive metals have moderate Pauling electronegativities ($1.4 < \chi_P < 1.9$) and standard reduction potentials ($-1.6\text{V} < E^{\circ} < 0\text{V}$), and include the moderately active metals such as Fe whose cations are borderline acids.
Electronegative metals have high Pauling electronegativities for metals ($1.9 < \chi_P < 2.55$) and high standard reduction potentials ($E^{\circ} > 0$V), and include the inactive metals such as Au whose cations are soft acids.
Electronegative nonmetals have low Pauling electronegativities for metals ($1.9 < \chi_P < 2.8$) and include relatively inactive nonmetals such as S whose anions are soft bases.
Very electronegative nonmetals have high Pauling electronegativities ($\chi_P > 2.8$) and include active nonmetals such as fluorine whose anions are borderline or hard bases.

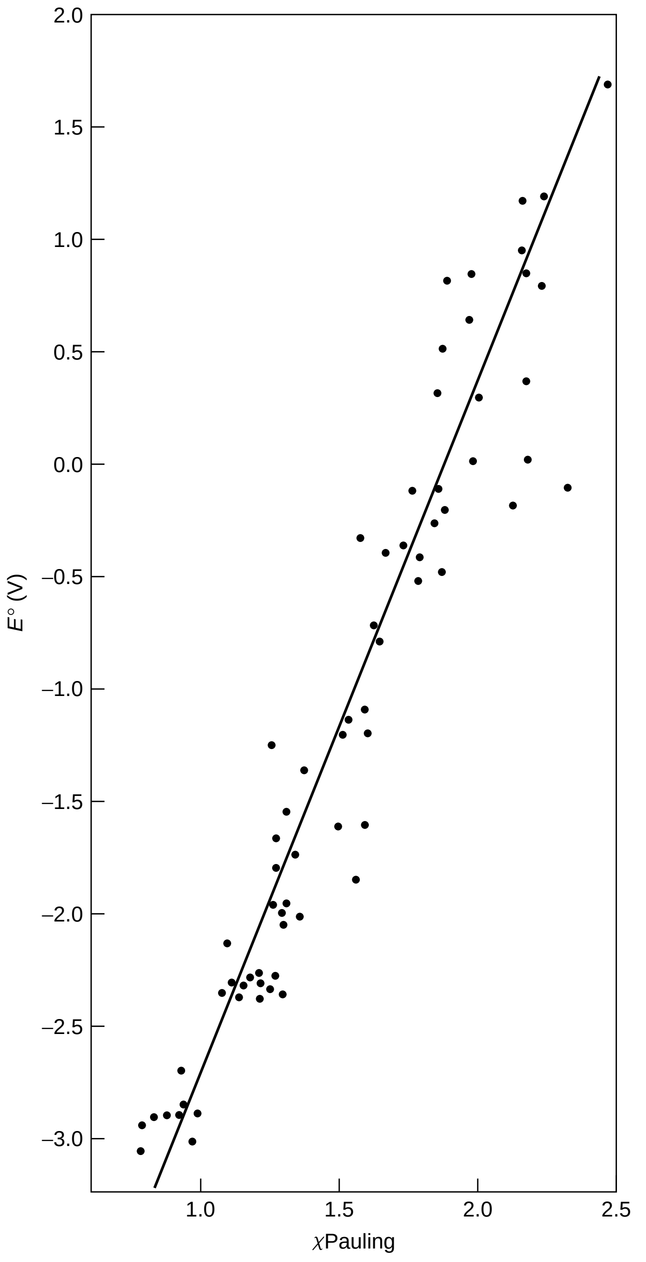

Figure 3 The standard reduction potential ($E°$) of the most common cation of each metallic element versus its Pauling electronegativity. (Ref. 3. Reproduced by permission of University Science Books)

($E°$/pH, pE/pH) diagrams[26] (*see Pourbaix Diagram*) of the elements (Figure 4), a form of expressing redox reactivity which is seldom taught by pure inorganic chemists,[1] but which is widely used by applied chemists such as environmental and soil scientists and corrosion engineers. With such diagrams, one does not have to remember the sign conventions of electrochemistry: the reaction of two species is favored thermodynamically if their predominance areas do not overlap; the further apart the predominance areas, the more exothermic or potentially explosive the reaction is.

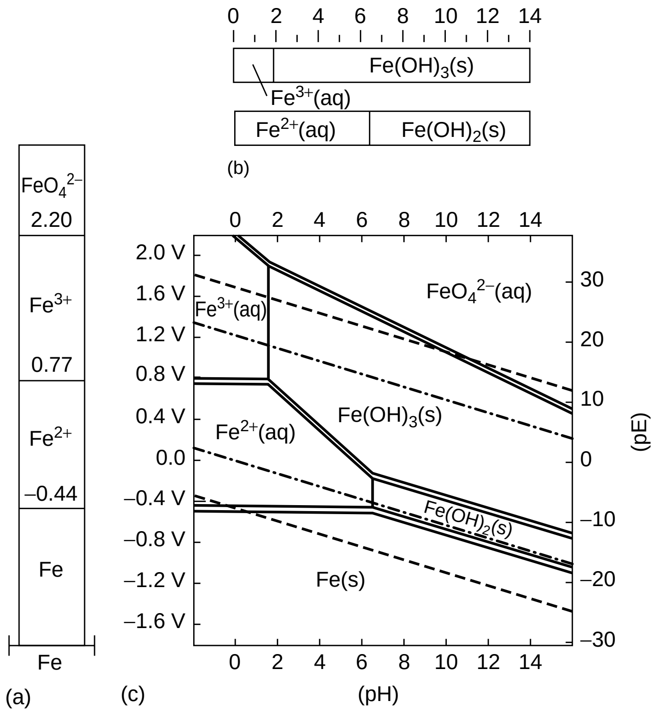

Figure 4 (a) At left, the redox predominance diagram for iron; (b) above, the acid–base predominance diagrams for Fe(III) and Fe(II); and (c) above right, the Pourbaix diagram showing the predominant form of iron at any given combination of redox potential and pH for 1 M iron solutions. Solid single lines (———) separate species related by acid–base equilibria; solid double lines (═══) separate species in different oxidation states. Dash-dotted lines (-·-·-·-) enclose the theoretical and dashed lines (- - - -) enclose the practical region of stability of water to oxidation or to reduction. (Ref. 3. Reproduced by permission of University Science Books)

Information is quite crowded in Pourbaix diagrams, so that students can benefit if reduction potentials are first provided at the standard pH of 0 in lower-dimensional vertical redox predominance diagrams (Figure 4). In these diagrams, strong oxidizing agents are confined to the top and strong reducing agents are confined to the bottom, which mirrors where they would be found in stratified natural waters that are well aerated at the top but oxygen-starved at the bottom. Thus, in the two predominance diagrams of Figure 5, the strongest oxidizing agent shown is FeO_4^{2-} and the strongest reducing agent is Mn(s). Since their (shaded) predominance areas do not overlap, MnO_4^- and Fe^{2+} are thermodynamically favored to react; but since the areas of MnO_4^- and Fe^{3+} do overlap, these two species do not react but instead can coexist in equilibrium.

Connections between the HSAB classifications of ions and their redox properties have long been noted: soft-acid cations tend to be good oxidizing agents and soft-base anions tend to be good reducing agents. It follows, of course, that the redox activities of the parent elements are also related to the HSAB classifications: the metals resulting from the reduction

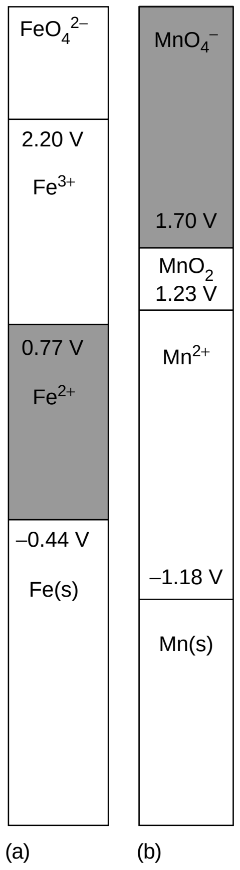

Figure 5 Redox predominance diagrams for iron (a) and manganese (b); boundaries represent the standard reduction potential for reduction of the (thermodynamically-stable) species above the boundary to the (thermodynamically-stable) species below the boundary. If the redox predominance regions of two species (e.g., the gray regions of Fe^{2+} and MnO_4^-) do not overlap along the y-axis when the two diagrams are superimposed, reaction between the two species is thermodynamically favored

of soft-acid cations are 'noble', that is, very poor reducing agents, which are geochemically also classified as siderophiles (*see Siderophiles*) since they are concentrated in the iron core of the molten earth and are depleted in the crust (but not in asteroids or in the deposits laid down on earth at the time the dinosaurs became extinct).

6 PHYSICAL PROPERTIES OF ELEMENTS, COMPOUNDS, AND MATERIALS

The major new area of materials science includes the study of the physical properties of solids and focuses on solids that have extended structures in at least one dimension (and thus usually excludes gases, liquids, and molecular solids containing small molecules); such solids are of importance not only to metallurgists and materials and surface scientists and workers in heterogeneous catalysis but also (especially when the structures are based on polysilicates) to geochemists, soil and agricultural chemists, and environmental chemists. Important materials fall among many classes of substances: elements and alloys, oxides, nitrides, sulfides, and so on. Many elements, oxides, and nitrides, however, are not of interest as materials because they consist of small molecules, which are not found in the solid state at a convenient temperature, or if they are, they lack extended structures to give rise to interesting bulk properties. A first question one would ask would be whether one could predict (from the simplest formula of a substance) if it would form a solid with an extended structure that might have interesting properties.

Extended structures of (at least) binary compounds EX_n most frequently involve covalent bonding between the simplest formula units E_1X_n via E and X atoms or groups that are bridging (two-coordinate or higher), rather than terminal (one-coordinate). Moderately accurate predictions of periodic trends in structural types for EX_n can be made using stoichiometry and radius-ratio calculations (starting with the premise that the compound can be formed, at least conceptually, from cations of E and anions of X). (1) If the radius ratio of the ions in the compound EX_n lies between 0.225 and 0.414, E is predicted to have a total coordination number of 4; if the ratio lies between 0.414 and 0.732, E should have a total coordination number of 6; if the ratio is above 0.732, E should have a total coordination number of 8. (2) Once the coordination number of E is predicted, the average coordination number of the 'anionic' element X can be predicted:

$$\begin{aligned}&(\text{Coordination number of E})(\text{Number of E in formula})\\&\quad = (\text{Coordination number of X})(\text{Number of X in formula})\end{aligned} \tag{13}$$

(3) If the coordination number of either atom (in practice, normally X) is 1.00, the structure is molecular and not extended. As the average coordination number of X increases, there are more and more bridging interactions involving X-atom bridges, so the structure becomes more extended, proceeding from one-dimensional polymerization through two-dimensional sheet and then to three-dimensional network (ionic or covalent) structures.

Among the halides (*see* ***Fluorides: Solid-state Chemistry*** and *see* ***Halides: Solid-state Chemistry***) and oxides (*see* ***Oxides: Solid-state Chemistry***) of the elements in their maximum oxidation states in a given period, on the left of the period, where oxidation states are low, the coordination numbers of both the metal ion and the halide or oxide ion are high, allowing the construction of three-dimensional network (ionic or polymeric covalent) structures (Table 7). As oxidation states rise to the right in a period, the average coordination number of the X (halide or oxide) atom or ion necessarily drops; when this falls below two, oligomeric and eventually monomeric molecular structures are adopted (e.g. Mn_2O_7 and PtF_6, OsO_4, RuO_4, and FeO_4 in the d-block; Cl_2O_7 and SF_6, IF_7, and XeO_4 in the p-block). This

trend in structures has drastic effects on the properties of the halides or oxides as materials: their volatility and gaseous, liquid, or solid status is affected, the possibilities for magnetic interactions (*see* ***Magnetism of Extended Arrays in Inorganic Solids***) and conductivity are completely changed, and so on. These differences in structure are often so pronounced as to form the bases of classification schemes for certain types of compounds: molecular or covalent hydrides (*see* ***Hydrogen: Inorganic Chemistry***) and organometallics are found to the right of the periodic table as contrasted to saltlike or polymeric hydrides and organometallics, found at the left.

Research workers in applied chemical fields are especially interested in the polysilicates and aluminosilicates, which are so important in geochemistry, soil chemistry, environmental chemistry, and in catalysts such as zeolites (*see* ***Zeolites***) and clays (*see Clay Minerals*) such as montmorillonite (on which, according to one heretical theory, life first originated).[27] These materials often contain polysilicate and polyaluminosilicate ions of varying degrees of polymerization, which can be rationalized from their stoichiometries. SiO_2 itself is a three-dimensional network solid, as are the zeolites in which the oxygen-to-(aluminum plus silicon) ratios in the framework are also 2:1. Polysilicates are produced by reaction of this acidic oxide with basic metal oxides; as the ratio of oxygen to silicon (or silicon plus aluminum) in the anion increases, the average (covalent bond) coordination number of the oxygen in the polyanion decreases, hence successively less polymeric ions are produced. Two-dimensional (layer) polymeric ions such as $[Si_4O_{10}]_n^{4-}$ are found in mica and clays; two-stranded, one-dimensional (needle) polymeric ions such as $[Si_4O_{11}]_n^{6-}$ are found in some forms of asbestos; one-dimensional (linear and cyclic) structures such as $[SiO_3]_n^{2-}$ are found in pyroxenes and beryl; finally oligomeric $[Si_2O_7]^{6-}$ and monomeric $[SiO_4]^{4-}$ ions are found in thortveitite and olivine. The less polymerized the polysilicate anion, the more readily minerals containing the ion are weathered to release their nutrient cations. Minerals such as olivine are generally found only in deserts or other ‘youthful’ soils; they readily release nutrient ions to water, accounting for the high productivity of desert soils upon irrigation. Conversely, only highly polymeric, insoluble oxides can persist in tropical soils exposed to high levels of heat and rainfall; in slash-and-burn

agriculture the tropical soil is quickly reduced to a content of such hard, polymeric, infertile oxides known as laterite. Polysilicates and polyaluminosilicates also offer a fertile field in which one can introduce the concept of isomorphous (*see Isomorphous*) substitution of different ions of similar radii and the same total charge.

The same question of the building up of extended structures comes up among elements, but since they are not binary compounds, one cannot apply radius ratios. In contrast to oxides, halides, and so on, the most nonvolatile and high-melting elements are found in the middle of their periods (carbon in the second period; tungsten in the sixth period). The rules of Engle and Brewer[28,29] relate this trend to the average number of unpaired valence electrons per atom available for bonding, which reaches a maximum approximately in the middle of a block of the periodic table. As electrons pair in valence orbitals to the right in the p-block, the degree of polymerization of the element decreases, from two- or three-dimensional network polymeric structures (diamond, graphite) to one-dimensional structures (Se_x) to small molecules (Cl_2) and finally to individual atoms (He). Among metals at the left or right of the d-block, the degrees of polymerization and coordination numbers do not decrease, but the average bond order does: full explanation of this finally requires the use of the Molecular Orbital Theory (*see* ***Molecular Orbital Theory***) or band theory (*see Band Theory*), which are unlikely to be accessible to the nonspecialist. As bond orders decrease to the left or right in the d-block, so do the melting points and physical hardness of the metals.

While the argument continues of whether the bonding in metals is of a type distinct from ionic and covalent bonding, one point of view is that metallic bonding is not distinct from covalent bonding.[30–32] Clearly there are some important differences in physical properties of metallic substances from those of covalent (even covalent network) substances that need explanation; these include not only the obvious differences in conductivity but also such properties as malleability and ductility.[33] Density functional calculations[34] (*see Crossover Experiment*) point to a particular feature of the electronic distribution in metals: it is not concentrated on the most electronegative atom, as in ionic compounds, nor especially in the regions between neighboring atoms, as in molecular or network covalent substances, but is found in the regions between nonadjacent atoms so that the electron density has a nonlocalized 'flatness' of distribution across the space between all of the metal atoms (Figure 6). This flatness means that

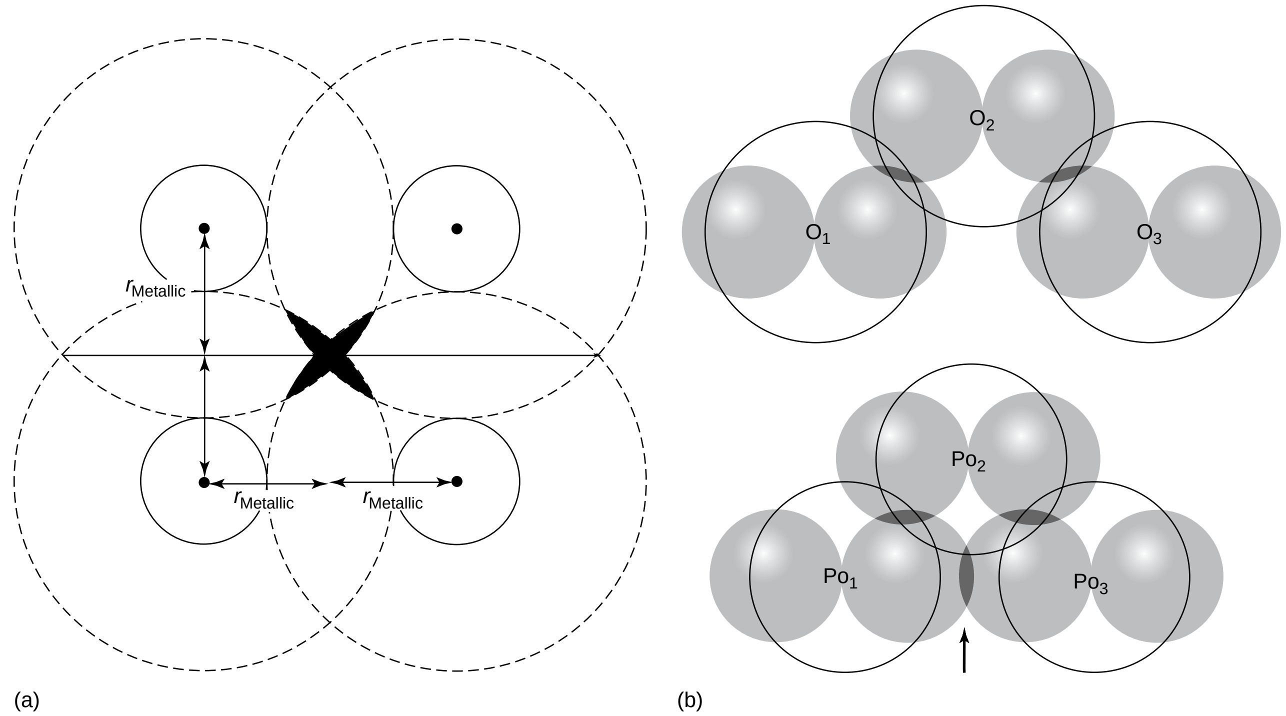

Figure 6 Two illustrations of overlap (shaded in darkest color) of nonadjacent orbitals that participate in ''flat'' molecular orbitals involved in metallic conduction. (a) Drawing of four atoms in a metallic solid. Inner solid circle = largest filled (core) orbital of a metal; outer (dashed - - - -) circle = partially occupied valence orbital. Note the overlap of the valence orbitals of the nonadjacent top left and bottom right atoms, and the overlap involving the top right and the bottom left atoms. (b) Drawing of three atoms of hypothetical chain polymeric allotropes of oxygen and polonium (selected to have the structure actually found for μ-sulfur, selenium, and tellurium). Inner solid circle = filled valence s orbital of the element; gray shaded double circles = partially occupied valence p orbital of the element. Overlap of the p orbitals of the nonadjacent first and third atoms occurs only for Po, since the p orbital extends further beyond the s orbital in the case of Po than in the case of O. (Ref. 3. Reproduced by permission of University Science Books)

bonding ability is not lost when atoms are displaced from their original positions during hammering or drawing a metal into a wire; it also gives a rationale for the classical description of metals as 'metal ions in a sea of electrons.'

Provided that there is a large 'radius ratio' between the partially filled atomic orbitals involved in conduction and the last filled atomic orbitals, and provided that the geometric arrangement of the atoms is appropriate, one can sketch situations as in Figure 6, in which partially filled atomic orbitals will overlap other such orbitals on nonadjacent atoms, giving rise to 'flat' molecular orbitals involved in conduction. This large radius ratio tends to be found among atoms early in the periodic table (especially groups 1 and 2) and, in the p-block, among atoms lower in a group.

Chemists have long tried to classify substances into the broad categories of ionic, metallic, and covalent (or covalent network and covalent molecular) on the basis of the fundamental atomic properties, in particular, electronegativity; the earliest of these attempts was the van Arkel triangle[35–37] (*see* ***Structure & Property Maps for Inorganic Solids***), which has been gradually refined by Sproul, most recently to a graph for elements and binary compounds comparing the electronegativities of the element of lowest electronegativity and the element of the highest electronegativity.[38] In such a graph, metallic elements and alloys are predicted when the element of higher electronegativity has an electronegativity less than about 2.2 (gold is clearly an exception). Electronegativities cannot explain, however, the great differences in conductivities of different allotropes (*see Allotrope*) of some elements (especially carbon); in different allotropes, the different arrangements of atoms may sometimes allow or exclude the overlap of orbitals of nonadjacent atoms to give 'flat' molecular orbitals.

7 CHEMICAL PROPERTIES OF COMPOUNDS

Space allows us to consider only one example. Even in General Chemistry courses, it is often pointed out that the acidity of metal oxides increases to the right in the periodic table. With the classification scheme for simple ions (Table 1), it is possible to rationalize and amplify this periodic trend: oxide ion is a very strongly basic anion; in combinations with nonacidic and feebly acidic cations, it is reasonable that the basic properties of the oxide ion should prevail, giving water-soluble basic oxides. Oxides of weakly and moderately acidic cations are insoluble according to Solubility Rule I, but it is reasonable that the basic properties of the oxide ion should still prevail so that these oxides dissolve in acid and are also generally classified as basic oxides. (Some are amphoteric oxides; unfortunately we have found no way to use our classification schemes with any high degree of accuracy to predict amphoterism.) At the other end of the periodic table, oxides of very strongly acidic 'cations' tend to be acidic oxides; they tend to be water-soluble if the oxo acid formed on hydrating them is very strongly, strongly, or moderately acidic. However, if the element has reached its penultimate total coordination number in its oxide, it is unable to add hydroxide or oxide ions, and hence is a neutral oxide. With these concepts, it is easy to explain the presence of acidic oxides (CrO_3, Mn_2O_7, OsO_4) and even a neutral oxide (FeO_4) in the middle of the d-block.

8 CONCLUSIONS

A systematic, across-the-periodic-table overview of reactivity trends, based primarily on simple concepts of the periodicity of charge or oxidation number, size, and electronegativity, provides benefits: (1) to nonspecialists, who will more readily grasp the inorganic aspects of their chosen fields, and in the future will more readily see opportunities for collaboration with inorganic chemists; (2) to inorganic chemists, who (a) will more readily grasp many of the properties of the compounds and materials that are the focus of modern 'pure' inorganic research and (b) will more readily see areas of applied chemistry to which they can direct their own research efforts later in their careers, as the tendency toward applied and interdisciplinary research continues.

Glossary

Catenaphosphate: the infinite chain phosphate, $(PO_3^-)_\infty$
Cyclophosphates: cyclic anions of two-connected phosphate tetrahedra, $P_nO_{3n}{}^{n-}$
Diphosphate: the $P_2O_7{}^{4-}$ anion
Metaphosphates: cyclo and catenaphosphates
Orthophosphate: the $PO_4{}^{3-}$ anion
Polyphosphates: chain anions of two-connected phosphate tetrahedra, $P_nO_{3n+1}{}^{(n+2)-}$
Ultraphosphates: anions formed by two and three-connected phosphate tetrahedra, $P_nO_{3n-1}{}^{(n-2)-}$

Abbreviations

ADP = Ammonium Dihydrogen phosphate, $NH_4H_2PO_4$; AlPO = A framework aluminophosphate; HUP = Hydrogen uranyl phosphate; KDP = Potassium Dihydrogen phosphate, KH_2PO_4; KTP = Potassium Titanyl Phosphate, $KTiOPO_4$; NASICON = Sodium Superionic Conductor.

1 INTRODUCTION

Phosphates are compounds that contain oxyanions of phosphorus(V), ranging from the simple orthophosphate group to condensed chain, ring, and network anions.[1] Oxyanions of phosphorus in lower oxidation states such as phosphite, $HPO_3{}^{2-}$, are also known.

A very large number of solid phosphates have been prepared or found as minerals. Their diversity results from variations in the phosphate species, the large number of cations to which they may be coordinated, and the presence of other anions or molecules, notably H_2O. Their chemistry is similar to that of solid silicates (*see* ***Zeolites***) and borates (*see* ***Borates: Solid-state Chemistry***).

Attention will be focused on phosphates of metallic elements and other small cations (H^+, $NH_4{}^+$), although it should be noted that a variety of phosphate salts of large organic or inorganic coordination complex cations are also known. Background information of the chemistry of phosphates and related phosphorus species can be found in the texts by Corbridge[2] and Kanazawa[3] (*see also* ***Phosphorus: Inorganic Chemistry***).

Phosphate structures are generally rigid, resistant to chemical attack, and (when anhydrous) insoluble and thermally stable. This leads to some applications as nuclear waste immobilization hosts or negative thermal expansion materials. Many solid phosphate hosts permit diffusion of extra-framework species, leading to potential uses as ion exchangers (*see Ion Exchange*) and conductors (*see* ***Ionic Conductors***), and as microporous catalysts (*see* ***Porous Inorganic Materials*** and ***Zeolites***). Phosphate anions do not absorb significantly in the UV-visible region and so solid phosphates can also find use as optical materials such as glasses, phosphors (*see Phosphorescence*), nonlinear media (*see Nonlinear Optical Materials*) and lasers.

Solid phosphates constitute many minerals, notably Apatites, which are also found in living organisms as rigid components such as bones and teeth (*see* ***Biomineralization***). Amorphous Phosphorite deposits are important sources of phosphate fertilizers.

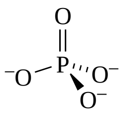
2 PHOSPHATE ANIONS

Solid phosphates are conveniently classified according to the anions they contain.

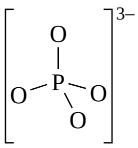
2.1 Orthophosphates

The orthophosphate group, $PO_4{}^{3-}$, (often shortened to ‘phosphate’) is the most ubiquitous oxyanion of phosphorus. In solid orthophosphates, all four oxygen atoms are usually coordinated to cations resulting in a strongly bonded three-dimensional framework, although layered or chain structures sometimes result.

The covalent bonding in the tetrahedral $PO_4{}^{3-}$ anion may be described as the average of four resonance hybrids such as (**1**), giving the average structure (**2**) with tetrahedral (T_d) symmetry. These two views of the bonding illustrate important features of phosphate chemistry. (**1**) shows that up to three



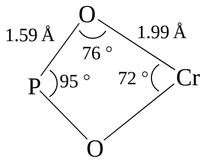
(**1**)



(**2**)

covalent (P)O–X bonds may be formed with high-valent elements X, notably P^V in condensed phosphates, whereas (**2**) shows that all four oxygen atoms are equally involved in predominantly ionic bonding in metal orthophosphates. In ionic phosphates, terminal P=O and $P–O^-$ bonds within the same tetrahedral group are equivalent and are strengthened by $P{:}3d_\pi$-$O{:}2p_\pi$ overlap (*see π-Bond*).

The orthophosphate group usually displays a near-regular tetrahedral geometry. Analysis of geometric data from 85 reliably determined crystal structures gives a mean P–O bond length (*see Bond Length*) of 1.536 Å with distances lying in the range 1.50–1.58 Å, and tetrahedral angles between 97 and 115°.[4] Distorted geometries can occur when the orthophosphate group acts as a bidentate ligand (*see Ligand*), resulting in a strained four-membered ring. (**3**) shows the geometry of the ring formed by phosphate tetrahedra and CrO_6 octahedra sharing a common edge in α-$CrPO_4$, as determined by low-temperature neutron diffraction.[5]



(**3**)

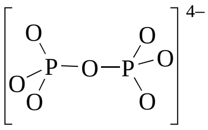
The acid orthophosphate anions, (mono)hydrogenphosphate HPO_4^{2-} and dihydrogenphosphate $H_2PO_4^-$, also have extensive solid-state chemistries. Protonation lowers the bonding symmetry as the P–O(H) bonds have single bond character and the unprotonated oxygens are consequently bonded more strongly to phosphorus. Analysis of 21 acid orthophosphate structures gives P–O(H) distances in the range 1.56–1.62 Å,[4] whereas the average $P–O_t$ bond distance (O_t = terminal oxygen) of 1.52 Å is slightly shorter than that in orthophosphates. The unprotonated oxygen atoms are readily coordinated to cations whereas the protonated sites are often uncoordinated, but are hydrogen bonded to nearby P–OH groups or other suitable species. This tends to result in more open structures with lower dimensionalities for acid orthophosphates than for orthophosphates.

The great diversity of orthophosphates is illustrated throughout this entry. Structural variety results from the large number of cations that form stable orthophosphates and the incorporation of additional molecules, notably water, or anions. Virtually every metallic element forms an orthophosphate, sometimes in a variety of oxidation states, for example, from V^{II} to V^V in $NaV^{II}V^{III}_2(PO_4)_3$, $V^{III}PO_4$, $V^{IV}O(H_2PO_4)_2$, and V^VOPO_4. The former compound is one of many mixed valent orthophosphates (*see* ***Mixed Valence Compounds***). A very large number of mixed cation orthophosphates are also known; a complex example is $Mg_{21}Ca_4Na_4(PO_4)_{18}$. Hydrated phosphates are common, and variation of the water content may be possible; $VO(HPO_4){\cdot}nH_2O$ structures have been characterized for $n = 1/2$, 1, 2 (two forms), 3, and 4.[6] Orthophosphates containing additional anions include $Ca_2(PO_4)F$, $Fe_2(PO_4)O$, $Ca_{10}(PO_4)_6S$, $LiMn(PO_4)(OH)$, $Zr_2(WO_4)(PO_4)_2$, $Ca_5(PO_4)_2(SiO_4)$, $Pb_3Mn(PO_4)_2(SO_4)$, and $Na_3Ca(SiO_3)PO_4$(containing an infinite catenasilicate chain). Solid solutions involving substitutions of the cations or the orthophosphate group (e.g. for ortho- arsenate, vanadate, and silicate groups) further extend the range of possible phases.

2.2 Diphosphates

The diphosphate anion, $P_2O_7^{4-}$ (also known as pyrophosphate), is the simplest polyphosphate anion and is found in many solids. Variations in composition and structure are similar to those described above for the orthophosphates.

The bonding and consequent geometry of the O_b-PO_3 (O_b = bridging oxygen) group is very similar to that of the (H)O–PO_3 group. $P–O_b$ distances are in the range 1.58–1.64 Å whereas the reported mean $P–O_t$ distance for 17 diphosphates is 1.512 Å.[4] P–O–P angles lie in the range 120–160°. Unusually large values are a result of disorder of the bridging oxygen atom, notably in the 'linear', centrosymmetric diphosphate groups (**4**) present in Thortveitite type transition metal diphosphate structures, $M_2P_2O_7$. Disorder is evidenced by anomalous $P–O_b$ distances and O_b-P–O_t angles, and a large amplitude of thermal vibration for the bridging oxygen. Careful refinement of $Mn_2P_2O_7$ using single crystal X-ray and powder neutron diffraction data shows that the bridging oxygens lie 0.2 Å on either side of the inversion center, giving a P–O–P angle of 166°, in better agreement with well ordered diphosphate groups.[7] In general, apparently linear P–O–P linkages in condensed phosphates arise from such disorder and do not reflect a stable geometry.



(**4**)

All three acid diphosphate anions have been found in the solid state, for example, $Mn(HP_2O_7)$, $Na_2(H_2P_2O_7){\cdot}6H_2O$, and $Cs(H_3P_2O_7){\cdot}H_2O$. However, trihydrogendiphosphate salts are rare owing to the low pK_a (*see Acidity Constants*) of the doubly protonated phosphate group (*cf* H_3PO_4 has $pK_1 = 2.1$). The bridging oxygen is of very low basicity and does not coordinate

even to highly charged cations. This is a universal feature in the chemistry of condensed phosphates.

2.3 Polyphosphates

Linking phosphate tetrahedra into chains through two vertices results in polyphosphate anions, $P_nO_{3n+1}{}^{(n+2)-}$, also known as oligophosphates.[8] Examples are shown in Table 1. Finite chains containing up to six tetrahedra have been found in the solid state. They become less common with increasing n.

A large number of anhydrous and hydrated triphosphates have been characterized, including structures containing the mono- and dihydrogentriphosphate anions. Only the terminal phosphate groups are protonated, as bridging –OP(O_2H)O– groups have lower pK_a's. The layered triphosphates $MH_2P_3O_{10}\cdot 2H_2O$ (M = Al, Cr, Mn, Fe) are intercalation hosts (*see* ***Intercalation Chemistry***) like the lamellar orthophosphates described in Section 5.3.

Tetraphosphates are less common than triphosphates, and the best-defined examples are crystalline, anhydrous materials. An acid tetraphosphate, $(NH_4)_4H_2P_4O_{13}$, has been reported. Pentaphosphate anions have been structurally characterized in $Mg_2Na_3P_5O_{16}$, $CsM_2P_5O_{16}$ (M = V, Fe) and the mixed phosphate $Rb_2Ta_2H(PO_4)_2(P_5O_{16})$. One hexaphosphate, $Ca_4P_6O_{19}$, has been reported, but the structure has not been determined. There is evidence for longer polyphosphate anions up to at least $P_8O_{25}{}^{10-}$ in solution, but no well-defined solid derivatives have yet been prepared.

A number of solid structures containing two polyphosphate anions have been reported. All have complex stoichiometries involving at least two cationic species, examples are $K_2Ni_4(PO_4)_2P_2O_7$, $CsTa_2(PO_4)_2P_3O_{10}$, $NH_4Cd_6(P_2O_7)_2P_3O_{10}$, and $CaNb_2O(P_2O_7)P_4O_{13}$. $KAl_2(H_2P_3O_{10})P_4O_{12}$ contains the dihydrogentriphosphate and cyclotetraphosphate anions

Table 1 Polyphosphates and cyclophosphates classified by the number of linked tetrahedra, n

n	Polyphosphates	Cyclophosphates
3	$Na_5P_3O_{10}$, $FeH_2P_3O_{10}\cdot H_2O$, $KEuHP_3O_{10}$	$K_3P_3O_9$, $Cd_3(P_3O_9)_2\cdot 7H_2O$, $LiFeP_3O_9$
4	$Gd_2P_4O_{13}$, $(NH_4)_6P_4O_{13}\cdot 2H_2O$, $(NH_4)_2SiP_4O_{13}$	UP_4O_{12}, $CoAg_2P_4O_{12}\cdot 5H_2O$, $KNdP_4O_{12}$, $Yb_4(P_4O_{12})_3$
5	$Na_3Mg_2P_5O_{16}$, $CsV_2P_5O_{16}$	$Na_4(NH_4)P_5O_{15}\cdot 4H_2O$
6	$Ca_4P_6O_{19}$	$K_6P_6O_{18}$, $Cu_3P_6O_{18}\cdot 14H_2O$, $Ag_4Li_2P_6O_{18}\cdot 2H_2O$
8	Na8$P_8O_{24}\cdot 6H_2O$,$Cu_3(NH_4)_2P_8O_{24}$, $Ag_9NaP_8O_{24}(NO_3)_2\cdot 4H_2O$	
10		$K_{10}P_{10}O_{30}\cdot 4H_2O$, $Ag_4K_6P_{10}O_{30}\cdot 10H_2O$
12		$Cs_3V_3P_{12}O_{36}$

2.4 Cyclophosphates

Previously known as cyclopolyphosphates, these rings may contain up to 12 tetrahedra, but those with three, four, and six units are most common (see Table 1). The cyclotri- and cyclotetraphosphate rings adopt puckered geometries typical of saturated six and eight atom rings. The predominance of even membered cyclophosphates reflects their ability to pack efficiently in the solid state, rather than any inherent stability over odd membered ones. This is often reflected by a high internal symmetry in the crystalline state; an analysis of thirty reliably determined cyclohexaphosphate structures shows that 18 have inversion symmetry and a further seven have threefold (D_{3d}) internal symmetry.[9]

Both hydrated and anhydrous cyclophosphates have been prepared, but no acid anions have been found in these solids owing to the low basicity of two-connected phosphate groups. A common structural feature, especially with large rings, is the formation of layers of cyclophosphate groups. This enables a large range of hydration numbers to be observed, as cations can be coordinated between two layers in anhydrous salts, or by cyclophosphate groups on one side and water molecules on the other in some hydrated compounds. Fully hydrated cations can also lie between the layers and further noncoordinated water molecules may occupy the intra-annular and interlamellar spaces. Examples of highly hydrated cyclohexaphosphates are $Nd_2P_6O_{18}\cdot 12H_2O$ and $Cu_3P_6O_{18}\cdot 14H_2O$.

2.5 Catenaphosphates

The infinite chain catenaphosphate anion $(PO_3{}^-)_\infty$ represents the infinite limit of the poly- and cyclophosphate series. Catenaphosphates are formed at high temperatures and so all reported structures are anhydrous, for example, $Al(PO_3)_3$, $UO_2H(PO_3)_3$, and $Cs_2Co(PO_3)_4$. P–O_t and P–O_b distances are ~1.48 and ~1.60 Å, respectively, similar to values for two-connected phosphate tetrahedra in other anions. The cations lie between parallel, infinite polyphosphate chains resulting in strongly bonded three-dimensional structures. Thermal decomposition of hydrogenphosphates has resulted in the acid catenaphosphates $Na_2H(PO_3)_3$, $BiH(PO_3)_4$ and $UO_2H(PO_3)_3$. In $BiH(PO_3)_4$, one of the terminal oxygens on every fourth phosphate tetrahedron is protonated; this is the only nonbridging oxygen not to coordinate to Bi^{3+}.

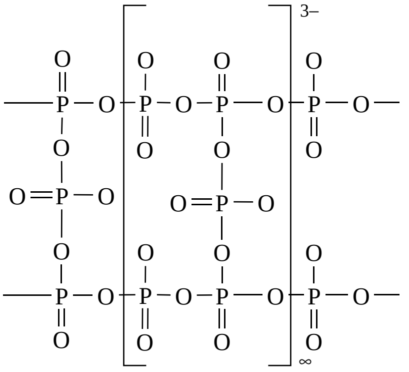
As cyclophosphates and the catenaphosphate anion (together termed metaphosphates) share the basic composition $(PO_3{}^-)_n$, crystal-structure analysis is often the only way to determine which species is present, although IR spectroscopy may be useful (see Section 3.2.1). Different isomers of the same metaphosphate composition are often found. Six crystal forms (A-F) of $M(PO_3)_3$ (M = Al, Cr, Mn, Fe, Ga) have been identified, three of which have been structurally characterized and found to contain cyclotetraphosphate (form A), cyclohexaphosphate (B), and catenaphosphate (C) anions.

However, structures containing two metaphosphate anions are very rare, an example is $Pb_2Cs_3(P_4O_{12})(PO_3)_3$ in which both cyclotetraphosphate and catenaphosphate groups are present.

2.6 Ultraphosphates

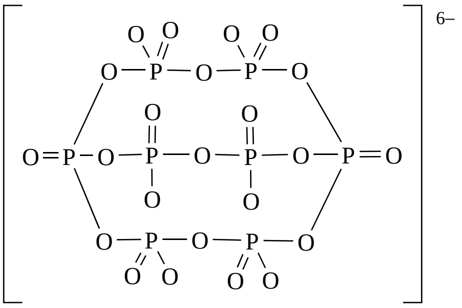
Possible ultraphosphate anions containing x two-connected and y three-connected tetrahedra have stoichiometry $P_{x+y}O_{3x+5y/2}{}^{x-}$. All observed anions have $y = 2$, and so may be written $P_nO_{3n-1}{}^{(n-2)-}$, where $n = 4$, 5, 6, and 8.[10] Solid ultraphosphates are anhydrous, as the P–O–P bridges between three-connected phosphate tetrahedra are susceptible to hydrolysis. The potential of lanthanide ultraphosphates MP_5O_{14} as laser materials has driven the exploration of ultraphosphate chemistry. The list of characterized ultraphosphates is now MP_4O_{11} (M = Mg, Ca, Mn, Co, Ni, Cu, Zn), MP_5O_{14} (M = Lanthanide, Y, Bi), $NiHP_5O_{14}$, $M_2P_6O_{17}$ (M = Ca, Cd, Sr), $(UO_2)_2P_6O_{17}$, $(TaO_2)_4P_6O_{17}$, and $Na_3MP_8O_{23}$ (M = Al, V, Cr, Fe, Ga). The structures of these anions vary from discrete anions to infinite ribbons, sheets, and three-dimensional frameworks.

The MP_4O_{11} structures contain infinite layers of fused eight- and twelve-membered rings, but the MP_5O_{11} structures vary with the cation radius and fall into three principal types. Types I (M = La-Ho, Bi) and III (M = Dy-Lu, Y) both contain infinite ribbons (**5**), while in type II materials (M = Tb-Lu, Y) a complex three-dimensional phosphate framework is formed. A unique polymorph of CeP_5O_{11} contains infinite sheet anions. Sheets of fused 14-membered rings are found in $M_2P_6O_{17}$ compounds, whereas $UO_2P_6O_{17}$ contains an infinite three-dimensional anionic network. The $Na_3MP_8O_{23}$ structure contains the unique cage phosphate anion $P_8O_{23}{}^{6-}$ (**6**), which has a threefold symmetry axis. This is the only molecular ultraphosphate anion to have been characterized.

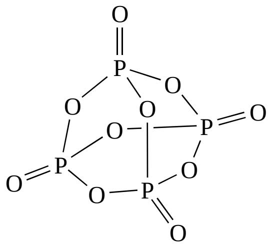


(**5**) $P_5O_{14}{}^{3-}$

Phosphorus pentoxide may be regarded as a neutral ultraphosphate containing only three-connected phosphate tetrahedra. Two extended forms of P_2O_5 are known, one containing infinite sheets, and the other a three-dimensional framework. The third form, molecular P_4O_{10} (**7**), consists of four tetrahedra each joined through three vertices and is the most highly condensed phosphate species.



(**6**)



(**7**)

2.7 Substituted Anions

Condensing phosphate tetrahedra with other $XO_4{}^{n-}$ groups results in P-substituted anions such as the polyphosphate derivatives $Na_3PS_2O_{10}$, $Na_4P_2S_2O_{13}$, $Na_3PCr_3O_{13}\cdot 3H_2O$, and $Li_3PCr_4O_{16}$. The phosphate groups are found in the bridging positions of these chains. Infinitely extended tetrahedral anions formed by condensing phosphate and other tetrahedral groups are described in Section 5.1.

Electronegative nonmetals can substitute for oxygen in phosphate anions. Many fluoro- and difluoro-orthophosphates are known, for example, $CaPO_3F\cdot 2H_2O$, $Cu(PO_2F_2)_2$, and sodium salts of all the thioorthophosphate anions $PO_{4-n}S_n{}^{3-}$ ($n = 1$–4) have been crystallized. Condensed thiophosphates have also been reported, for example, $Cs_3P_3O_6S_3$ and $Na_4P_4O_8S_4\cdot 6H_2O$, and analogous cycloimidophosphate anions are found in $K_3P_3O_6(NH)_3$ and $Cs_4P_4O_8(NH)_4\cdot 6H_2O$. In the cyclothiophosphates, one terminal sulfur atom is present on each phosphate unit, however, the NH groups occupy the bridging positions in the cycloimidophosphate rings. Many monovalent and divalent cation salts of the $P_3O_6(NH)_3{}^{3-}$ anion have been prepared. $AgPO_2(NH_2)_2$ is a rare example of a diamidophosphate, the nitrogen analog of a dihydrogenphosphate.

3 CHARACTERIZATION

3.1 Diffraction Methods

These provide the most complete structural characterization for crystalline phosphates (*see* ***Diffraction Methods in Inorganic Chemistry***). Single crystal X-ray diffraction is used whenever possible, but powder X-ray diffraction (*see* ***Solids: Characterization by Powder Diffraction***) has been applied increasingly over the last decade to the many phosphates that can only be prepared in a polycrystalline form. Unknown structures determined using powder data include $KZrH(PO_4)_2$, $VOHPO_4{\cdot}2H_2O$, the framework aluminophosphates MCS-1 and SAPO-40, and the zeolitic nickel(II) phosphate VSB-5 using laboratory X rays, and α-$CrPO_4$,[5] $MnPO_4{\cdot}H_2O$, and $(VO)_3(PO_4)_2{\cdot}9H_2O$ from highly resolved synchrotron X-ray diffraction data.

Neutron diffraction is used to determine oxygen positions precisely and to locate hydrogen atoms in hydrated or acid phosphates, enabling hydrogen bonding arrangements to be elucidated. Electron diffraction and High-Resolution Electron Microscopy (*see Electron Microscopy*) imaging can be applied to structures that have at least one simple projection, such as the phosphate tungsten bronzes discussed in Section 6.1.

3.2 Spectroscopies

Vibrational and nuclear magnetic resonance (NMR) spectroscopies complement diffraction methods in the study of solid phosphates. They characterize the local environments around phosphate tetrahedra such as the number of bridges to other phosphate groups and the nature of local cations. They are particularly useful in the study of highly disordered or amorphous phosphates.

3.2.1 Vibrational

Infrared (*see Infrared Spectroscopy*) and Raman (*see Raman Spectroscopy*) spectroscopies are used to study the vibrations of P–O bonds in solid phosphates. The frequencies and splittings of the stretching and bending vibrations can be related to the local symmetry and connectivity of the phosphate groups. Coupling of the phosphate bending vibrations with low-frequency lattice modes may be significant for light or strongly bonded cations so that features in the P–O stretching region (700–1400 cm^{-1}) are of greatest diagnostic use (Table 2).[11] However, even these vibrations may be shifted when strong M–O(P) bonds are present so that they are no longer characteristic of the anion alone.

The IR spectrum of a tetrahedrally symmetric (T_d) orthophosphate anion is characterized by a strong transition in the stretching region (Table 2) and a strong bending mode at 500–600 cm^{-1}. The Raman spectrum is dominated by the totally symmetric stretch. These bands may be broadened or split if the anions are distorted from T_d symmetry. Both the IR and Raman spectra of orthophosphates are notable for an absence of bands in the 700–900 cm^{-1} region, unlike condensed phosphates, but hydrogenphosphate groups or other species (e.g. H_2O) may contribute in this region. Acid

Table 2 Infrared and Raman stretching frequency ranges (cm^{-1}) for phosphate anions in the solid state.[11] The intensities of the bands (s = strong, m = medium, w = weak) and their assignments (s = symmetric, as = antisymmetric vibrations) are shown

Anion	IR	Raman
PO_4^{3-}	1000–1070(s) as(PO_4)	930–970(s) s(PO_4)

$P_nO_{3n+1}^{(n+2)-}$ (Polyphosphates)	900–940(s) as(POP) 1120–1150(s) as(PO_3) 1200–1300(s) as(PO_2)	1000(s) s(PO_3) 1100–1160(s) s(PO_2)
$P_nO_{3n}^{n-}$ (Cyclophosphates)	$n = 3$ 760–780(s) s(POP) $n = 4$ 670–750(m) $n = 3,4$ 970–1050(s) as(POP) $n \geq 6$ 910–940(s) 1250–1300(s) as(PO_2)	$n = 3$ 620–650(m) s(POP) $n = 3,4$ 650–690(s) s(POP) $n \geq 6$ 700–760(s) 1150–1200(s) s(PO_2)
$(PO_3^{-})_\infty$ (Catenaphosphates)	670–780(m) s(POP) 860–950(s) as(POP) 1250–1300 as(PO_2)	650–750(s) s(POP) 1150–1200(s) s(PO_2)
$P_nO_{3n-1}^{(n-2)-}$ (Ultraphosphates)	600–800(w) s(POP) 950–1050(s) as(POP) 1250–1300(s) as(PO_2) 1300–1400(s) (PO)	600–800(w) s(POP) 1150–1200(s) s(PO_2)

phosphate groups are also distinguished by O–H stretches at 2300–2800 cm^{-1}.

Diphosphates are distinguished from orthophosphates by the vibrations of the P–O–P bridge. The antisymmetric P–O–P stretch (ν_{as}) gives a strong IR absorption at 900–950 cm^{-1}, whereas the symmetric stretch (ν_s) around 750 cm^{-1} is weak in the IR spectrum, and may not be apparent in near-linear diphosphates such as $Mn_2P_2O_7$, but is strong in the Raman spectrum. In the approximation that the P–O–P unit vibrates independently from the rest of the anion, the quantity Δ (equation (1)) is predicted to vary smoothly with the bridge angle. This has been verified using data from 15 diphosphates;[11] the resulting curve enables the P–O–P angle to be estimated from the vibrational spectrum.

$$\Delta = \frac{(\nu_{as} - \nu_s)}{(\nu_{as} + \nu_s)} \qquad (1)$$

Correlations between the structures and vibrational spectra of finite polyphosphate chains have not been widely investigated. The spectra are complex owing to the presence of, and coupling between, bridging PO_2 and terminal PO_3 groups. As the chain length increases the PO_2 group frequencies increase to approach those in catenaphosphates.

Metaphosphates are characterized by the high frequencies of the asymmetric and symmetric PO_2 stretches in their IR and Raman spectra, respectively. The $(\text{–P–O–})_n$ rings in cyclophosphates give diagnostic vibrations in the 600–850 cm^{-1} region, which can be used to identify cyclotri- and cyclotetraphosphates (Table 2). The antisymmetric stretch of the $(\text{–P–O–})\infty$ chain at $\sim$900 cm^{-1} distinguishes catenaphosphates from the common small-ring cyclophosphates.

The short, strong P=O bond in ultraphosphates gives the highest IR absorption of all phosphates, at 1300–1400 cm^{-1}. Otherwise the spectra of ultraphosphates (which consist of fused rings) resemble those of cyclophosphates.

3.2.2 NMR

NMR spectroscopy is extremely useful for the study of phosphates,[12] as the ^{31}P nucleus has a spin of 1/2 and is 100% abundant. The magic angle spinning technique (MASNMR) is used to obtain highly resolved spectra from solid phosphates with linewidths of a few ppm, comparable to those of solution ^{31}P spectra. Information about the local environments in solid phosphates is derived from the number and intensities of ^{31}P signals, their anisotropies and mean (isotropic) chemical shifts, possible spin–spin couplings through asymmetric P–O–P bridges, and any line broadening interactions. MASNMR can also be used to study kinetic processes, such as the crystallization of the phosphates from solution.

The isotropic ^{31}P chemical shifts move to high-field values with increasing connectivity of phosphate tetrahedra and increasing charge on the coordinated cations. For orthophosphates and one-, two- and three-connected phosphate tetrahedra the isotropic shifts usually lie in the ranges -30 to $+15$, -35 to $+5$, -50 to -5, and -65 to -45 ppm, respectively. The sensitivity of the chemical shift to local cations can be used to resolve different local environments in disordered materials.

Paramagnetic cations can give a large contact or pseudo-contact shift and may broaden the ^{31}P resonance. Chemical shifts of up to 1650 ppm have been found in vanadyl phosphates and used to estimate the magnetic exchange constants between vanadyl electronic spins.[6]

The anisotropy of the chemical shift tensor reflects the asymmetry in the bonding to the four oxygens, and so increases with increasing connectivity of the phosphate tetrahedra. A MASNMR study of the crystalline forms of P_2O_5 reveals axially symmetric chemical shift tensors in all three cases. The shifts perpendicular and parallel to the principal axis lie in the ranges -52 to -24 and $+211$ to $+244$ ppm. This axis corresponds to the P=O direction as the double bond gives a strong shielding.

4 SYNTHESIS

Preparative routes for solid phosphates are typical of those used in solid-state chemistry. Reactions in which cations and phosphate anions are combined can take place in solution under atmospheric or hydrothermal pressures, or by direct combination at high temperatures. Transformations of phosphates into new structures can be achieved thermally or through topotactic exchange reactions. Hydrothermal and chemical vapor transport techniques are used to facilitate crystal growth.

4.1 Solution

Soluble phosphates can be deposited from aqueous solutions, and this method may also yield suitable single crystals for structure determination and physical measurements. This method is commonly used to obtain hydrated and acid phosphates of soluble cations, for example, alkali and alkaline earth metals, NH_4^+. Acid phosphates such as KDP (KH_2PO_4) may be prepared by partial neutralization of phosphoric acid with metal hydroxides or carbonates.

Insoluble phosphates can be precipitated by mixing cation and phosphate solutions, or by generating one species in situ, for example equation (2). Condensed phosphates can be prepared from polyphosphoric acids, made by adding a small amount of water to P_2O_5.

$$Mn^{2+}{}_{(aq)} + PO_4{}^{3-}{}_{(aq)} \xrightarrow{\text{c. HNO}_3} Mn^{III}PO_4{\cdot}H_2O_{(s)} \qquad (2)$$

4.2 Hydrothermal

Phosphates of divalent and more highly charged cations are usually insoluble at ambient pressures, and precipitated samples are often poorly crystalline. The solubility of such phosphates increases at higher temperatures and pressures, and so hydrothermal conditions are used to obtain more crystalline products, as well as many phases not observed at atmospheric pressure (*see* ***High Pressure Synthesis of Solids***). This method is also used to grow large single crystals of materials such as $KTiOPO_4$ (Section 5.2.2).

Hydrothermal bombs containing aqueous mixtures of a metal compound and phosphoric acid are typically heated to temperatures of 100–350 °C, generating autogenous pressures up to 300 bar. The pressure rises more rapidly above the critical temperature of water, 373 °C, and hydrothermal pressures of ~3000 bar are typically generated at 600–1000 °C in sealed metal tubes surrounded by a supporting pressure of an inert gas.

The products of such reactions depend upon the pressure, temperature, pH, phosphate, and cation concentrations, and may be difficult to predict or rationalize. For example, the equation (3) produces an acid phosphate and a phosphate hydroxide. Microporous aluminophosphates and related phases (see Section 5.1.2) are prepared in hydrothermal bombs using hydrated cations or molecular templates such as organic amines or ammonium cations to direct the porous framework. Many new structures with metal phosphate chains, layers, or three-dimensional networks have been prepared hydrothermally in recent years, for example, templated vanadium phosphates[13] and iron phosphates.[14]

$$Fe_2O_3 + {\sim}3H_3PO_4 \xrightarrow{700\,°C,\ 3\,kbar} Fe_2(P_2O_7)(HPO_4) + Fe_4(OH)_3(PO_4)_3 \quad (3)$$

4.3 Solid State

Heating intimate mixtures of a metal salt and P_2O_5 or an ammonium phosphate is a convenient route to many anhydrous phosphates. To minimize evaporation of P_2O_5, the reactants are often dissolved in dilute acid and the solution is heated to dryness, giving a precursor residue for firing. This method gives a good control of stoichiometry, for example, $CrPO_4$, $Cr_4(P_2O_7)_3$, or $Cr(PO_3)_3$ may be obtained by varying the Cr:P ratio in the initial solutions.

4.4 Ion Exchange

Ion-Exchange (*see Ion Exchange*) reactions in solution are used to produce phosphates of soluble cations, for example, equation (4). Solid-state reactions such as (5) and (6) may be used to exchange mobile cations and are usually topotactic (*see Topotactic*). In the notable equation (6), the exchange of Li^+ for H^+ is accompanied by a migration of the Mn^{3+} cations from one set of octahedral sites to another, within an unchanged $(PO_4)(OH)$ lattice.[15]

$$Ag_6P_6O_{18}\cdot H_2O + 6NaCl_{(aq)} \longrightarrow Na_6P_6O_{18} + 6AgCl \quad (4)$$

$$\alpha\text{-}Zr(HPO_4)_2 \xrightarrow{NaCl,\ 200\,°C} ZrNaH(PO_4)_2 + ZrNa_2(PO_4)_2 \quad (5)$$

$$MnPO_4\cdot H_2O \xrightarrow{LiNO_3,\ 200\,°C,\ 4\ weeks} LiMnPO_4(OH) \quad (6)$$

4.5 Thermal Transformations

Gentle dehydration gives many anhydrous phosphates. Further thermal decomposition often yields new phases; in particular, dehydration of acid phosphates can result in condensed phosphate anions. If neighboring hydrogenphosphate groups are present then the new structure may be related to the old, for example, the dehydration (**7**) is thought to form diphosphate bridges between the zirconium phosphate layers (see Section 5.3.1). The structures of the reactant and product in equation (8) are so closely related that a single crystal of the hydrogenphosphate may be thermally transformed into a crystal of the diphosphate.[16] Equations (9) and (10) exemplify the formation of more highly condensed phosphates.

$$\alpha\text{-}Zr(HPO_4)_2 \xrightarrow{\Delta} ZrP_2O_7 + H_2O \quad (7)$$

$$2Fe_2(P_2O_7)(HPO_4) \xrightarrow{\Delta} Fe_4(P_2O_7)_3 + H_2O \quad (8)$$

$$Ga(H_2PO_4)_3 \xrightarrow{140\,°C} GaH_2P_3O_{10}\cdot 2H_2O \xrightarrow{230\,°C} GaH_2P_3O_{10} \longrightarrow Ga(PO_3)_3 \quad (9)$$

$$NH_4GaHP_3O_{10} \xrightarrow{450\,°C} Ga_2P_6O_{18} \quad (10)$$

4.6 Flux Growth

Slow cooling of phosphate-rich melts can be used to grow large crystals for optical characterization, for example, the lanthanide ultraphosphates, MP_5O_{14}, are grown from M_2O_3–P_2O_5–H_2O melts by cooling from 400–500 °C. Phosphate glasses are obtained by quenching melts.

4.7 Vapor Transport (*see Chemical Vapor Deposition*)

Anhydrous metal phosphates can be transported across thermal gradients at high temperatures (~1000 °C) using halogens as carrier gases. Transport takes place through the formation and decomposition of volatile metal and phosphorus halides and oxyhalides.[17] This method has been used to grow crystals of several phosphates, for example, $TiPO_4$, $Fe_2P_2O_7$, RhP_3O_9, and to prepare the new compounds such as the low-valent chromium diphosphates $Cr_2P_2O_7$ and $Cr_3(P_2O_7)_2$.

5 STRUCTURAL CLASSES

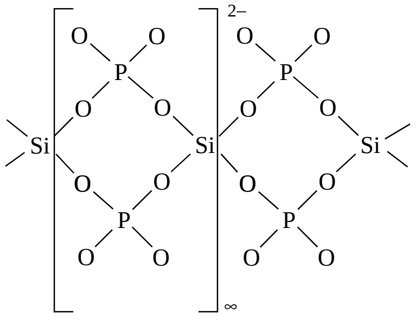
Solid phosphates show a huge variety of crystal structures, and it is not practical to classify them in terms of structural types as is done with simple oxides, halides, etc. However, some general classes of metal phosphate structures will be considered: three-dimensional frameworks of linked phosphate tetrahedra and tetrahedrally or octahedrally coordinated cations, layered phosphates, and phosphate glasses. In all of these materials the size and topology of pores within the structure are of importance, as these determine the ability of ions and molecules to move within the structure, giving rise to useful ion exchange, ionic conduction, or catalytic properties. Ion exchange can also be used to modify the properties of the host network, for example, the nonlinear optical behavior of potassium titanyl phosphate (KTP) derivatives.

5.1 Tetrahedral Networks

Phosphate tetrahedra can share up to three apices with each other or tetrahedral anions of high-valent elements. This limits the formation of infinite phosphate anions to the catena and ultraphosphates. However, with MO_4^{n-} groups of divalent or trivalent cations, in which there is a strong ionic component to the (P)O–M bonding, all four corners of the phosphate group may be shared. This enables infinite networks of alternating PO_4 and MO_4 tetrahedra to be prepared, analogous to highly connected silicate structures (*see* ***Zeolites***).

5.1.1 Silicophosphates

In well-defined silicophosphate anions, the phosphate groups are found to be one or two-connected owing to the covalent nature of the P–O–Si bonds. However, the silicate groups share all four corners enabling infinite anion networks to be built up in some cases. Simple columnar anions are found in $VO(P_2SiO_8)$ and $Cd_2(P_4SiO_{11})$ consisting of silicate tetrahedra bridged by phosphate (**8**) and diphosphate groups, respectively.



(**8**) $SiP_2O_8^{2-}$

The discrete $(P_6Si_2O_{25})^{12-}$ anion $[O(Si(OPO_3^{2-})_3)_2]$ is found in a large number of solids: $M_3P_6Si_2O_{25}$ (M = Si, Ge) $AM_3P_6Si_2O_{25}$ (A = K, Rb, Cs, Tl; M = Mo, Ti) and $M_3P_5SiO_{19}$ (M = V, Mo). The latter compounds may be written $M_6(P_6Si_2O_{25})(P_4O_{13})$ as they contain separate $(P_6Si_2O_{25})^{12-}$ and tetraphosphate anions. $Si_5P_6O_{25}$ is notable for containing two tetrahedrally coordinated and three octahedrally coordinated silicon atoms. In MP_3SiO_{11} (M = Fe, Mo, Ru), phosphate groups from different $P_6Si_2O_{25}$ units are linked through a shared apex to give an infinite three-dimensional silicophosphate framework of corner-sharing diphosphate and disilicate groups.

In addition to the above well-defined silicophosphates, there have been many attempts to substitute phosphate anions into four-connected silicate zeolites (*see* ***Zeolites***). Substitution of 5–25% phosphate into zeolites such as Faujasite have been reported, but these materials are less well-characterized than the aluminophosphates and silicon aluminophosphates described below.

5.1.2 Aluminophosphates and Metalloaluminophosphates

Tetrahedral networks containing equal amounts of M^{III} and P^{V} are silicate analogs. They are most common for M = Al, but tetrahedral structures with M = B, Ga, and Fe are also known, for example, the borophosphate $CsHB_2P_2O_9$.[18]

One-, two-, and three-dimensional aluminophosphate structures have been prepared.[19] An infinite chain anion is found in $MoOAlP_2O_8$ which is isomorphous to VOP_2SiO_8, with Al replacing Si in the anion (**8**). Sheet anions such as $Al_2P_3O_{12}^{3-}$ and $Al_3P_4O_{16}^{3-}$ have been prepared hydrothermally using various alkylammonium templates which lie between the layers.

$AlPO_4$ (the mineral Berlinite) is the aluminophosphate analog of SiO_2, and adopts a structure based on that of α-quartz, with Al and P atoms ordered in alternate layers. There has been considerable interest in making similar analogs of zeolitic silicates, known as aluminophosphates (AlPOs).[20] Many of these also display new microporous structures; a notable AlPO is the large pore material VPI-5 containing one-dimensional channels in which the connecting windows have diameters of 12 Å enabling the structure to reversibly sorb large molecules such as $(C_4F_9)_3N$.[21]

Further variation of the structural and catalytic properties of four-connected tetrahedral frameworks is obtained by the substitution of silicon or metal cations,[22] giving materials known as SAPO's and MeAPO's, respectively.[20] More than twenty metal aluminophosphate frameworks have been identified with Mg, Mn, Fe, Co, or Zn substituents. These give the possibility of framework redox activity (e.g. Fe^{2+}/Fe^{3+}) in catalysis as well as the usual Brønsted acidity. For further information about zeolitic and microporous phosphate frameworks (*see* ***Porous Inorganic Materials*** and ***Zeolites***) and recent reviews.[23,24]

5.1.3 Divalent Metal Frameworks

Be^{2+}, Mg^{2+}, Co^{2+}, and Zn^{2+} can form anionic tetrahedral networks, for example, the mineral Beryllonite, $NaBePO_4$, is isostructural with $NaAlSiO_4$. New microporous variants of $NaBePO_4$, $AgBePO_4$, and $AgZnPO_4$, in which the monovalent cations reside within the divalent metal phosphate framework, have been reported in recent years.

5.2 Octahedral-tetrahedral Frameworks

A vast number of transition metals and post-transition elements form phosphates in which the tetrahedral anions and octahedrally coordinated cations build up an infinite framework. Some notable examples follow.

5.2.1 NASICON Types

The framework of $NaZr_2(PO_4)_3$ consists of corner-sharing ZrO_6 octahedra and orthophosphate tetrahedra (Figure 1). Large cavities within the structure are linked by narrow passages to give a three-dimensional network of pores in which up to four cations per formula unit may be accommodated. In $NaZr_2(PO_4)_3$, Na^+ occupies the type I site in the cavities, and the three type II sites in the narrow connecting passages are vacant, whereas in the silicate analog $Na_4Zr_2(SiO_4)_3$, all four sites are filled. The two compounds form a complete series of solid solutions $Na_{1+x}Zr_2(PO_4)_{3-x}(SiO_4)_x$, $(0 < x < 3)$. The sodium ion conductivity of intermediate compositions is very much higher than those of the end members, owing to the expansion of the type II sites by substitution of silicate for phosphate, and the creation of sodium vacancies to compensate for the substitution of phosphate for silicate. Compositions in the range $1.8 < x < 2.2$ have very high ionic conductivities and have been named NASICON (NA Super Ionic CONductor) (*see* ***Ionic Conductors***).

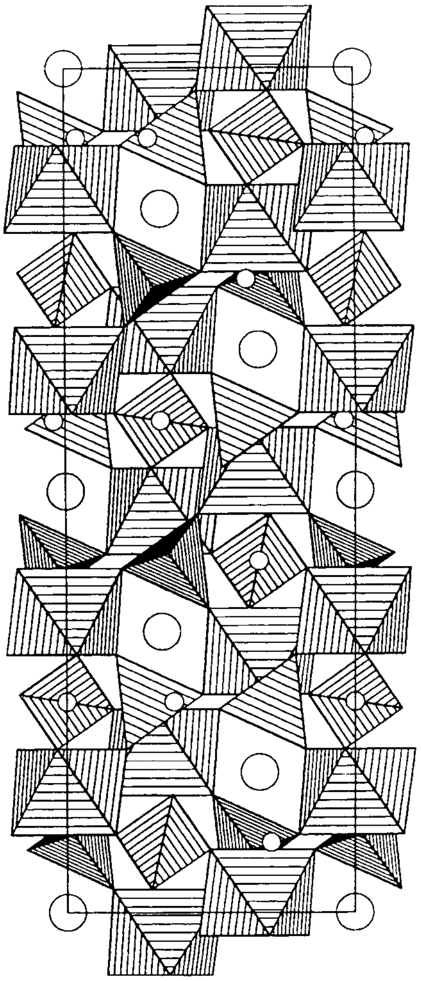


Figure 1 A polyhedral view of the NASICON unit cell containing linked ZrO_6 octahedra and PO_4 tetrahedra. Large and small circles represent type I and II Na^+ sites, respectively

$NaZr_2(PO_4)_3$ can be prepared by solid-state and hydrothermal reactions or grown as crystals from melts and ion-exchanged derivatives $AZr_2(PO_4)_3$ (A = K, NH_4, H) have been prepared. A large number of substituted NASICON frameworks are known, for example, $AM_2(PO_4)_3$ (A = Na, Ca, Sr, Ba; M = Ti, Mo), $Na_3M_2(PO_4)_3$ (M = Sc, Cr, Fe), $Na_3MgZr(PO_4)_3$, $NbTi(PO_4)_3$ and $Nb_2(PO_4)_3$. The channels are vacant in the latter two compounds.

5.2.2 KTP Types

$KTiOPO_4$, abbreviated to KTP, is an important nonlinear optical material (*see Nonlinear Optical Materials*).[25,26] Helical chains of TiO_6 octahedra are interlinked by orthophosphate groups to give a framework containing one-dimensional channels in which K^+ ions reside (Figure 2). The Ti^{4+} ions lie away from the centers of the octahedra owing to the formation of dipolar Ti=O 'titanyl' groups, and give rise to a net hyperpolarizability (a second order electric susceptibility), as the structure is acentric. KTP is an efficient second harmonic generator, converting the near-IR emission of Nd-YAG lasers (1064 nm) into blue–green light with twice the frequency (532 nm). It may also be used for optical frequency mixing, in electro-optic modulation devices and optical waveguides.

KTP powders can be prepared by direct solid-state reactions, and single crystals are grown from K_2O–P_2O_5 fluxes or hydrothermally. The KTP structure permits a large number of cation substitutions. Attention has been focused on exchanging K for other cations to modify the nonlinear properties. $ATiOPO_4$ derivatives (A = Rb, Cs, Tl, NH_4) can be prepared directly and the A = Na and Ag compounds are obtained by ion-exchange reactions of KTP with molten salts. KTP type frameworks can be prepared in which Ti is replaced by V, Ge, Sn, Zr, Ga or Nb, and P by As or Si. The phosphate fluorides NH_4MPO_4F (M = Fe, V) also adopt this structure.

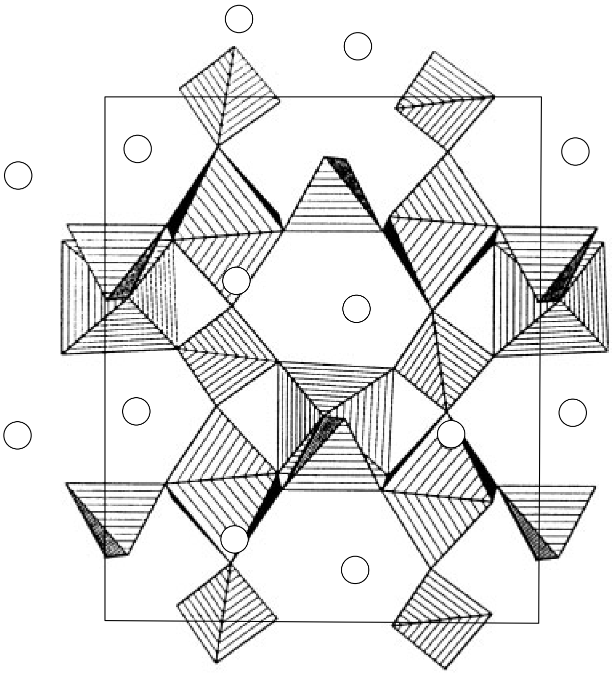

Figure 2 A projection of the cell of KTP showing the linking of TiO_6 octahedra by PO_4 tetrahedra and K^+ ions (circles) in the channels

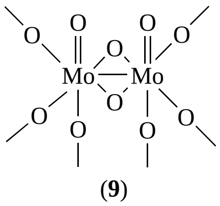
5.2.3 *Reduced Molybdenum Phosphates*

Molybdenum forms a large number of phosphates, including Keggin ions such as $PMo_{12}O_{40}{}^{3-}$, and a large number of frameworks built from MoO_6 octahedra and phosphate tetrahedra. The Mo oxidation state in these solids is usually in the range +3 to +5 and the frameworks can vary from being densely packed, for example, MoP_2O_7, to layered and microporous structures containing large voids.[27] Similar framework structures are found in reduced phosphates of Ti, V, and Nb.[28]

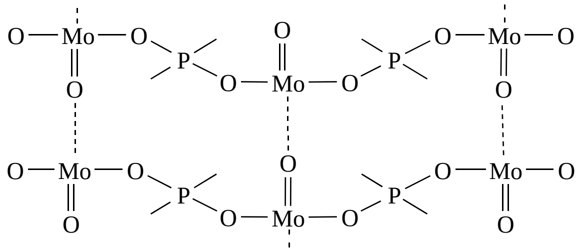
The MoO_6 octahedra are often distorted owing to the formation of a strong Mo=O bond by Mo^V (*cf* Ti^{IV} in KTP above) and Mo–Mo bonds between face or edge-sharing octahedra. A single Mo^V–Mo^V bond is often found in dimeric units (**9**), and larger Mo–Mo bonded clusters or multiple bonds may result, for example, the triply bonded molybdenum dimer in $Cs_2[Mo^{III}{}_2(HPO_4)_4(H_2O)_2]$ (*see* ***Molybdenum: Inorganic & Coordination Chemistry***).



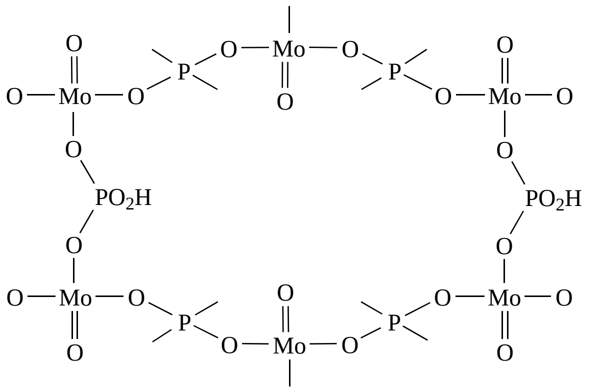
(**9**)

Dense octahedral-tetrahedral frameworks have been crystallized by heating alkali-metal, molybdenum, and phosphorus oxides with molybdenum metal in evacuated silica glass tubes at 900–1100 °C.[28] Many phases are formed as the Mo/P ratio and Mo oxidation state vary. For example, more than 15 compounds have been found in the Cs–Mo–P–O system; typical phases are $CsMoP_2O_7$, $CsMoP_2O_8$, $CsMo_2P_2O_{10}$, $CsMo_2P_3O_{13}$, $Cs_3Mo_4P_3O_{16}$, $Cs_3Mo_6P_{10}O_{38}$, and $Cs_4Mo_{10}P_{18}O_{66}$. Ortho- and diphosphate anions are found in these materials, and the latter phase contains both di- and triphosphate chains. Some of these structures, for example, $Cs_3Mo_4P_3O_{16}$, contain cubane-like Mo_4O_4 clusters of interpenetrating Mo_4 and O_4 tetrahedra in which the six Mo–Mo bonds are bridged by phosphate groups.

Open framework molybdenum phosphates with 15–40% micropore volumes can be prepared hydrothermally, providing further examples of phosphate-based porous inorganic materials (*see* ***Porous Inorganic Materials***). The $[Mo_2O_2(PO_4)_2H_nPO_4]^{(3-n)-}$ ($n = 1$, 2) framework (**10**) is particularly versatile; it is formed by inserting additional H_nPO_4 groups into the layered structure of $MoOPO_4$ (**11**), described in Section 5.3.2, and can accommodate Cs^+, H_3O^+, and $CH_3NH_3{}^+$ cations.



(**10**) $MoOPO_4$ layers



(**11**) $Mo_2O_2(PO_4)_2H_2PO_4^-$ framework

Hydrothermal preparations have also resulted in several layered materials such as $Na_3Mo_2O_4H(PO_4)_2{\cdot}2H_2O$ and alkylammonium derivatives of $Mo_4O_8(PO_4)_2{}^{2-}$. These show properties comparable to the materials described in the next

section; the former material is a proton and sodium ion conductor and the latter can act as a host for intercalation and ion exchange chemistry.

5.3 Layered Phosphates

Lamellar materials can show similar ion exchange and conducting properties to the three-dimensional frameworks described above, but the additional ability to increase the interlayer spacing allows large molecules to be intercalated (*see* ***Intercalation Chemistry***). Pillaring the layers with large inorganic clusters or organic molecules can further enhance the intercalation of guest molecules. Many layered phosphates are known; three important examples are described below.

5.3.1 *α-Zirconium Phosphate*

The layered structure of α-$Zr(HPO_4)_2{\cdot}H_2O$ is shown in Figure 3. The hydrogenphosphate groups use three unprotonated oxygens to coordinated Zr^{4+} octahedrally, and the P–OH groups point into the interlamellar spaces and are hydrogen bonded to the water molecules. Successive layers are 7.6 Å apart, and are held together only by weak Van der Waals Forces (*see van der Waals Forces*). This enables the layers to adjust their spacing or stacking pattern to adjust to external conditions and any intercalated species, giving α-$Zr(HPO_4)_2{\cdot}H_2O$ a diverse chemistry.[29]

One or both of the hydrogens can be replaced by monovalent and divalent cations, and these phases can show various degrees of hydration. For example, eight different sodium-exchanged forms have been identified, in which the interlayer spacing varies from 7.6 Å in $ZrNa_2(PO_4)_2$ to 11.8 Å in $ZrNaH(PO_4)_2{\cdot}5H_2O$. Polar molecules such as amines can be reversibly intercalated into α-$Zr(HPO_4)_2{\cdot}H_2O$, which can act as an acid catalyst for their reactions. Amine-intercalated α-$Zr(HPO_4)_2{\cdot}H_2O$ and other layered phosphates can be pillared, for example, with the Keggin ion $Al_{13}O_4(OH)_{24}{\cdot}12H_2O^{7+}$ or chromium acetate polymers.[30]

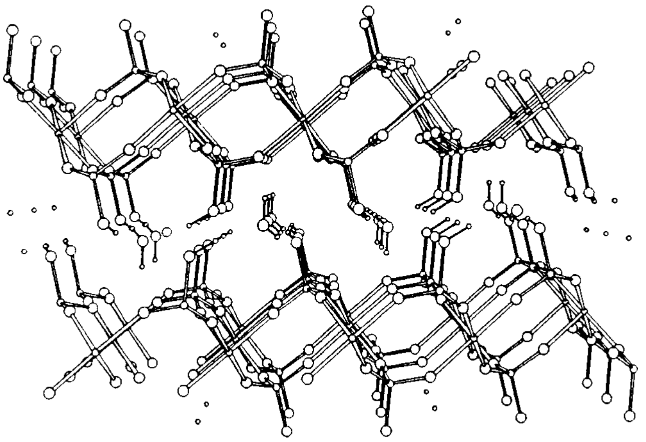


Figure 3 α-$Zr(HPO_4)_2{\cdot}H_2O$ layers

The diffusion of protons in the interlamellar regions results in ionic conductivities of 10^{-3}–$10^{-5}\,\Omega^{-1}\,cm^{-1}$ for α-$Zr(HPO_4)_2{\cdot}H_2O$ materials at room temperature. The dispersion in these values is due to variations in the water content, as proton exchange between H_3O^+ cations can enhance the conductivity.

Isostructural $M^{IV}(HPO_4)_2{\cdot}H_2O$ materials have been obtained with M = Ti, Hf, Ce, and Sn and $SbH(PO_4)_2{\cdot}H_2O$ also adopts this layered structure. In addition, a large number of layered phosphonates $M^{IV}(RPO_3)_2$ have been prepared in which the alkyl groups R lie between the inorganic layers in place of the OH groups in the hydrogenphosphates.

5.3.2 *Vanadyl Phosphate*

α-$VOPO_4$ is one of a series of layered oxysalts $MOXO_4$ (M = V, Nb, Ta, Mo; X = P, As, S),[31] shown schematically in (**11**) for $MoOPO_4$. Each vanadyl group is coordinated by four phosphate groups and vice versa. Weak V=O···V=O interactions hold the layers together, which enables one equivalent of Lewis base molecules to be intercalated through coordination to the vanadyl group. $VOPO_4{\cdot}L$ derivatives are formed with L = H_2O, ROH, py. In $VOPO_4{\cdot}2H_2O$ the second, uncoordinated, water molecule lies in the interlamellar space. Cross-linked layers are found in $VOPO_4$. $(4,4\text{-bipyridine})_{1/2}$, analogous to the pillaring of $MoOPO_4$ layers by hydrogenphosphate groups in the $[Mo_2O_2(PO_4)_2H_nPO_4]^{(3-n)-}$ frameworks described in Section 5.2.3. Cation insertion reactions occur under mildly reducing conditions giving a variety of $M_xVOPO_4{\cdot}nH_2O$ derivatives, for example, $Na_{0.2}VOPO_4{\cdot}2H_2O$. This results in a decrease in the interlayer spacing due to the electrostatic attraction between the anionic layers and the inserted cations.

5.3.3 *HUP*

Hydrogen uranyl phosphate (HUP), $HUO_2PO_4{\cdot}4H_2O$, consists of $UO_2PO_4^-$ planes similar to the $VOPO_4$ layers described above. The two dimensional network of hydrogen-bonded water molecules lying between the layers accommodates the extra proton, which gives rise to very high proton conductivities of $\sim10^{-2}\ \Omega^{-1}cm^{-1}$ at 300 K. HUP and other members of the Torbenite group of minerals can undergo cation exchange, for example, Autunite, $Ca(UO_2PO_4)_2{\cdot}nH_2O$, can reversibly exchange Ca^{2+} for K^+, Ba^{2+}, Mn^{2+}, Cu^{2+}, and Mg^{2+} in aqueous solutions.

5.4 Phosphate Glasses

Rapid cooling of phosphate melts gives vitreous materials in which no long-range order is present, but with similar local environments and connectivity of phosphate tetrahedra

to crystalline phases of comparable compositions (*see* ***Noncrystalline Solids***).[32]

Vitreous P_2O_5 and phosphate-rich glasses are difficult to prepare, owing to the volatility of P_2O_5, and are very moisture sensitive. Vibrational and MASNMR spectra show that they contain three-dimensional phosphate networks comparable to those in the extended forms of P_2O_5 and ultraphosphates.

M_2O–P_2O_5 glasses ($M = $ Li, Na, K, Rb, Cs, Ag) containing over 30% M_2O are straightforward to prepare and handle, and the ionic conductivities and optical properties of these materials have been studied extensively. Raman, MASNMR, and X-ray photoelectron spectroscopies have been used to study the proportions of n-connected ($n = 0-3$) tetrahedra in these glasses. The M_2O–P_2O_5 glasses can incorporate M halides giving materials with useful ionic conductivity. It has been proposed that microphase separation occurs in $AgPO_3$-AgI glasses, giving small regions of highly conducting α-AgI. The glassy matrix suppresses the structural phase change that drastically reduces the ionic conductivity of AgI below 150 °C.

Phosphate glasses have also been investigated as nuclear waste forms.[33] These are typically made with nonvolatile, high-valent metals such as Fe, Zr, lanthanides, or Th, sometimes with additions of lead to promote glass formation, for example, Fe–Pb-phosphate glasses. Crystalline waste forms based on the $NaZr_2(PO_4)_3$ NASICON structure (see Section 5.2.1) have also been studied as these can exchange Na for Cs, which is difficult to immobilize.

6 PROPERTIES

Notable chemical or physical properties of phosphates are usually not due to the phosphate group itself. However, the general stability associated with the strength of the P–O and M–O(P) bonds and the inertness of the phosphate group to chemical attack and redox reactions are important in determining the durability of these materials. Furthermore, a lack of electronic absorption bands in the UV-Visible–Near IR regions of the electromagnetic spectrum allows phosphates to be useful optical materials.

6.1 Electronic Conductors

Most metal phosphates are insulators; however, phosphate substitution has been demonstrated in some notable conducting oxides. For example, superconducting $MBaSrCu_{2.8}(PO_4)_{0.2}O_{6.2}$ ($M = $ La-Ho, Y) analogs of $YBa_2Cu_3O_7$ (*see* ***Superconductivity***) have been prepared, with critical temperatures up to 38 K.[34]

The largest series of electronically conducting materials are the phosphate tungsten bronzes.[35] These have similar properties to oxides bronzes such as Na_xWO_3 (*see* ***Oxides: Solid-state Chemistry***) and are strongly colored metals or semiconductors. They are formed by inserting planes of orthophosphate or diphosphate anions into the ReO_3 type WO_3 lattice, analogous to the formation of shear phases in the reduction of this structure (*see* ***Defects in Solids***). The stability of these reduced phases results from the good match between the shortest O–O distances in WO_6 octahedra and PO_4 tetrahedra. The lower connectivity of the phosphate groups results in the formation of small channels in the WO_3 structure.

Three principal families of phosphate tungsten bronzes have been identified, all of which have general composition $A_x(PO_2)_4(WO_3)_{2m}$. Orthophosphate bronzes with pentagonal tunnels are formed without additional cations ($x = 0$), for $m = 2, 4-16$, whereas orthophosphate tungsten bronzes with larger hexagonal tunnels are stabilized by $A = $ Na and K cations and have $1.75 < x < 3$ and $4 < m < 13$. Diphosphate bronzes containing hexagonal tunnels (Figure 4) are formed with larger cations, $A = $ K, Rb, Tl, and Ba, in which $m = 4-20$. The conductivities of these materials are highly anisotropic and are typically $\sim 10^{-3}\ \Omega^{-1}cm^{-1}$ in the optimum direction and $\sim 10^{-5}\ \Omega^{-1}cm^{-1}$ in perpendicular directions. The low-dimensional electronic properties of these materials have been studied in detail.

6.2 Fast Ion Conductors

Appreciable ionic conductivity is found in open framework or layered materials containing mobile cations (*see* ***Ionic Conductors***). Several phosphates have been found to be good ionic conductors and are described above: NASICON (Section 5.2.1), α-zirconium phosphates (Section 5.3.1), HUP (Section 5.3.3), and phosphate glasses[36] (Section 5.4). Current interest in lithium ion-conducting electrolytes for battery applications has led to many lithium-containing phosphate glasses and crystalline solids such as NASICON type titanium phosphate being studied.[37]

6.3 Ferroics

Ferroics can be switched between two or more oriented states under appropriate forces. The charge separation present

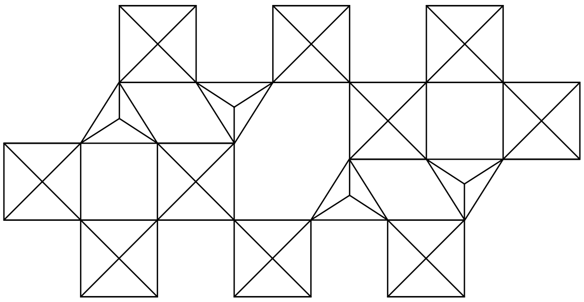

Figure 4 Idealized structure of a diphosphate tungsten phosphate bronze containing hexagonal channels formed by the insertion of diphosphate groups (projected down the P–P axis) into the WO_3 lattice of WO_6 octahedra (projected down a fourfold axis)

in metal phosphates gives rise to electric dipoles which can result in ferroic properties for which the switching forces are electrical or mechanical.[38]

6.3.1 Ferroelectrics

These (*see Ferroelectricity*) possess a net polarization due to parallel ordering of local dipoles; this requires a noncentrosymmetric crystal structure. Many solid phosphates are ferroelectrics,[39] the potassium dihydrogenphosphate (KDP) family, MH_2PO_4 (M = Na, K, Rb, Cs), are the best known examples. In KDP, a net polarization results from the ordering of asymmetric P–O–H···O–P hydrogen bonds below $T_c = 123$ K. Additional N–H···O–P hydrogen bonding in $NH_4H_2PO_4$(ammonium dihydrogen phosphate, ADP) gives a slightly different ordering of the acidic protons in which the dipoles cancel out; this is an antiferroelectric phase.

Ordering of orthophosphate anions results in ferroelectricity in $K_2Bi_3O(PO_4)_2$ whereas in $AM_2(PO_4)_3$ types (A = Li-Cs, Ag, Cu; M = Ce, Th, U) it results from the alignment of A cation displacements from the center of AO_8 polyhedra. $A^IM^{II}PO_4$ materials (e.g. A = Rb, Cs; M = Mg, Co, Zn) containing tetrahedral MPO_4^- frameworks can undergo ferroelectric transitions due to the coupled rotations of the tetrahedra.

6.3.2 Piezoelectrics

Coupling of mechanic stress and electrical polarization results in piezoelectricity. KDP type materials are piezoelectrics at room temperature and ADP was formerly used in submarine applications to emit and receive ultrasonic waves. Berlinite, $AlPO_4$, is structurally related to the common piezoelectric α-SiO_2 (see Section 5.1.2) and has superior properties in some respects.

6.4 Optical Materials

6.4.1 Nonlinear Materials

Phosphates showing a bulk polarization (i.e. ferroelectric phases) may be used for nonlinear optical processes (*see Nonlinear Optical Materials*) such as second harmonic generation and electro-optic switching. KTP (Section 5.2.2) and related phases (NH_4TiOPO_4 and $KTiOAsO_4$) are very efficient nonlinear materials. The ferroic phosphates described above also show nonlinear properties. KDP materials are inferior to KTP types but they find use in electro-optics as they are very transparent over a wide frequency range.

6.4.2 Phosphors

Nonabsorbing phosphate hosts doped with impurities to act as absorption and emission centers provide useful phosphors (*see Phosphorescence*). In particular, Fluoroapatite ($Ca_5(PO_4)_3F$) doped with Sb and Mn is used as a coating in commercial fluorescent lamps to convert 254 nm mercury UV radiation into visible light. $Na_3(Ce_{0.65}Tb_{0.35})(PO_4)_2$ and lanthanide-doped $Zn_3(PO_4)_2$ are also efficient phosphors.

6.4.3 Laser Materials

The basic requirements for a laser material are similar to those for phosphors: a low concentration of active centers in a nonabsorbing host lattice. Both crystalline and glassy phosphate materials have been extensively researched as laser materials.[40] The low cation concentration in the lanthanide ultraphosphates MP_5O_{14} leads to large cation–cation separations, enabling stoichiometric NdP_5O_{14} to lase without excessive fluorescence quenching. Other self-activated neodymium phosphate laser crystals are the cyclotetraphosphates $MNdP_4O_{12}$ (M = Li, Na, K) and the orthophosphates $M_3Nd(PO_4)_2$ (M = Na, K).

Nd-doped phosphate glasses are also used in a variety of high-gain or high-power laser applications. These materials are typically metaphosphate glasses such as $NaPO_3$ or $Al(PO_3)_3$ containing <1% Nd. Vitreous NdP_5O_{14} can also be used.

6.5 Catalysis

The phosphate group has no inherent catalytic activity, but many phosphates are useful catalysts by virtue of the metals present and their structures.

6.5.1 Surface Oxidation Catalysis

Several transition metal phosphate systems are found to catalyze mild oxidations of organic molecules.[41] Catalytic activity is due to transition metal redox couples (*see* ***Oxidation Catalysis by Transition Metal Complexes*** and ***Oxide Catalysts in Solid-state Chemistry***), but the phosphate groups are important in determining the underlying and surface structures.

A variety of vanadium phosphates catalyze the selective oxidation of linear C_4 hydrocarbons to maleic anhydride through the in situ formation of $(VO)_2P_2O_7$. The catalytic sites are thought to be formed on surfaces perpendicular to the direction of the V=O bonds, and so the structure of the initial vanadium phosphate is important in determining the morphology and catalytic activity of the $(VO)_2P_2O_7$ particles. Highly active, platy microcrystallites can be prepared through the topotactic decomposition of layered precursors such as $VOHPO_4{\cdot}1/2H_2O$.

Iron phosphates catalyze the oxidative dehydrogenation of isobutyric acid to methacrylic acid. The initial Fe^{II} or Fe^{III} phase is converted to the mixed valent orthophosphate $Fe_7(PO_4)_6$, but the catalytically active phase may be a diphosphate $Fe_3(P_2O_7)_2$.

$CuTi_2(PO_4)_3$ and related NASICON type phases (see Section 5.2.1) catalyze the oxidation of propylene to acrolein and alcohol dehydrogenations. The open framework of this structure enables Cu ions to diffuse to the surface under oxidizing or reducing conditions (equations (11) and (12), respectively) giving surface growths of Cu or CuO. These redox properties and the ability of $Cu_{0.5}Ti_2(PO_4)_3$ to absorb hydrogen give rise to the catalytic activity.

$$Cu^{I}Ti_2(PO_4)_3 + \frac{1}{4}O_2 \rightleftharpoons Cu^{II}{}_{1/2}Ti_2(PO_4)_3 + \frac{1}{2}CuO \qquad (11)$$

$$Cu^{I}Ti_2(PO_4)_3 + \frac{x}{2}H_2 \rightleftharpoons Cu^{II}{}_{1/2-x}Cu^{I}{}_{x}H_xTi_2(PO_4)_3 + \frac{1}{2}Cu \qquad (12)$$

6.5.2 Lamellar, Microporous, and Mesoporous Catalysts

Phosphates having these types of open structures can act as shape-selective acid catalysts, for example, for the cracking and isomerization of hydrocarbons. For examples of lamellar materials, see Section 5.3 and (*see* ***Intercalation Chemistry***). Microporous catalysts are described above and in (*see* ***Porous Inorganic Materials*** and ***Zeolites***). Mesoporous AlPO materials have larger pores within a matrix of amorphous $AlPO_4$.[42]

6.6 Magnetism

Phosphates of transition metal and lanthanide cations possessing unpaired spins behave as paramagnets (*see Paramagnetism*; ***Magnetism of Transition Metal Ions***) at ambient temperatures. On cooling they can display a variety of magnetic ordering phenomena due to superexchange interactions through phosphate groups and other bridges between the cations (*see* ***Magnetism of Extended Arrays in Inorganic Solids***). M–O–P–O–M interactions are usually antiferromagnetic (*see Antiferromagnetism*) with exchange constants $J/k \sim -1$ to $-10\,K$. The ease of preparation and structural variety of metal phosphates has resulted in the study of magnetic ordering phenomena in many compounds, for example, an incommensurate spiral of ordered Cr^{3+} moments is found in β-$CrPO_4$ below 25 K.[43] However, low ordering temperatures and the tendency of metal phosphates to order antiferromagnetically precludes their practical use as magnetic materials.

6.7 Battery Cathode Materials

Solids that can reversibly take up and lose lithium ions (accompanied by reduction or oxidation) can be used as cathode materials in rechargeable lithium batteries. Several transition metal phosphates, for example, $Li_3V_2(PO_4)_3$, $LiVOPO_4$, and $LiFePO_4$, that can undergo oxidative de-intercalation of lithium have been investigated in recent years.

6.8 Negative Thermal Expansion Ceramics

Useful zero thermal expansion composites are made by combining materials that show the unusual property of negative thermal expansion (i.e. contraction) with normal (positive) expansion materials. Examples of phosphates showing negative thermal expansion are the diphosphate-divanadate solid solutions $ZrP_{2-x}V_xO_7$ and the microporous aluminophosphate AlPO-17 which shows a particularly large effect.[44]

6.9 Biomaterials

Materials that are compatible with biomineralized phosphates (see Section 7.2) may be useful for implants.[45] A variety of synthetic calcium phosphates have been investigated. $Ca_3(PO_4)_2$ can be used as a biodegradable bone implant, which is gradually replaced by autogenous bone, and less degradable apatite implants can attach to natural bone without inflammation. Bioinert zinc phosphate cements are used in prosthetic dental applications.

7 NATURAL PHOSPHATES

Phosphate minerals are found in rocks and living systems, and many biologically important molecules are phosphate esters (*see* ***Phosphorus: Inorganic Chemistry***). The balance between insoluble and soluble phosphates in the biosphere has been adversely affected by the use of phosphate fertilizers, water softeners and detergents.

7.1 Minerals

Several hundred phosphate minerals (*see Mineralogy*) are known, virtually all of which are orthophosphates.[46] An exception is Canaphite, $CaNa_2P_2O_7{\cdot}4H_2O$. The important mineral Apatite, $Ca_5(PO_4)_3X$ is found in igneous pegmatite rocks and hydrothermal veins. Fluoro-, Chloro-, and Hydroxy-apatites are found (X = F, Cl, OH, respectively) as well as many substituted varieties.

Poorly crystalline or amorphous Phosphorite sediments made from the hard remains of marine organisms are the principal commercial source of phosphates, although Apatites are also mined. Treatment of phosphate minerals with sulfuric acid yields ‘superphosphate’ fertilizer, a mixture of $Ca(H_2PO_4)_2$, H_3PO_4 and $CaSO_4$. Phosphoric acid treatment gives ‘triple superphosphate’, rich in $Ca(H_2PO_4)_2$. Other soluble fertilizers such as ammonium phosphates are obtained from these products.

Many of the f-block elements are extracted from phosphate minerals. Monazite, MPO_4, can contain the lanthanide metals, Y and Th, at the cation sites M. The Torbenite and other

groups of minerals related to HUP (see Section 5.3.3) are sources of uranium.

7.2 Biominerals

Phosphates are found in soft organic tissues as phosphate esters, and in hard tissues, notably bones and teeth, as solid calcium orthophosphates (*see* ***Biomineralization***).[47] Hard tissues are composites of Apatite and an organic matrix: collagen in bone, dentin, and dental cement, and keratin in dental enamel. The Apatite phases are defective with Ca/P ratios of 1.6–1.8 and can incorporate other cations (Na^+, K^+, Mg^{2+}) or anions (F^-, Cl^-, $CO_3{}^{2-}$, citrate).

1 INTRODUCTION

This article deals with metal phosphides in the solid state.[1–13] Since the first contribution to this Encyclopedia in 1994, a huge number of original publications on the synthesis, crystal growth, crystal chemistry, and the physical properties of phosphides have appeared. The largest field compromises the rare earth-transition metal phosphides. Most of this work was done in the groups of Guérin, Jeitschko, Kuz'ma, and Mewis and has been reviewed by Kuz'ma and Chykhrij.[14,15] Other recent research topics cover the crystal chemistry and chemical bonding of new metal-rich phosphides, phosphide oxides, and intensive studies of the largely varying physical properties of these intriguing materials. Compounds with a high phosphorus content are common and the polyphosphides are of particular interest because they exhibit an unexpected wealth of chemical composition, physical properties, and structural features.[16,17] No other element approaches phosphorus in the variety of homoatomic connected polyanions formed, as a result of its relatively low electronegativity and stereochemical features. The threefold bonded neutral P atom acts like a fragment of surface structures and, therefore, the structures of the different phosphorus modifications will be maintained in a large frame of redox steps down to very small ones: P_{15}^- (KP_{15}), $P_{12}^{\pm 0}$ (CuI charge transfer, $(CuI)_3P_{12}$) or P_{14}^{2+} ($P_{14}S$).

2 COMPOUNDS: GENERAL RELATIONSHIPS

It has long been known that binary compounds with phosphorus are formed by most elements; the few exceptions are Hg, Pb, Sb, Bi, Te, Po, and the noble gases. However, ternary compounds like $HgPbP_{14}$ are readily formed. The established compounds are listed in Tables 1–5, ordered from metal rich to phosphorus rich, and from main-group binary compounds to binary and ternary polyphosphides, and metal-rich phosphides.[1] The phosphides MP_x and $(M,M')P_x$ have been ordered according to ascending x(P) and ascending numbers of M and M′ (Tables 4 and 5, respectively), using the general formula and not the alphabetical order of M, M′ atoms. The crystal structures are characterized by structure type and Pearson code, and the phosphorus partial structures of the polyphosphides are classified by their linkage types. In some cases of site occupancy factors <1, the Pearson code for full occupancy minus the unoccupied part has been given. Because of the still increasing number of phosphides, the tables cannot be complete. Besides the books, reviews, and databases listed in Ref. 1–13, most literature on phosphides is easily accessible via the SciFinder Scholar data base.[18] The broad range of composition from $M_{15}P_2$ to MP_{15} is remarkable, as is the fact that some elements form only one distinct phosphide, while others form up to 10. The various phosphides differ greatly in their chemical and physical properties, which can be related

Table 1 Phosphides and polyphosphides of group 1–3 and 11–14 metals

	Ti, Hf, Zr (β)	TiAs	*hP* 8
	Nb, Ta	NbAs	*tI* 8
	Zr (α), Th	NaCl	*cF* 8
	Mo	WC	*hP* 2

to structure and bonding. However, there is a general lack of systematic physical data available, and in particular for hydrogen phosphides such as MPH_2 (M = Li, K, Rb). These compounds and higher derivatives such as KP_5H_2 and anions $P_9H_2^-$ are therefore only discussed marginally.

In principle, all phosphides are compounds with valence electrons in localized states, and even in 'metallic' compounds only a few valence electrons are substantially delocalized. Classification into metallic and semiconducting types is therefore a poor way to differentiate between these compounds. The name 'phosphide' defines the P atoms as the most electronegative ones in a compound MP_x, forming the anionic part with the mean oxidation state $q(P_x) = -q(M)$. A broad classification of phosphide types can be made using the oxidation states: (a) 'normal' phosphides with only heteroatomic bonds, $3x = q(M)$; (b) polyphosphides, $3x > q(M)$; and (c) metal-rich phosphides, $3x < q(M)$. With type (b), P–P bonds are expected, and with type (c), electrons are available for metal-to-metal bonds. The value for $q(P_x)$ may be derived from $q(M)$ or from the structural details. Whatever the real effective charges are, formal oxidation states (P^{3-}, P^{2-}, P^-, P^0, P^+, etc.) can be assigned from the homoatomic P–P bond numbers (i.e. twofold-linked = (2b) etc.) of the involved species (0b)P^{3-}, (1b)P^{2-}, (2b)P^-, (3b)P^0, (4b)P^+, according to $q(P_x) = -x(3A + 2B + C - E)/N$, with $N = (A + B + C + D + E)$. Here A, B, C, D, and E are the quantities of these species in the structure per formula unit. Another way is to count the number of P–P bonds, $\sum_b$, and to calculate $q(P_x) = -x(3 - 2\sum_b/N)$, or to calculate $\sum_b$ from $q(M)$ according to $\sum_b = N/2(3 - q(M)/x)$.
